MESSAGE FROM THE PRESIDENT

The Hydrogen Technologies Association has continued its mission of promoting research, development, and innovation in the field of hydrogen energy, while fostering collaboration between academia, industry, and government at both national and international levels. Over the years, the Association has organized numerous scientific and technical events, creating valuable opportunities for knowledge exchange and partnership building. These efforts have strengthened Turkey's role in the global hydrogen community and contributed to advancing sustainable energy solutions.

The 9th International Hydrogen Technologies Congress (IHTEC-2025) was successfully held in İzmir, Türkiye, from May 25 to 28, 2025, under the joint organization of Dokuz Eylül University and the Hydrogen Technologies Association. This year's congress brought together more than 500 participants from 25 countries and numerous companies with their latest products and technologies, providing a dynamic platform for presenting the latest scientific findings and technological developments in hydrogen production, storage, and utilization, and their applications in various sectors. The program featured a rich combination of thematic sessions, special sessions, panel discussions, and a dedicated workshop, contributing to productive conversations and new collaborations. The successful realization of IHTEC-2025 was made possible by the dedication and efforts of the Rector of Dokuz Eylül University and Honorary Chair, Prof. Dr. Bayram Yılmaz, and the Congress Co-Chairs, Prof. Dr. Can Özgür Çolpan and Prof. Dr. Azize Ayol. I also sincerely thank the organizing and executive committees, technical chairs, session chairs, speakers, authors, and volunteers for their valuable contributions. I would like to thank our sponsors for their generous support.

I believe that the networks established and the knowledge shared during IHTEC-2025 will continue to inspire progress towards a cleaner, more sustainable, and innovative hydrogen energy future. I look forward to welcoming our community to IHTEC-2026 in the Istinye University in Istanbul, where we will strengthen international cooperation and further contribute to the global advancement of hydrogen technologies.

Prof. Dr. İbrahim Dinçer
President, National Hydrogen Association

FOREWORDS

MESSAGE FROM THE CHAIRS

We are delighted to present the proceedings of the 9th International Hydrogen Technologies Congress (IHTEC-2025), held in İzmir, Türkiye, from May 25 to 28, 2025, under the joint organization of Dokuz Eylül University and the Hydrogen Technologies Association.

IHTEC-2025 brought together over 400 participants from 25 countries, creating a dynamic international platform for the exchange of scientific and technological knowledge in hydrogen energy. The scientific program featured 269 oral and 73 poster presentations across 36 thematic sessions, along with 2 special sessions, 2 panel discussions, and 1 dedicated workshop, covering key topics ranging from hydrogen production and storage to its applications in industry and defense.

The congress officially opened with addresses by Prof. Dr. Can Özgür Çolpan and Prof. Dr. Azize Ayol (Congress Co-Chairs), Prof. Dr. Bayram Yılmaz (Rector of Dokuz Eylül University and Honorary Chair), and Dr. Süleyman Elban (Governor of İzmir), whose participation and support we gratefully acknowledge. The plenary session continued with an insightful overview by Prof. Dr. İbrahim Dinçer (President of the Hydrogen Technologies Association), followed by a special talk by Dr. Abdullah Buğrahan Karaveli (President of TENMAK), both of whom provided valuable perspectives on hydrogen's strategic importance.

We were honored by the contributions of distinguished keynote and invited speakers, including Prof. Luigi Crema (President of Hydrogen Europe Research / Fondazione Bruno Kessler, Italy), Prof. Adélio Mendes (University of Porto, Portugal), Prof. John Irvine (University of St Andrews, UK), Prof. Eileen Yu (University of Southampton, UK), Prof. Feridun Hamdullahpur (University of Waterloo, Canada), Prof. Saim Özkar (Middle East Technical University, Türkiye), and Dr. Tareq Al-Ansari (Qatar Environment and Energy Research Institute, Qatar), who greatly enriched the scientific program.

Two high-level panel sessions enriched the IHTEC-2025 program. The pre-congress panel, titled "Innovative Hydrogen Policies in Combating Climate Change," was moderated by Prof. Dr. Adnan Midilli (ITU Energy Institute), featuring Prof. Dr. Arif Hepbaşlı (Yaşar University), Osman Arda Göçmen (Ford Otosan), Elis Şaşmaz (Topkapı Industry), and Yusuf Can Uz (Filament Technology). The second panel, "Hydrogen Technologies in the Defense Industry," was coordinated by Prof. Dr. Can Özgür Çolpan and Prof. Dr. Hüseyin Turan Arat (Sinop University) and moderated by Prof. Dr. Selmiye Alkan Gürsel (Sabancı University). This panel included key experts from the national defense sector: Deniz Demirci (Presidency of Defense Industries - SSB), Hüseyin Devrim (TEKSİS), Uğur Kayasal (Roketsan Missiles Inc.), Devrim Köseoğlu (TUSAŞ), and İbrahim Pamuk (LENTATEK). We sincerely thank all moderators and panelists for their valuable insights into the policy and strategic dimensions of hydrogen technologies.

A dedicated workshop on "Innovations on Hydrogen-based Processes & Technologies" was organized by Dr. Adolfo Iulianelli (CNR-ITM, Italy) and Dr. Canan Acar (University of Twente, Netherlands). The workshop provided a focused environment for discussions on membrane processes, hydrogen production systems, and fuel cell innovations. In addition, a special session on "Membrane Technologies in Hydrogen Production, Separation and Utilization" was coordinated by Prof. Dr. Can Özgür Çolpan and Dr. Adolfo Iulianelli. The session covered a broad range of timely topics including membrane engineering in the hydrogen economy, renewable sources and catalytic systems for hydrogen generation, hydrogen separation/purification and utilization by membrane technologies, hybrid industrial plant solutions for decarbonized hydrogen generation, and hydrogen and fuel cells. We extend our sincere thanks to all speakers who contributed their expertise and insights to this special session.

The successful realization of IHTEC-2025 was made possible through the commitment and collaboration of many individuals and institutions. We extend our sincere gratitude to Prof. Dr. Bayram Yılmaz, Rector of Dokuz Eylül University, for his unwavering support, and to Prof. Dr. İbrahim Dinçer, President of the Hydrogen Technologies Association and General Chair of the congress, for his visionary leadership. We would also like to thank Prof. Dr. Mehmet Akif Ezan and Assoc. Prof. Dr. Mustafa Umut Karaoğlan, the Technical Co-Chairs, for their outstanding efforts in shaping the scientific program, as well as the organizing and executive committees, the international scientific board, the reviewers, and the volunteers.

We are deeply grateful to our sponsors, whose generous support ensured the successful execution of the event. These include TENMAK, ARMELSAN Enerji, HABAŞ, Anton Paar, Hydrogenix, International Association for Hydrogen Energy (IAHE), BPlas, Doğu İklimlendirme, Koç University Hydrogen Technologies Center, TÜBİTAK, Consapp Engineering, Truva Bakır, Kurukahveci Mehmet Efendi, BREW MOOD COFFEE TEA, KFC Gıda, Dimes A.Ş., and Eker.

We believe that the knowledge shared and the collaborations formed during IHTEC-2025 will contribute meaningfully to the advancement of hydrogen-based solutions for a more sustainable future. Serving as Co-Chairs of this international event has been a great honor and a reflection of our shared commitment to progress in hydrogen technologies.

We thank all participants for their valuable contributions and hope to see continued collaboration and innovation in future editions of IHTEC.

Kind regards,

Prof. Dr. Can Özgür Çolpan & Prof. Dr. Azize Ayol
Congress Co-Chairs, IHTEC-2025

Figen, O. K. Özdemir* **#277** "H_2 Evolution Reaction Pathways of Cobalt Based Molecular Catalysts Investigated by AB-initio Simulations" *Y. Gurdal* **#98** "Next-Gen Energy Catalysis: MXENE-Based Composites for High-Impact Hydrogen Evolution Reaction" *D. Onaylı, D.Ö. Özgür*
	Ivana Perović *Vinca Institute of Nuclear Sciences, Serbian National Institute, Serbia* **Lecture 2: Advances in Electrochemical Catalysts for Enhanced Hydrogen Production in Membrane Reactors**	
	Antonio Vita *National Research Council – Institute of Advanced Technologies for Energy, Italy* **Lecture 3: 3D-printed Ni-alloy based Structured Catalysts with Locally Tuned Porosity and Shape for Process Intensification of Ammonia Synthesis and Decomposition**	
	David Alique *Rey Juan Carlos University of Madrid, Spain* **Lecture 4: Towards the Industrialization of Pd-based Membranes Synthesis for Hydrogen Applications: Continuous Flowing Electroless Pore-Plating**	
10:30 10:50	**Coffee Break (with Poster Session-2)**	
	KEYNOTE SESSION 2 (HALL A) **Session Chair: Azzam Abu Rayash**	
10:50 11:30	**John T. S. Irvine**, *University of St. Andrews* **Interfacial Engineering in Solid Oxide Cells**	
11:30 12:10	**Eileen Yu**, *University of Southampton* **An Electrolysis and Microbial Electrochemical Hybrid System for Hydrogen Production and Wastewater Treatment**	
12:10 14:00	**LUNCH** *(Lokal Çatı Restaurant, Dokuz Eylul University Rectorate)*	

SCIENTIFIC PROGRAM

Tuesday – May 27, 2025

PARALLEL SESSIONS – 3			
Conference Registration			
HALL C	**HALL D**	**HALL E**	**EXHIBITION**
Session 12. Combustion of Hydrogen and Fuel Mixtures – I **Session Chair: Selda Ozkan**	**Session 13. Hydrogen in Smart Grids and Microgrids** **Session Chair: Damla Eroğlu Pala**	**Session 14. Hydrogen Safety** **Session Chair: Nader Javani**	
#177 "Numerical Investigation of the Effect of the Co-Combustion of Hydrogen and Natural Gas on Temperature and Carbon Emissions in Ceramic Furnace" *B. Kılıç, K. Bayramoğlu, S. Yılmaz, T. Bayramoğlu, A. Özarslan, A. Akbay* **#185** "Investigation of NO_x Reduction by NH_3-SCR in Aftertreatment System for H_2 Internal Combustion Engine" *T. B. Sarı, S. E. Bozbağ, D. Ş. Yıldız, C. Erkey* **#207** "Probative Assessment of Hydrogen Enriched Methane Induction in Gasoline Direct Injection Engine for Homogeneous Stoichiometric Lean Mixture Formation" *E. G. Varuvel, J. Stanley, L. J. Martin* **#302** "An Alternative Fuel for Afterburner: Energy and Economic Comparison for NH_3/H_2 and JP-8" *E. Oğur, A. Koç, H. Yağlı, Ö. Köse, Y. Koç* **#311** "CFD-Based Thermal and Emission Analysis of a 2D Hydrogen-Fueled Combustor Using Real Engine Data at Cruise Altitude" *Y. F. Görgülü, S. Ekici, T. H. Karakoc* **#312** "Combustion and Emission Behavior of a Hybrid Ammonia–Jet-A Blend Under Real Jet Engine Operating Conditions" *Y. F. Görgülü, S. Ekici, T. H. Karakoc*	**#40** "Use of Conventional and Renewable Energy in Türkiye's Hydrogen Supply Chain: A Grid-based Risk Assessment" *H. Kırış, M.G. Güler, Ö.N. Bilişik* **#213** "Type-2 Fuzzy MPPT Control of Fuel Cells Using a Hybrid Genetic-Grey Wolf Optimizer" *Ö. F. Özcan* **#214** "Hybrid Optimized Takagi Sugeno Type 2 Fuzzy-Based Voltage–Frequency Controller for Fuel Cell Integrated Isolated Microgrid" *Ö. F. Özcan, H. Kılıç, Ö. F. Özgüven* **#228** "Enhancing Longevity of Hydrogen-Powered Electric Vehicles, an Adaptive Neuro Fuzzy Control-Based High-Gain, Low-Stress Power Converter" *M. Özden, D. Ertekin, K. Baltacı* **#229** "Design and Implementation of Pseudo Levenberg-Marquardt Learning Artificial Neural Network Controller for Power Conversion in Fuel Cell to Battery Charging Systems, Improving Power Efficiency and Reliability" *M. Özden, D. Ertekin, K. Baltacı* **#261** "Sustainable Energy Based on Optimizing Load Frequency Control in Military Microgrid" *M. T. Özdemir, S. Çelikdemir, B. Yıldırım*	**#44** "Hydrogen Detection and Electrical Properties of Perovskite $BaTiO_3$ Schottky Diode" *L.B. Tasyurek, H. Karakurt, N. Kilinc* **#52** "Evaluation of Deformation via in situ SEM and EBSD on Hydrogen Embrittlement" *S.H. Nahm, H.S. Yun* **#127** "HAZOP and Fault Tree Analysis of Ammonia Leakage in a Ship's Ammonia Fuel System" *B. Zincir, B.A. Zincir* **#291** "Systematic Risk Analysis for Hydrogen Fuel Cell Vehicles and Safety Management in Fuel Cells" *N. Özaslan, B. Tanç* **#271** "SIC Schottky Diodes: Electrical Characterization and Gas Sensor Applications" *L. U. Kendirli, L. B. Taşyürek, N. Kılınç*	
Coffee Break (with Poster Session-2)			
LUNCH *(Lokal Çatı Restaurant, Dokuz Eylul University Rectorate)*			

SCIENTIFIC PROGRAM

Tuesday – May 27, 2025

PARALLEL SESSIONS – 4		
	HALL A	**HALL B**
14.00 16:00	**SPECIAL SESSION** **Membrane Technologies in H_2 Production, Separation, and Utilization - II** **Session Chairs: A. Iulianelli & C.O. Colpan**	**Session 15. Fuel Cells and Applications – II** **Session Chair: İnci Eroğlu**
	Giuseppe Barbieri *National Research Council – Institute on Membrane Technology, Italy* **Lecture 5: Revolutionizing Syngas and Biogas Valorization: Advanced Membrane Gas Separation for CO_2 and H_2 Recovery**	**Sarp Kaya** *Koç University* **Koç University Hydrogen Technologies Center (KUHyTech): Pioneering Sustainable Innovation for the Future**
	Simona Liguori *Clarkson University, United States* **Lecture 6: Engineering a Paradigm Shift in How We Think About Reactors: Metallic Membranes for Highly Intensified Hydrogen Production**	**#12** "Development of Operation Strategies for Improving Polymer Electrolyte Membrane Fuel Cell System Water Management and Hydrogen Circulation" *J. Bae, H. Park, I.J. Son, S. M. Park* **#24** "A-site Deficient $La_{0.4}Ca_{0.4}Ti_{0.995}Pt_{0.005}O_3$ with Low Pt Substitution as an Oxygen Reduction Electrocatalyst for Fuel Cell Applications" *S. Ozkan, S.Kim, J.T.S. Irvine* **#32** "Analysis of $MgCr_{2-x}Mn_xO_4$ (X=0.1/0.5/1) Spinel and LSM Composite Coatings as a Protective Layer for SOFC Interconnect" *H. Unsal, C.D. Savaniu, J.T.S. Irvine* **#102** "Experimental Analysis of Reversible Solid Oxide Cells Performance Degradation from Varying Power Ratios and Switching Frequencies in Operation" *N. Ali, G. Loreti, D. Pumiglia, Y.De Pra, L.D. Seta, V. Cigolotti, G. Monteleone, D. Borello* **#109** "Investigation of LSC-Based Composite SOFC Cathode Layers by ESD Coating Method" *E. Erğen, S. Akkurt* **#233** "Investigation of Carbon Felt Fabric as a Gas Diffusion Layer in PEM Fuel Cells: Stability and Coating Capability" *A. Şirin, J. H. Özdemir, O. K. Özdemir, N. Alp, M. Alp, E. Akarsu* **#234** "Investigation of Fuel Cell Performances by Recycling Used Membranes" *B. Aktaş, O. K. Özdemir, J. H. Özdemir*
	Simona Liguori *Clarkson University, United States* **Lecture 6: Engineering a Paradigm Shift in How We Think About Reactors: Metallic Membranes for Highly Intensified Hydrogen Production**	
	Kamran Ghasemzadeh *University of Edinburgh, United Kingdom* **Lecture 7: In situ Hydrogen Production, Utilisation and CO_2 Valorisation for Fuel Production by Membrane Reactor Technology**	
	Gabriel Bernardo *University of Porto, Portugal* **Lecture 8: Carbon Molecular Sieve Membranes for the Purification of Hydrogen**	
	#63 "Synthesis, Characterization of MOFs, and Evaluation as Adsorbents in Hydrogen Purification" *Z. Bilgin, D. Dumlu, N. Ayas* **#4** "Optimization of Green Hydrogen Electrolyser Plant Efficiency and Required Power Quality Solution" *T. Aydın, H. Bezerra* **#11** "The Potential of Offshore Wind Farms as Hydrogen Fuel Station: A Case Study of Marmara Sea" *V. Dixit, C. Acar*	
16:00 16:30	**Coffee Break (with Poster Session-3)**	

SCIENTIFIC PROGRAM

Tuesday – May 27, 2025

PARALLEL SESSIONS – 4			
HALL C	**HALL D**	**HALL E**	
Session 16. Catalysts for Hydrogen Applications – III **Session Chair: Tsong-pyng Perng**	**Session 17. Hydrogen Economy, Infrastructure, and Policy – I** **Session Chair: Emrah Erginer**	**Session 18. Gasification and Reforming Technologies** **Session Chair: Eileen Yu**	**EXHIBITION**
#163 "NASICON ($Na_3NiCo_2(PO_4)(SO_4)_2$) Doped Polyaniline as a New Candidate Electrocatalyst in Hydrogen Evaluation Reaction" *S. M. Yılmaz, A. K. Figen* **#181** "Development of Ce-Promoted Ni-Based Methanation Catalysts for Enhanced CH_4 Production" *B. Acar, B. S. Çağlayan, A. E. Aksoylu* **#182** "A Mechanistic Drifts-MS Investigation and Active Intermediate Determination of DRM at Low Temperature over Ru-La/ZrO_2 Catalyst" *O. Ordulu, A. Uzun, C. Öztepe, B. M. Eropak, B. S. Çağlayan, A. E. Aksoylu* **#183** "Operando Drifts Investigation of Active Intermediates in CO_2 Methanation over Ni-La/γ-Al_2O_3 Catalysts Under Low H_2/CO_2 Feed Ratios" *C. Öztepe, O. Ordulu, A. Uzun, B. M. Eropak, B. S. Çağlayan, A. E. Aksoylu* **#74** "Shaped Ni/Mesoporous CeO_2 as Active Catalysts in Hydrogen Production from Acetic Acid Oxidative Steam Reforming" *Á.M. de la Calle, A.J. Vizcaíno, A. Carrero, J.A. Calles, P.J. Megía* **#154** "Preparation of Zinc and Cobalt with Boron Doped Nickel Electrodes for Alkaline Electro-catalytic Hydrogen Production Activities" *A.D. Tümer, C. Demir, B. C. Filiz* **#226** "High-Entropy $NiCoCuFeMoMnO_x$ Oxide Thin Films Deposited via Open-Air Pulsed Laser for Efficient Electrocatalytic Oxygen Evolution Reaction" *H. Mahdavi, A. A. Alamdari, U. Ünal, H. Jahangari*	**#83** "Hydrogen Fuel Viability in EU Maritime Transport with Emissions and Policy Implications" *B.A. Zincir, B. Zincir* **#97** "Planning And Managing Renewable Gas Integration in the Portuguese Natural Gas Network" *F. Machado, L. Fernandes, L. Marcon* **#155** "Design of a Future Hydrogen Supply Chain Under Carbon Emission Constraints: The Case Study of Central Anatolia" *T. Ulusoy, A. Döyen, M.G. Güler* **#173** "Impact of Transportation Constraints on Hydrogen Supply Chain Performance of Türkiye" *B. Türkali-Özbek, A. Erdoğan, M. G. Güler* **#227** "The Role of Hydrogen Energy in Net Zero City Strategies" *M. T. Balta, M. Ö. Balta* **#256** "A Comparison of Systemic Performance: The Framework Models of Hydrogen Strategies in (Inter)National Energy Policies for Clean Energy Transition" *E. Gürler, A. Gürler Akdeniz, Y. Ateş, A. R. Boynueğri* **#356** "A Novel Framework of Synergistic Hydrogen City Design for Urban Decarbonization and Net-Zero Energy Autonomy" *A. Abu-Rayash*	**#73** "Hydrogen from Bio-oil: Thermodynamic Insights on Steam Reforming Technologies" *P.J. Megía, C. Rocha, A.J. Vizcaíno, A. Carrero, J.A. Calles, L.M. Madeira, M.A. Soria* **#87** "Steam Reforming of Sugar Beet Pulp with Dolomite-Based Ni-La Catalyst" *S. Karadeniz, .K. Kanatlı, N. Pourmoghadam, Ş. Genç, S.M.A. Aljafreh, N. Ayas* **#195** "In Situ Characterization of Pt-Re-Na/CeO_2 System and Operando Analysis of WGS Mechanism on its Sites by FTIR-DRIFTS-MS" *B. M. Eropak, A. Uzun, B. S. Çağlayan, A. E. Aksoylu* **#215** "Transfer Learning from Steam and Dry Reforming of Methane to Tri-Reforming of Biogas for Syngas Production" *R. Yıldırım, A. Coşgun, M. E. Günay* **#248** "A Simulation Study for Hydrogen Production from Low Rank Turkish Lignite Through Gasification in Trijen Pilot Plant in Soma" *Ö. O. Er, G. Kavas, M. Ünsal, A. S. Kartay, N. Ünlü, E. Muşdu, Ö. Ataç* **#259** "Thermal Modelling of Autothermal, Steam, and Partial Oxidation Solid Oxide Fuel Cell Reformers" *M. T. Çoban, H. Genceli, M. Asker, O. E. Turgut, M. S. Turgut* **#294** "Experimental and Theoretical Study of an Active Ni Nanocatalyst for the Hydrolysis of Sodium Borhydride and Dimethylamine Borane" *E. Karabulut, M. S. İzgi, E. Onat, S. Faal, F. A. Çelik, Ö. Şahin* **#347** "Sewage Sludge and MSW Gasification for Hydrogen Production: Integrating Renewable Energy with Desalination and Agriculture" *O. Tezer, A. Ayol*	
Coffee Break (with Poster Session-3)			

SCIENTIFIC PROGRAM

Tuesday – May 27, 2025

PARALLEL SESSIONS – 5		
	HALL A	**HALL B**
16:30 18:30	**WORKSHOP** **Innovations on Hydrogen-based Processes & Technologies** **Session Chair: Adolfo Iulianelli & Canan Acar**	**Session 19. Electrolysis and Electrolyzer Technologies – I** **(Sponsored by ARMELSAN Energy)** **Session Chair: Mustafa Kaan Baltacıoğlu**
	Alberto Figoli *National Research Council – Institute on Membrane Technology, Italy* **Operational Plan for Hydrogen Research, POR H_2 – EU/ NextGeneration EU – Program Agreement MASE/ENEA PNRR**	**#78** "Dynamic Modeling of an Anion Exchange Membrane Electrolyser" *S. Obut* **#305** "Electrolysis-Based Hydrogen Production Using Coaxial Cylindrical Electrodes with a Scrubber-Wire Cathode" *D. Erdemir, A. Y. G. Kara, I. Dincer* **#144** "Enhanced PEM Water Electrolysis with Low Equivalent Weight Aquivion® Membranes" *F. Giacobello, S. Siracusano, M.A. Mancuso, V. Cicciò, A. Muscolino, A.S. Aricò* **#90** "Green Hydrogen Production through AEM Electrolysis Technology" *V. Cicciò, S. Siracusano, S.C. Zignani, M. Pascale, A.S. Aricò* **#91** "MOS_2-Based Catalyst for Hydrogen Production in PEM Electrolysis" *M.A. Mancuso, S. Siracusano, F. Giacobello, V. Cicciò, A. Muscolino, A.S. Aricò* **#100** "Rapid and Scalable Synthesis of 3D Gas Diffusion Electrodes for AEM Water Electrolysers" *F. Lisi, R. Viscardi, I. Gualandi, E. Scavetta, F. Mariani, A. Fasolini, F. Basile* **#120** "Text-mining and Bibliometric Analyses for Proton Exchange Membrane Electrolyzers" *A. Fırtın, A. Yılmaz, İ. Eroğlu, R. Yıldırım, D. Eroğlu* **#130** "Synthesis of New Polystyrene Based Anion Exchange Membrane for Alkaline Electrolyzer" *L. Başat, M. Farsa, G. Kardaş*
	Selmiye Alkan Gürsel *University of Sabanci, Türkiye* **The Hydrogen Valley Project of Türkiye: HYSouthMarmara Hydrogen Shore**	
	Jan Veres *Technical University of Ostrava, Czech Republic* **Research Excellence for Region Sustainability and High-Tech Industries, REFRESH – International Project**	
	Antonio Agresta *National Agency for New Technologies, Energy and Sustainable Economic Development, Italy* **Driving Innovation Towards Future Aviation with Cutting-Edge Refuelling Technologies and Processes ALRIGH2T – EU Project**	
	Krzysztof Kapusta *Clean Coal Technology Centre – Centre for Climate and Renewable Energy Research, Poland* **Development of H_2 Oriented Municipal Waste Refinery Based on a Novel Borehole Gasification Process Combined with Advanced Gas Separation Techniques, HYDROMINE – EU Project**	
	Alessandra Beretta *Politecnico di Milano, Italy* **EMERALD – A Novel Electrified Reactor with Radial Current and Flow for the Intensification of Endothermic Catalytic Processes** **Research Project Funded by Air Liquide**	
19:00 21:00	**Banquet** *(Lokal Çatı Restaurant, Dokuz Eylul University Rectorate)*	

SCIENTIFIC PROGRAM

Tuesday – May 27, 2025

PARALLEL SESSIONS – 5			
HALL C	**HALL D**	**HALL E**	
Session 20. Hydrogen Storage Systems – I **Session Chair: Tugba Akkas Boynuegri**	**Session 21. Renewable Hydrogen Technologies and Integration** **Session Chair: Anıl Erdoğan**	**Session 22. Hydrogen Use in Industrial Applications** **Session Chair: Ismail Ekmekci**	
#6 "Numerical Study of Novel Thermal Management Methods for Hydrogen Storage in a Metal Hydride Reactor" *F. Selimefendigil, G.Şenol, H.F. Öztop* **#16** "FEM Based Numerical Study of Hybrid Nanofluid Enhanced Hydrogen Absorption in a Metal Hydride Reactor" *F. Selimefendigil, G. Şenol, H.F.* Öztop **#35** "Statistical Analysis of Hydrogen Storage on Boron Materials via Machine Learning" *A. Stif, E.C.Özcan* **#116** "Influence of the Technology for Obtaining IMC of the Mg-7%Ni-3%Ce System on the Evolution of Phase Transformations" *N. Ukhamedova, A. Miniyazov, Z. Ospanova, A. Sabyrtaeva, K. Shaikieva* **#118** "Integrating Metal Hydride-based Hydrogen Storage Tank with a PEM Fuel Cell Stack for Enhanced Energy Efficiency in Underwater Applications" *B. Sezgin, T.Öztürk, İ. Eroğlu* **#122** "Role of Hydrogen Adsorption and Desorption in Underground Storage within Coal Seams" *Ö. İmir, Ş. Merey, A. Fişne* **#158** "Optimization of Assembly Torque and Lubrication Amount for Hydrogen Tank Valves" *O. Özkan* **#322** "Production and Characterization Sulfonated Polyphenyl Sulfone PEM Membrane for Vanadium Redox Battery" *E. Çolak, S. Kahraman, B. Çetin, D. Ünlü, F. Ugur Nigiz*	**#8** "Solar Thermochemical Hydrogen Generation with a 250-kW Structured Reactor: Experiences from Tests at the Jülich Solar Tower" *T. Fend, V.K.Thanda, J. Lampe, S.Menz, S.Schmitz, G.Piesche, S.Berger* **#50** "Securing Geothermal Energy Projects: Hydrogen Production and Underground Storage as a Solution for Electricity Market Fluctuations" *H. Aydın, S. Merey* **#77** "AI-Based Optimization of a PV-Battery-Electrolyzer System for Green Hydrogen Production" *A. Yılmaz, N. Aksoy, G. Bayrak* **#236** "The Evaluation of Renewable Energy Alternatives in Hydrogen Supply Chain in Türkiye Using Hybrid Fermatean Fuzzy AHP-WPM Approach" *H. Kırış, Ö. N. Bilişik* **#202** "Thermodynamic Evaluation of Hybrid Thermochemical Process for Lignin to Hydrogen and Methane Conversion" *S. Yadav, F. Khalid* **#201** "Thermodynamics Assessment of a New Three-Step Cycle for Methane to Methanol and Hydrogen Production" *V. Yadav, I. Khan, F. Khalid* **#306** "An Experimental Investigation for Improved Hydrogen Production from Magnesium-Seawater Reaction" *Y. Hafez, I. Dincer* **#307** "Application of Synthesized Ammonium Formate as an Electrolyte in Stainless Steel-Stainless Steel Electrode H-Cell Configuration" *C. G. Turk, I. Dincer*	**#133** "Optimizing Energy Investments for Growing Demand of Türkiye: Hydrogen-Based Batteries and Renewable Integration" *A.O. Kabil, M.G. Güler* **#232** "Designing a Multiple Production System Based on CO_2 Capture and Utilization in Glass Industry" *I. Akgun, I. Dincer* **#281** "Theoretical Investigation of Using of Hydrogen and Natural Gas Blending in Slab Tundish Heating Systems for Green Steel Revolution" *H. T. Arat, M. K. Baltacıoğlu, S. M. Has* **#358** "Solar-based Green Hydrogen Production for Decarbonizing Natural Gas: An Emissions Perspective" *Habip Şahin* **#206** "Utilization of a Boron Co-Doped Activated Carbon/Starch Based Metal-Free Biocathode for Hydrogen Production" *A. T. Goren, I. Dincer* **#199** "Activated Charcoal for Sustainable Solid State Hydrogen Storage by Physical Adsorption" *A. Capoglu, I. Dincer*	**EXHIBITION**
Banquet *(Lokal Çatı Restaurant, Dokuz Eylul University Rectorate)*			

SCIENTIFIC PROGRAM

Wednesday – May 28, 2025

PARALLEL SESSIONS – 6		
08:30 08:45	**Conference Registration**	
	HALL A	**HALL B**
	Session 23. Hydrogen Economy, Infrastructure and Policy – II **(Sponsored by ARMELSAN Energy)** **Session Chair: Jan Veres**	**Session 24. Hydrogen Vehicles and Mobility – II** **Session Chair: Antonio Vita**
08:45 10:45	**Invited Speaker** **Tareq Al-Ansari** *Qatar Environment and Energy Research Institute* **Role of Hydrogen in the Energy, Water and Food Nexus** **#359** "A Policy on H_2/SAF Valley in Türkiye" *A. Midilli* **#255** "Hydrogen Value Chains in Positive Energy Districts: A Multi-Level Analysis on the Dynamics between Energy Transition Plans and Integrated Spatial Planning" *A. Gürler Akdeniz, E. Gürler, Y. Ateş, A. R. Boynueğri* **#253** "Critical Path Analysis for a Future Hydrogen Supply Chain: A Case Study for Central Anatolia" *M.G. Güler, T. Ulusoy, A. Döyen, F. Kosanoğlu* **#265** "Optimizing Hydrogen Refueling Infrastructure in Qatar: A Maximum Coverage Location Model Approach" *C. Méndez, R. Baldacci, M. Contestabile, Y. Bicer* **#310** "Techno-Economic Analysis of Green Hydrogen Production: Investigating Hybridization Potential in İzmir" *E. D. Gülay, C. O. Colpan, M. A. Ezan*	**#188** "Comparative Life Cycle Carbon Emissions Assessment of Utilizing Diesel Oil and Hydrogen Fuel on a Ferry" *O. Konur, M. E. Aydın, M. S. Aydın* **#204** "High Voltage Gain LLC Resonant Converter Design for Energy Transfer from Fuel Cell Electric Vehicle to Electric Vehicle" *M. Akkuş, E. Akboy, A. R. Boynueğri* **#211** "Investigation of T-Class Fuel Cell Hybrid Electric Off-Road Vehicle" *Z. S. İşleyen, M. U. Karaoğlan* **#221** "Performance Analysis of a Small Hybrid Vehicle on Inclined Roads Under WLTP Class 2 Drive Cycle" *B. Yılmaz, C. O. Colpan* **#225** "Uninterrupted Communication with PEMFC-Enhanced UAVs in Disaster Scenarios" *M. Kayaoğlu, S. Unal, B. Calisir* **#251** "Design of a Standalone Electric Vehicle DC Fast Charging Station Based on a Hybrid Energy System with Fuel Cell and PV for a Tourist Resort" *M. Yıldırım, S. Unal* **#314** "Numerical and Experimental Investigation of Electric and Fuel Cell Hybrid Mini UAV" *İ. Sağlam, Z. İşleyen, M. Karaoğlan, Ş. Yavuz* **#174** "Mathematical Modeling and Ground Tests of a Fuel Cell Hybrid Unmanned Aerial Vehicle in Cruise Phase" *M. Azer, M. U. Karaoğlan, C. O. Colpan, T. H. Karakoc*
10:45 11:05	**Coffee Break (with Poster Session-4)**	

SCIENTIFIC PROGRAM

Wednesday – May 28, 2025

PARALLEL SESSIONS – 6			
Conference Registration			
HALL C	**HALL D**	**HALL E**	**EXHIBITION**
Session 25. Fuel Cells and Applications – III **Session Chair: Adele Brunetti**	**Session 26. Thermodynamics of Hydrogen Energy Systems** **Session Chair: Aysel Kantürk Figen**	**Session 27. Sustainable Hydrogen Technologies – II** **Session Chair: Ivana Perović**	
#125 "Development of Flat-Tubular Solid Oxide Fuel Cells via Mold Casting" *K. Bilgil, Ç. Timurkutluk, S. Onbilgin, B. Timurkutluk* **#129** "Microtubular Solid Oxide Fuel Cells with Ytterbium Doped Zirconia Electrolytes" Ç. Timurkutluk, E. Yıldız, *G. Germen Tutaş, S. Onbilgin, B. Timurkutluk* **#132** "Lightweight and Optimized End Plates for PEM Fuel Cells: A Comparative Structural Analysis" *F. Çetiner, A.E. Kılıç, S. Çelik, S. Toros, R.E. Ece* **#142** "Developing and Designing Different Channel Types for Micro Direct Methanol Fuel Cells Based on Mitochondria Cell Structure" *M. Menteş, A.E. Kılıç, S. Çelik, F.D. Güzel, M.K. Birhanu* **#157** "Scale up Techniques for PEMFC: Fluid Mechanics Approach" *G. Tol, A.C. Türkmen, C. Çelik, F.G. Boyacı San* **#212** "Impact of Current Density on Temperature and Water Content Distribution in a PEM Fuel Cell using a Coupled Heat and Mass Transfer Model" *M. Jahanbakhsh, E. Aydın, C. Erkey*	**#5** "Efficiency and Performance Analysis of IT-SOFC Integrated with S-CO_2 Brayton Cycles: A Comprehensive Study on Waste Heat Utilization" *S. Beygül, Y. Kalıncı* **#197** "Thermodynamic Analysis of Synthetic Fuel Production from Carbon Dioxide Obtained from Carbon Capture Facility in Oil Refinery by Combination of Hydrogen Production and Power Conversion" *S. B. Sungur, E. Kayabasi, E. Alp* **#198** "Analysis of Synthetic Fuel Production Utilizing the Waste Heat from Blast Furnace Hot Stoves by Combination of Thermal Energy Storage and Power Cycle" *S. B. Sungur, E. Alp, E. Kayabasi* **#192** "Performance Assessment of Hydrogen Production from Geothermal-Solar Based ORC System" *Y. N. Atak* **#208** "Thermodynamic Modeling of an Innovative Integrated Polygeneration System Using Sustainable Energy Resources" *M. A. Sabbaghi, C. O. Colpan, H. Genceli* **#330** "Green Hydrogen Production Station: Applying Exergetic Sustainability Parameters to a 1 MW PEM Electrolyzer" *A. E. Aluç, A. Midilli* **#308** "Mathematical Modeling and Simulation of an Anion Exchange Membrane Water Electrolyzer Using COMSOL Multiphysics" *A. Demirtaş, C. O. Colpan, Y. Devrim, Y. N. Atak* **#141** "Thermodynamic and Electrochemical Modeling of Direct Methanol Fuel Cell System for Portable Applications" *E. Kalkan, M. Alobeid, S. Çelik, H. Özcan*	**#333** "An Efficient and Sustainable Approach to Green Hydrogen Production Using PV Systems" *H. Topcan, A. Akpolat, U. Aydemir* **#343** "Hybrid Hydrogen Systems for Mitigating Sub Synchronous Oscillations in Weak Power Grids" *S. Shahzad, H. Kilic* **#313** "Boosting Photocatalytic Hydrogen Production through Ni_2P/g-C_3N_4/Ti_3C_2 Quantum Dots" *D. Akyüz, B. Güven, E. Demirbaş* **#338** "Metal-organic Frameworks for Hydrogen Storage" *S. Demir* **#283** "Manta Ray Foraging Optimization for Accurate Parameter Estimation of Proton Exchange Membrane (PEM) Fuel Cell Model" *D. Yağcı, H. Genceli, O. E. Turgut* **#89** "Plasma-catalytic Method of Methane Conversion in Microwave Discharge" *M. Skakov, A. Miniyazov, T. Tulenbergenov, I. Sokolov, A. Agatanova* **#151** "Speed Control of a Synchronized Induction Motor Powered by Hydrogen Fuel Cell" *H. Erdoğan*	
Coffee Break (with Poster Session-4)			

SCIENTIFIC PROGRAM

Wednesday – May 28, 2025

PARALLEL SESSIONS – 7		
	HALL A	**HALL B**
	PANEL **Hydrogen Technologies in the Defense Industry**	**Session 28. Electrolysis and Electrolyzer Technologies – II** **Session Chair: Gülfeza Kardaş**
11:05 12:50	**Moderator** **Selmiye Alkan Gürsel** *Sabancı University, Türkiye* **PANELISTS** **Deniz Demirci** *Secretariat of Defense Industries (SSB), Türkiye* **Hüseyin Devrim** *TEKSIS, Türkiye* **Uğur Kayasal** *Roketsan Missiles Inc., Türkiye* **Devrim Köseoğlu** *Turkish Aerospace Industries (TUSAŞ), Türkiye* **İbrahim Pamuk** *LENTATEK, Türkiye* *This panel aims to provide insights into how hydrogen can revolutionize military propulsion systems, enhance energy resilience, and support sustainable logistics.*	**#138** "Synthesis of NiFeMo HER Catalyst on Nickel Foam for AEM Electrolyser" *Y.S. Adam, M. Farsak, G. Kardaş* **#166** "Simulation-Based Performance and Cost Optimization of Alkaline Electrolysers" *S. Ş. Demirezen, H. Özcan, S. Çelik* **#168** "Comparison of IrO_2-FeVS and IrO_2-FeVS-Co Catalysts in PEM Electrolysis at Different Temperatures" *M. Çokyaşa, A. Ekinci, Ö. Şahin, O. Baytar* **#243** "Experimental Analysis of Proton Exchange Membranes for Water Electrolyzers Across a Range of Operating Parameters" *A. Albadwi, S. B. Selçuklu, M. F. Kaya* **#48** "Optimization of Boron-doped Nickel Electrodes for Enhanced Hydrogen Production via Alkaline Electrolysis" *C. Demir, K.A. Uğurlu, D. Türkyılmaz, A.D. Tümer, B.C. Filiz* **#139** "Investigation of Long-term Degradation Effects in PEM Electrolyzers" *A. Çankaya, S. Çelik, B. Sevinç, K. Dağıdır, H. Özcan* **#148** "Design of Single Porous Transport Layer with Strut-based Lattice Structures for PEM Electrolyzers" *K. Dağıdır, A. Çankaya, S. Çelik*
12:50 13:30	**LIGHT LUNCH** *(Foyer)*	
KEYNOTE SESSION 3 (HALL A) **Session Chair: Azize Ayol**		
13:30 14:10	**Feridun Hamdullahpur**, *University of Waterloo* **Green Ammonia: A Pragmatic Pathway for Early Green Hydrogen Commercialization**	

SCIENTIFIC PROGRAM

Wednesday – May 28, 2025

PARALLEL SESSIONS – 7			
HALL C	**HALL D**	**HALL E**	
Session 29. Hydrogen Storage Systems – II **Session Chair: S. Aykut Korkmaz**	**Session 30. Sustainable and Renewable Hydrogen Technologies** **Session Chair: David Alique**	**Session 31. Biohydrogen and Waste-to-Hydrogen** **Session Chair: Krzysztof Kapusta**	**EXHIBITION**
#126 "Geological Hydrogen Storage for Long-duration Energy Resilience" *A. Özmumcu, A. Baba* **#180** "Performance Assessment of a Hybrid Compressed Air Energy Storage System Fed by Hydrogen from RES" *V. Tola, R. Caria* **#239** "Fly Ash-Derived Supported Iron Catalysts for Efficient Ammonia Decomposition: A Sustainable Approach for CO_x-free Hydrogen Storage" *B. Sekizkardeş, S. F. Kurtoğlu-Öztulum* **#361** "Intelligent Health monitoring of Hydrogen Storage and Transport Systems" *S. Sikdar*	**#298** "Sustainable Hydrogen Production Through Hybrid Nanofluid Integrated Evacuated Tube Solar Collectors with Organic Rankine Cycle" *S. G. Güngör* **#346** "From Agricultural Waste to Renewable Energy: Integration of Soil-based Microbial Fuel Cells in Biobed Systems for Sustainable Treatment of Olive Oil Mill Wastewater" *S. Gunes, A. Ayol* **#316** "Producing Hydrogen and Heat from Solar Towers: A Path toward Energy-Independent Cities" *E. Kocaman, H. Yağlı, H. Tutumlu, E. Oğur, R. Yumrutaş* **#106** "Investigation of the Conditions for the Use of New Generation Hydrogen Generator in Geothermal Power Plants: Kizildere Geothermal Field Case Study" *R. Ş. Çetin, F.G.Boyacı San, F. S. T. Haklıdır* **#334** "Hydrogen Production from NaCl, $CaCl_2$ and $MgCl_2$ Salts using Carbon Rods Extracted from Waste Batteries" *S. Damarseckin, M. Erden, A. Atiz, H. Karakilcik, M. Karakilcik* **#366** "Development and Analyses of a Nuclear-Driven Polygeneration System with Helium Brayton Cycle, Hydrogen and Ammonia Production, Ejector Cooling, and Desalination" *O. Kizilkan, G. Soytürk*	**#42** "Comparative Analysis of Biohydrogen Production Studies in Türkiye Using Evidence Synthesis Methodology" *K.K. Yiğit, T. Keskin-Gündoğdu* **#43** "Evaluating the Performance of Boosting Regressors for Predicting Biohydrogen Production under Variable Experimental Conditions" *M.A. Ergün, T. Keskin-Gündoğdu, B.E. Köktürk- Güzel* **#99** "Evaluation of Hydrogen Production Efficiency by Dark Fermentation Process of Various Airport-derived Wastes" *F. Altay, N. Semerci, A. Öngen, Ş. Duran, M.C. Altay, N. Yeşilova* **#219** "Challenges and Limitations of Dark Fermentative Hydrogen Production" *Ş. Arıcı, G. Koçar* **#220** "Integration of Dark Fermentation and Microbial Electrolysis Cells for Hydrogen Production from Wheat Straw" *Y. D. Yilmazel, İ. Konar, R. Kunayeva, İ. Bulat, R. Harb* **#345** "Comparative Assessment of Bioelectricity Generation from Various Industrial Wastewaters and High-strength Organic Wastes Using Microbial Fuel Cell Technology" *I. Biryol, A. Ayol* **#79** "Enhanced Catalytic Performance of Titanium Dioxide-supported CuCo Bimetallic Catalyst for Hydrolysis of Ammonia Borane" *M. Kılıç, E. Özdemir*	
LIGHT LUNCH *(Foyer)*		**Optional Social Tour (starts at 12:30)**	

SCIENTIFIC PROGRAM

Wednesday – May 28, 2025

14:10 14:30	**NHA AWARDS CEREMONY & REMARKS (HALL A)**	
PARALLEL SESSIONS – 7		
	HALL A	**HALL B**
	Session 32. Catalysts for Hydrogen Applications – IV **Session Chair: Hadi Genceli**	**Session 33. Sustainable Hydrogen Technologies – III** **Session Chair: Canan Acar**
14:30 16:30	**#23** "Development of Fe-C Microwave Catalysts for Conversion of H_2S into CO_x-free H_2" *Y. Ataseven, M.Y.Doğan, S.Yaşyerli, H.Arbağ, H.M.Taşdemir, N.Yaşyerli* **#29** "Ultrasonic Spray Synthesis of Coal Layered Double Hydroxide: A Novel and Scalable Approach to Oxygen Reduction Catalysis" *K. EXHIBITION

CLOSING REMARKS (HALL A)

SCIENTIFIC PROGRAM

Poster Session

Poster Sessions Chair: Olgun Konur

Poster Session – 1 (Monday – May 26, 2025 | 16:00 – 16:30)

#13 "Eco-friendly Leaching Strategies for Recycling Electronic Waste CPUs to Enhance Hydrogen and Oxygen Evolution" *S. Mitrović, S. Brković, M. Seović, M. Pijović Radovanović, P. Laušević, N. Zdolšek, I. Perović*

#14 "Electrochemical Surface Modification and Effects on the Catalytic Activity of Nickel-based Electrodes for Hydrogen Evolution" *S. Mitrović, S. Brković, M. Seović, P. Laušević, N. Zdolšek, Đ. Katnić, I. Perović*

#15 "Non-stoichiometric Tungsten-oxides as the Anode Catalyst Supports for PEM Fuel Cells" *S. Brković, I. Perović, M. Seović, S. Mitrović, P. Laušević, V. Nikolić, M.M. Kaninski*

#18 "Dual-doped Iron-copper Carbon Electrocatalyst for Enhanced Water Splitting Performance in Alkaline Media" *J. Georgijević, I. Perović, S. Brković, M. Seović, N. Zdolšek, J. Milikić, B.Šljukić*

#19 "Synthesizing Cost-effective, Dual-function Catalysts from Recycled CPUs and Lemon Peel for Water Splitting" *M. Seović, S. Brković, I. Perović, D. Jugović, J.M. Vukajlović, P.Laušević, S.Mitrović*

#21 "Life Cycle Assessment of Green Hydrogen Production via Electrolysis" *H. Camur, A. Isler-Kaya, F. Karaosmanoglu*

#22 "Development of Iron-Sulfide Catalysts for Green H_2 Production from H_2S" *N. Demirhan, H.Akansu, Y. Ataseven, M.Y.Doğan, S.Yaşyerli, H.Arbağ, H.M.Taşdemir, N.Yaşyerli*

#56 "Gasification of Agricultural Residual Biomass, Vector in the Production of Green H_2" *G.C. Lăzăroiu, L. Mihăescu, I. Pîșă, R.M. Grigoriu, D. Stoica, I. Simion*

#58 "Cost-effective Porous NiO/Ni@NF Nanosheet Catalysts for Hydrogen Production via Electrocatalytic Ethylene Glycol (EG) Oxidation" *S.A. Aladeemy, T.R.Al-Rijraji, M.S.Amer, P. Arunachalam, A.M. Al-Mayouf*

#60 "Results of Combustion Tests of H_2 – CH_4 Mixture with High H_2 Content" *L. Mihăescu Lucian, G. Lăzăroiu, A. Niculescu, D. Stoica, R.M. Grigoriu, M.G. Osman*

#61 "Ionic Liquid-enhanced Multifunctional Electrolytes for Hydrogen Evolution Reaction and Zn-based Batteries" *N. Zdolšek, A. Dimitrijević, I. Perović, S. Brković, M. Seović, P. Laušević, M.K. Roković*

#62 "Enhanced Electrochemical Performance of V_2O_5 Electrode with 1-butyl-3-methylimidazolium Salicylate Electrolyte for Hydrogen Evolution, Oxygen Evolution and Oxygen Reduction Reactions" *N. Zdolšek, A. Dimitrijević, I. Perović, S. Brković, M. Seović, M.K. Roković, M. Božiković*

#64 "Performance Analysis of Stand-alone Solar Systems in Coastal Environments: A Case Study" *M.G. Osman, G. Lazaroiu, C.V. Strejoiu, C. Panait, D. Stoica*

#65 "Increasing the Energy Efficiency and Economic Viability of a Photovoltaic Park in Craiova" *M.G. Osman, G. Lazaroiu, C.V. Strejoiu, C. Panait, D. Stoica*

Poster Session – 2 (Tuesday – May 27, 2025 | 10:30 – 10:50)

#80 "Synthesis and Characterization of Semiconductor Oxides CuO and ZnO for the Production of Green H_2 by Photo Catalysis under UV-visible Light" *N. Djamel, A. Samira, S. Farouk, F. Djawad, H.H. Aya*

#82 "Hydrogen Gas Production onto Fe_2O_3 and Clay/ Fe_2O_3 by Photo Chemical Conversion under UV-visible Light" *N. Djamel, A. Samira, S. Farouk, F. Djawad, H.H. Aya*

#88 "High-Value Carbon Production through Thermal Plasma Dry Reforming for E-fuel Viability" *A.R.C. Labanca, A.G. Cunha, R.P. Ribeiro, C.G. Zucolotto, M.B. Cevolani, M.A. Schettino Jr., F.G. Emmerich*

#92 "Innovative Electrolysis Using Non-Critical Raw Materials and Circular Economy Techniques to Improve Green Hydrogen Production" *A. Muscolino, A.S. Aricò*

#93 "A PEM Electrolyser with Low Precious Metal Loading" *V. Cicciò, S. Siracusano, A.S. Aricò*

#121 "Dehydrogenation of Dimethylamine Borane in the Presence of Ru^0/TiO_2 Catalyst" *A. Al-Areedheea, S. Karaboğa, İ.A. Morkana, S. Özkar*

#123 "Electrodeposition of Platinum on Electropolymerized ABA on Reduced Graphene Oxides as a Catalyst for Propanol Oxidation in Alkaline Solution" *P. Waenkaew, S. Sriwichai, S. Themsirimongkon*

#137 "Development of $NiCo(OH)_2$ Based OER Catalysis for Alkaline Water Electrolysis" *Y.S. Adam, G. Aksaray, E. Faki, M. Farsak, G. Kardaş*

#140 "Performance Analysis of Plant-Inspired Bipolar Plate Flow Channels for PEM Electrolysers using 3D Modelling" *M. Alobeid, S. Çelik*

#143 "Hydrogen Economy: Key Developments in China, Europe, and the USA" *D. Üngüder, A.C. Krutoff, M. Wappler*

#150 "The Role of Ammonia in Renewable Energy and Emergency Power Supply: A Feasibility Study" *H. B. Perçin, A. Çalışkan*

#152 "Exploring Hydrogen Mobility: A Feasibility Study on Sustainable Campus Transportation" *H. B. Perçin, A. Çalışkan*

#156 "Synthesis and Characterization of (Gd,Nd) – Doped $CeO_2/SrTiO_3$ Heterostructures for Lt-SOFC" *N. Kırkgeçit Aksoy, D. Kara, S. Kerli, M. Şaşmaz Güldal, O. Türkoğlu, H. Özlü Toru*

#159 "Seawater Electrolysis for an Advanced H_2 Production" *F. Giacobello, S. Siracusano, A. Muscolino, V. Cicciò, M. A. Mancuso, V. Antonucci*

#171 "Contribution of SM-Doped CeO_2 Nanoparticles to Hydrogen Production" *A. Kırkgeçit, H. Ö. Torun, N. K. Aksoy, M. Kisti, G. Özkırar, M. F. Kaya*

#175 "Development of Alkaline Electrolysis Catalyst Using Waste Zinc-Carbon Batteries" *H. Hançer, M. Farsak*

#200 "High-Efficiency Hydrogen Storage via Porous Germanene Nanostructures" *A. Miranda, G. González, B. J. Cid, M. Calvino, J. E. Santana, F. Salazar*

#222 "Energy Management in a Hybrid System Integrating PV Panels, PEM Fuel Cells, and Batteries" *B. Yılmaz, C. O. Colpan*

#235 "Electrooxidation of Methanol and Sodium Borohydride on Nano-Silver Electrode for Alkaline Fuel Cells" *A. Aytaç, F. Ö. Gökmen*

SCIENTIFIC PROGRAM

Poster Session

Poster Session – 3 (Tuesday – May 27, 2025 | 16:00 – 16:30)

#240 "Development of a New Generation Hybrid System for the Electric Vehicle" *A. Aytaç, O. Yılmaz*

#242 "Optimal Design of a New Photovoltaic-Electrolyser-Fuel Cell-Battery Hybrid System" *A. Aytaç, O. Yılmaz*

#246 "Impact of Operational Stoppages on the Stability of Anion Exchange Membrane Electrolysis" *M. Mizanur Rahman, A.H.M Monteverde, M. Santarelli*

#257(1) "Green Synthesis of Fuel Bioadditive Solketal Levulinate by Functional Catalytic Membrane" *N. Y. Yüzer, G. Hasırcı, A. O. Hoşöz, E. E. Çakırca, E. Alptekin, O. İlgen, M. Çanakçı, N. Hilmioğlu*

#257(2) "Development of Environmentally Friendly the Catalytic Membrane as a Catalyst for Synthesis of the Green Fuel Bioadditive Glycerin Carbonate" *G. Hasırcı, N. Y. Yüzer, A. O. Hoşöz, E. E. Çakırca, E. Alptekin, O. İlgen, M. Çanakçı, N. Hilmioğlu*

#258 "Integration and Storage of Hydrogen-Based Fuel Cells for Unmanned Aerial Vehicles" *M. F. Özbek, R. Ak, E. Telci, E. Çelik, H. Settaşı, S. Sezer, V. Alizada, E. C. Duğan, S. A. Angin, R. G. Akay, C. Çelik*

#264 "Sc- and Ti-Functionalized Doped SnC Nanosheets for Hydrogen Storage" *D. Romero, A. R. Montoya-García, L. G. Arellano, M. I. Iturrios, L. A. Pérez, M. Cruz-Irisson*

#269 "Kinetic Modelling on Transient Photocurrent Responses of WO_3 Photoanodes" *E. Ayral, F. Uçar, E. Haznedar, E. Altuntaş, S. Kaya*

#280 "Understanding the Kinetic Mechanism of WO_3 Photoanodes for PEC Applications" *E. İ. Haznedar, F. Uçar, E. Ardalı, E. Altuntaş, S. Kaya*

#295 "Performance Assessment of a Hydrogen Liquefaction Cycle Utilizing Liquefied Natural Gas Regasification and Photovoltaic Panel-Based Power Generation Unit" *M. Taghavi, C. O. Colpan*

#297 "Hydrogen and Volatile Fatty Acid Production from Posidonia Oceanica Seagrass by Dark Fermentation" *D. Kurtdemir, E. Taylan, Ş. Arıcı*

#300 "Thermodynamic Analysis of Claude Cycle for Hydrogen Liquefaction" *Y. Kumlutaş, C. O. Colpan*

#317 "Effect of MoP/g-C_3N_4/Ti_3C_2 Quantum Dots on Photocatalytic Hydrogen Production" *E. S. Şahin, D. Akyüz, E. Demirbaş*

#362 "Assessing Electrolyte Effects in Fuel Cell Systems" *E. Durar, B. Memişoğlu Güzelgün, S. Damarseckin, A. Atız, M. Karakılçık*

#363 "High-Pressure Hydrogen Direct Injection in Optical Combustion Research" *Y. Rousseeuw*

#369 "Scalable Electrode Design Using MPt (M: Cu, Co, Ni) Alloy Nanoparticles for Efficient and Durable Hydrogen Evolution in Seawater Electrolysis" *M.Z. Nezhad, O. Metin*

Poster Session – 4 (Wednesday – May 28, 2025 | 10:45 – 11:05)

#318 "Enhancement of Photocatalytic Hydrogen Production with CoP/g-C_3N_4/Ti_3C_2 Quantum Dots" *B. Camgöz, D. Akyüz, E. Demirbaş*

#320 "Development of a Novel Catalytic Membrane by Loading Silico Molybdic Acid to Polyvinyl Alcohol and its Use as a Catalyst for Fuel Additive Solketal Synthesis" *N. Yenihan Yüzer, N. Hilmioğlu*

#323 "Electrospun Copper-doped Recycled PVDF Membranes for Microbial Fuel Cell Applications" *A. Katırcı, Ö. Ipsalali, S. Kahraman, F. Ugur Nigiz*

#325 "Solar Energy Storage via H_2 Production Using a Thermochemical MnSO4/MnO Water Splitting Cycle" *R.R. Bhosale, A. Arnold, M. Ball, K. Collins, K. Hamilton, N. Heath, J. Hobbs, C. Howell, W. Johnson, C. Kouvarakis, V. Kyslytsya, C. Latham, G. Prater, M. Sanchez, R. Self, A. Sellers, M. Serven*

#335 "Evaluation of the Social Dimensions of Integrating Natural Gas and Hydrogen in Energy Consumption: The Case of Turkiye" *B. Yenihan, K. Çolak, O. Özcan*

#336 "Clean Energy Demand: Evaluating the Use of Hydrogen in Electricity Generation from a Corporate Cost Perspective" *K. Çolak, B. Yenihan, O. Özcan*

#339 "Hydrogen Storage Properties of a Zirconium Metal-organic Framework" *S. Demir, N. Bilgin*

E-mail: ibrahim.dincer@ontariotechu.ca

ABSTRACT
Energy has always been one of the most important needs of humanity throughout centuries, and its role has really been a critical asset for civilizations and their developments. It has closely affected humanity's basic needs, such as water, air and food, and it is as a crucial resource that has shaped the past, continues to shape the present and is expected to shape the future. The importance and need for clean energy in the process we are entering is a fact known by everyone. On the other hand, with the increasing use of fossil fuels (coal, oil and natural gas) used to meet energy needs, many problems related to air, water and food have emerged in the world and these problems have significantly affected human health and life. An unavoidable effect of fossil-based energy sources used in the process after the industrial revolution has made an energy change necessary with the intense carbon dioxide emissions that have emerged and the climate changes and global warming results on both regional and global scales. In a way, this has strengthened our transition from the carbon age to the hydrogen age as of 2020. This article evaluates historical transformations in energy options, highlights the role of hydrogen and answers the questions of what we should do in the hydrogen age.

Keywords: Clean water, clean air, clean food, clean energy, clean hydrogen, hydrogen age, sustainability

1. INTRODUCTION

Today, we are in an era where everything is designed to be smarter and better, and in this regard, new energy solutions are expected to be more efficient and effective. Of course, when we look around us, it is based on many things in daily life; smart materials, smart devices, smart phones, smart grid, smart measurement, etc. We need to make energy diversity and, in relation to this, the technologically improved processes under smart energy solutions. With advanced technologies and artificial intelligence applications, humanity can easily address the entire energy spectrum in five categories, as energy basics and concepts, energy materials, energy production, energy conversion and energy management, and this clearly shows that we need to change the roadmap, in short, our energy diet, regarding these issues. When we consider the energy dimensions and examine the historical processes, we see that energy affects many areas from technical dimensions to economic dimensions, from economic dimensions to environmental dimensions, from environmental dimensions to social dimensions and even the most important of these, political dimensions. In fact, historically, humanity's desire to own energy and energy sources in its energy journey has caused many clashes and wars. This article brings numerous dimensions to examine the needs for humanity in a general perspective and link all to clean energy where clean hydrogen becomes a crucial commodity and its role becomes critical for societal development and sustainable future.

2. BASIC NEEDS OF HUMANITY

It is apparent that there are four basic needs which are essential for human beings to live. These are: clean water, clean air, clean food and clean energy, as illustrated in Figure 1. One should note that if energy is not clean enough, the rest of the needs of humanity is greatly affected. This is exactly what has happened since industrial revolution.

Fig. 1. Four essential needs required for a sustainable future of humanity.

Looking into history, in terms of energy, humanity has used wood as the first source of energy for many of its daily tasks, and this period has evolved over the centuries into the coal era (which technically mobilized the industrial revolution through steam engines), the oil era (primarily after the first world war) and the natural gas era (increasingly after the 1980s). There is noticeably a final destination in this energy journey towards hydrogen as a carbon-free fuel and energy carrier. Throughout this journey, carbon/hydrogen (C/H) ratio has been decreasing, obviously over the centuries and is expected to bring us into a carbon free society where hydrogen economy is clearly expected to flourish. The humanity's journey is a clear indication of a shift towards a carbon-free economy or a carbon-free society.

3. A CLEAR TRANSITION FROM CARBON AGE TO HYDROGEN AGE

Historically, we all remember the metal ages, the copper age, then the bronze age and then the iron age. These have historically ended, of course, the end of these ages was not due to the end of copper, bronze or iron. This transformation was entirely due to the development of humanity and the increase in its technical capabilities and the efficient use of resources and the needs in life. In regards to energy, the beginning of the carbon-based age is the primary and intensive use of coal that started with the industrial revolution, followed by the intensive use of oil and then natural gas, which made this process intensively carbon-based and in parallel with this, the very rapid increase in carbon dioxide emissions and the negative environmental effects that came with it, regional and global climate changes and irregularities, global warming, etc. It is an inevitable result of its harmful effects. Now we are calling for hydrogen and this process has technically accelerated with the pandemic effect caused by the COVID-19 virus that broke out in the world in 2020 [1]. Therefore, the COVID-19 coronavirus pandemic, which directly or indirectly affects every person, has particularly affected the elderly, those with weak immune systems and those who suffer from various respiratory and cardiovascular diseases. This is clearly a turning point where we cannot continue the carbon age and can no longer leave ourselves vulnerable to such pandemics. This turning point is a decisive moment for the opening of a new era with hydrogen and the closing of the carbon age. As indicated in Dincer [1], the carbon age, which continued with hydrocarbon fuels until the coronavirus outbreak in 2020, will be replaced by the hydrogen age, where the use of hydrocarbon fuels (fossil fuels) will decrease exponentially and the use of hydrogen energy will increase. In this hydrogen age, the following benefits are expected to be provided: better environment, better ecosystem, better efficiency, better economy and economic development, better synchronization of use with renewable energy options, better health and healthier societies, and better sustainability development countable.

Furthermore, it is necessary to carefully consider the economic development periods and their roles historically. In this regard, Figure 6 is given to show the economic periods after the 1950s, basically after the second world war, and how such economic periods have impacted the humanity, societies and societal developments. The period between 1950 and 1970 was a labor-intensive era where industrial development depended heavily upon the human labor. This was followed by a skill-intensive period between 1970-1980 where societies started developing further to better train people and make them skilful for industrial development. Following this, there was a capital-intensive era, referring to a period where businesses or industrial enterprises required some significant capital investments and physical assets and infrastructure development with a goal to produce goods or services. By 1990 the technology era started while the innovation era began by the year 2000 which was followed by the digital intensive period by the year 2010, and obviously, more recently the hydrogen era has come to reality by the year 2020. We are now in hydrogen era, which is introduced by Dincer [2] as hydrogen age (*Hydrogen 1:0*). The current hydrogen age also requires all three periods of technology, innovation and digitalization combined with a common goal of humanity to achieve a sustainable future.

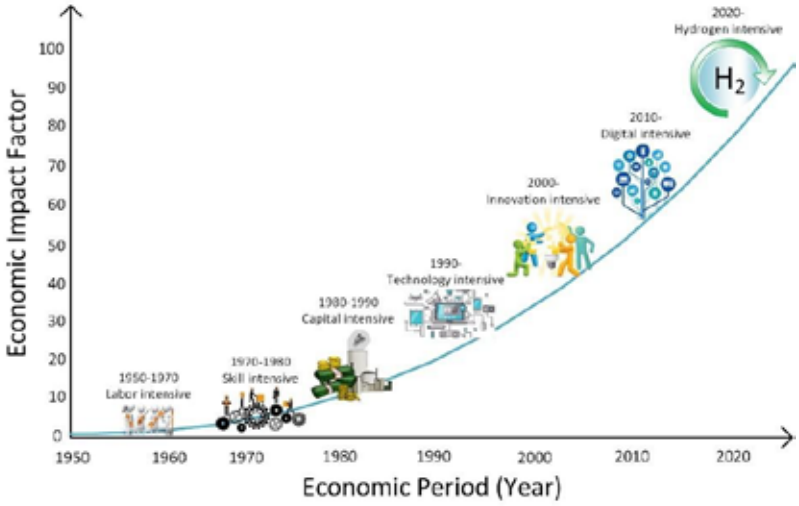

Fig. 2. An illustration of economic periods and their impacts historically after the second world war (Dincer [2]).

4. CLOSURE

The world has incredibly experienced rapid change and transformation processes throughout the history. These have actually been in every dimension of life and affected the way that humanity has covered their needs, including energy. Intensive local and global challenges have required clean energy solutions by addressing the need of carbon free solutions with a unique address towards clean hydrogen and its clean derivatives which will help achieve cleaner and more sustainable future.

ABSTRACT

This study investigates the performance of various hybrid systems, coupling intermediate temperature solid oxide fuel cell (IT-SOFC) with different supercritical carbon dioxide (S-CO_2) Brayton cycle configurations. The investigation aims to efficiently harness waste heat from IT-SOFC, converting it into useful work. At the standard operating conditions of the IT-SOFC (600°C, 0.3 A/cm^2), the efficiency of the isolated solid oxide fuel cell (SOFC) stack is 34.75%. The efficiencies of the novel hybrid systems are as follows: the SOFC/S-CO_2 Basic Brayton cycle (SBBC) hybrid system at 43.93%, the S-CO_2 Recompression Brayton cycle (SRCBC) at 49.8%, and the SOFC/S-CO_2 Regenerative Brayton cycle (SRBC) hybrid system achieving the highest at 54.66%. Different cycles favor different temperature ranges, with SRCBC being efficient at lower temperatures (<600°C) and SRBC thriving at medium-high temperatures (>600°C) due to the temperature sensitivity in the recuperator. The SOFC/SRBC hybrid system demonstrates superior efficiency with reduced complexity, making it a promising solution for effective waste heat utilization.
Keywords: Supercritical CO_2 Brayton cycle, Intermediate temperature solid oxide fuel cell, Waste heat, Hybrid system

1. INTRODUCTION

The global shift to eco-friendly energy highlights SOFCs and SOFC/gas turbine (GT) hybrid systems as efficient, flexible solutions to combat climate challenges. SOFCs directly convert the free energy of a chemical reactant to electrical energy and heat without the efficiency limitations typical of thermodynamic cycles. SOFC systems operate at temperatures of 500-1000°C, but high temperatures increase material costs and reduce lifespan. To address these challenges, IT-SOFCs have been developed to operate efficiently at 600-800°C [1]. The S-CO_2 Brayton cycle is an appropriate option for bottoming cycle due to the advantages of high efficiency and compact equipment sizes in the moderate temperature range (450-750˚C) [2]. With critical conditions of 30.98˚C and 7.38 MPa, CO_2 behaves like an incompressible fluid, reducing compression work. The S-CO_2 Brayton cycle has gained attention as an alternative for waste heat recovery, outperforming air cycles in intermediate-temperature applications [3]. Limited studies have analyzed fuel cell/S-CO_2 Brayton cycle hybrid systems. To summarize the studies on SOFC/S-CO_2 hybrid systems in the literature: Hybrid systems which integrate MCFC with a S-CO_2 Brayton cycle were investigated and compared with other hybrid systems based on SOFC/S-CO_2 [2,3]. Liu et al. [4] analyzed the novel hybrid system based on the SOFC/GT/CO_2 cycle. The energy efficiency of the system and the power generation efficiency of the SOFC reached about 79.81% and 50.96%, respectively. Schöffer et al. [5] compared several configurations of SOFC/S-CO_2 Brayton cycle hybrid system. It was found that recirculating cathodic air increases the efficiency of the system and decreases the size of the heat exchangers but increases the complexity of the system. Sadeghi et al. [6] investigated two S-CO_2 Brayton cycles for waste heat recovery in a SOFC-based system. Findings indicated that, at the optimized condition, the capability of a simple S-CO_2 cycle for recovering heat from the SOFC is 30.86% higher than a recompression S-CO_2 layout. Liu et al. [7] proposed an efficient energy system combining SOFC, S-CO_2 Brayton cycle, and CO_2 capture. Results showed 60.96% net electrical efficiency and 0.342 kg/kWh CO_2 reduction. Guo et al. [8] optimized a hybrid SOFC/S-CO_2 Brayton cycle, achieving improved power output and ecological performance over standalone SOFCs. Chen et al. [9] analyzed a hybrid system with SOFC, gas turbine, and recompression S-CO_2 Brayton cycle, finding the optimum point at 68% exergy efficiency and 0.0575 kWh^{-1} electricity cost. Integrating fuel cell technologies with S-CO_2 Brayton cycles is critical for enhancing efficiency and promoting sustainability. However, research on SOFC/S-CO_2 hybrid systems remains limited, leaving a significant gap in understanding their performance and optimization potential. This study addresses this gap by analyzing the performance and efficiency of IT-SOFC/S-CO_2 hybrid systems across various configurations. The key innovation lies in leveraging the waste heat from an intermediate-temperature commercial SOFC in different S-CO_2 cycle designs, providing valuable insights into intermediate-temperature waste heat utilization and system optimization.

2. MATERIALS AND METHODS

The study examines three different configurations: the integration of SOFC with SBBC, the combination of SOFC with SRBC, and the integration of SOFC with SRCBC. The hybrid system considered in this study is configured with main compressor (MC), low temperature recuperator (LTR), re-compressor (RC), high-temperature recuperator (HTR), heat exchanger (HEX), turbine, cooler, and SOFC stack the schematic diagram of which is shown in Fig. 1. The analysis implemented the metal-supported IT-SOFC cell developed by Ceres Power, which is suitable for integration into stacks

and larger systems [10]. The examined IT-SOFC functions under typical parameters of a temperature of 873 K and a current density of 0.3 A/cm^2 [10]. Inlet parameters of Brayton cycles were determined from an S-CO_2 Brayton cycle power system which has been operated by Sandia National Laboratories [11].

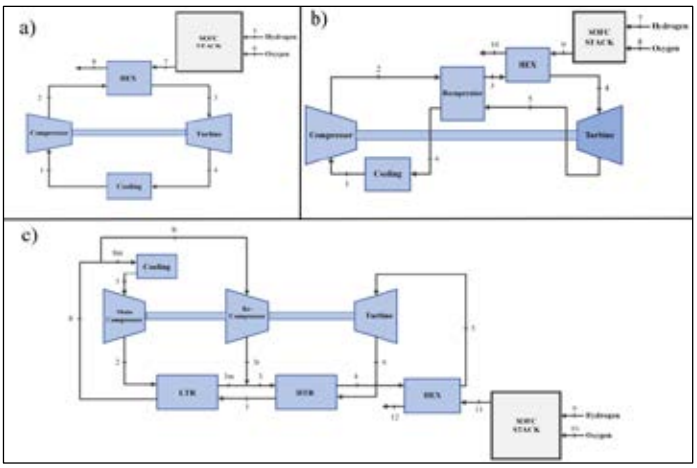

Fig. 1.SOFC/S-CO_2 hybrid systems; a) SOFC/SBBC hybrid system, b) SOFC/SRBC hybrid system (modified from [12]) c) SOFC/SRCBC hybrid system (modified from [13])

From thermodynamics of systems in equilibrium, Nernst Voltage and SOFC voltage:

$$V_n = V_{max} + \frac{\bar{R}\cdot T}{n\cdot F} ln\left(\frac{a_A^{v_A}\cdot a_B^{v_B}}{a_C^{v_C}\cdot a_D^{v_D}}\right) \quad (1)$$

$$V_{cell} = V_n - V_{act} - V_{ohm} - V_{con} \quad (2)$$

where the v's are the stoichiometric coefficients of the balanced electrochemical reaction, the a's are the thermodynamic activity coefficients for the reacting species, F is Faraday constant, n is the number of moles of the electrons transferred, where V_{act} is the activation, V_{ohm} ohmic and V_{con} concentration polarization. The power produced by the SOFC stack, which is calculated as follow:

$$\dot{W}_{SOFC} = N_{cell} \cdot A_{cell} \cdot i_{cell} \cdot V_{cell} \quad (3)$$

Where N_{cell} is the number of cells, A_{cell} is cell active area, and i_{cell} is the current density. The energy balance of the system is calculated based on the first law of thermodynamics. Brayton cycles efficiency is calculated as follow:

$$\eta_{cycle} = \frac{\dot{W}_{net}}{\dot{Q}_{in}} \quad (4)$$

Where $\dot{Q}$, $\dot{W}$, and $\dot{m}$, means heat rate, work rate and mass flow rate, respectively. The hybrid system's net power and efficiency is written as:

$$\dot{W}_{net,hybrid} = \dot{W}_{net} + \dot{W}_{SOFC} \quad (5)$$

$$\eta_{hybrid} = \frac{\dot{W}_{net}+\dot{W}_{SOFC}}{\dot{m}_{H_2,in}\times LHV} \quad (6)$$

3. RESULTS AND DISCUSSION

This study aims to evaluate the performance and efficiency of different configurations to identify optimal integration strategies. A 50 K temperature difference between TIT and SOFC operating temperature was maintained to prevent pinch point issues within the examined current density range (0.05–0.8 A/cm^2). Three intermediate temperatures (550°C, 600°C, and 650°C) were selected, and the Brayton cycle's mass flow rate was determined based on the SOFC's capacity and operating conditions. Fig. 2a. illustrates the efficiencies of the SBBC and SOFC/SBBC hybrid systems at different temperatures, considering varying current densities. The SBBC achieves efficiencies of 0.1510 at 823 K, 0.1514 at 873 K, and 0.1513 at 923 K, with the highest efficiency observed at 873 K, though the differences are minimal. This trend aligns with previous studies [14] and can be attributed to notable changes in the specific heat of S-CO_2 near its critical point. The efficiency of the SOFC/SBBC hybrid system varies with current density, primarily influenced by the SOFC performance, which impacts overall system efficiency. Higher current densities reduce efficiency due to increased polarization losses [15]. The highest efficiency is achieved at 923 K, as higher temperatures reduce irreversibility in the SOFC. Utilizing SOFC waste heat and integrating SBBC raises the hybrid system's efficiency to 43.93%. Fig. 2b. shows the efficiency of the SRBC and SOFC/SRBC hybrid system at different temperatures and SOFC current densities. At 0.3

A/cm^2 and 873 K, SRBC efficiency reaches 47.4%. Adding a recuperator to the SBBC improves Brayton cycle efficiency by 32.26%, with its impact increasing at higher temperatures. In the SRBC, the SOFC operating temperature plays a more critical role than in the SBBC. Incorporating SOFC waste heat into the SRBC raises the hybrid system's efficiency to 54.66%. Fig. 2c. reveals that, unlike the first two cycles, SRCBC efficiency decreases with rising SOFC operating temperature, dropping from 0.3654 at 823 K to 0.3612 at 923 K. Notably, the SRCBC achieves its peak efficiency at 823 K, highlighting its suitability for mid-low SOFC operating temperatures (<873 K). Higher SOFC temperatures increase turbine inlet temperature (TIT), raising the RC inlet temperature and reducing overall efficiency. The efficiency gap between SRCBC and SRBC is likely due to the additional compressor in SRCBC and the need for optimization of parameters such as temperature, split ratio, and heat exchanger effectiveness. The SOFC/SRCBC hybrid system achieves 49.8% efficiency at 0.3 A/cm^2 and 873 K. Fig. 2d. shows the power distribution between the SOFC and Brayton cycle at 873 K across varying current densities. As current density increases, the SOFC's power share decreases due to higher energy levels in the SOFC's output and increased irreversibility, while the Brayton cycle's share rises. At 0.3 A/cm^2, the SOFC power share is 79.1% in the SOFC/SBBC, 63.57% in the SOFC/SRBC, and 69.78% in the SOFC/SRCBC hybrid systems. The SOFC/SRBC stands out for its superior waste heat utilization and reduced complexity, making it the most efficient option.

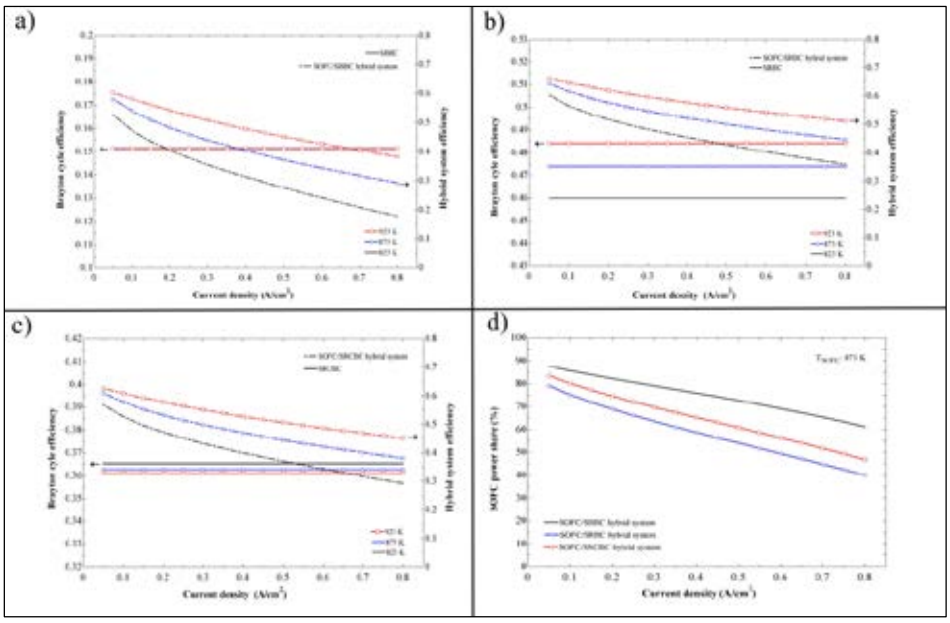

Fig. 2. a) The efficiency of SBBC and SOFC/SBBC hybrid system, b) the Efficiency of SRBC and SOFC/SRBC cycle hybrid system, c) Efficiency of SRCBC and SOFC/SRCBC hybrid system and d) The percentile of SOFC power in different hybrid systems according to current density change

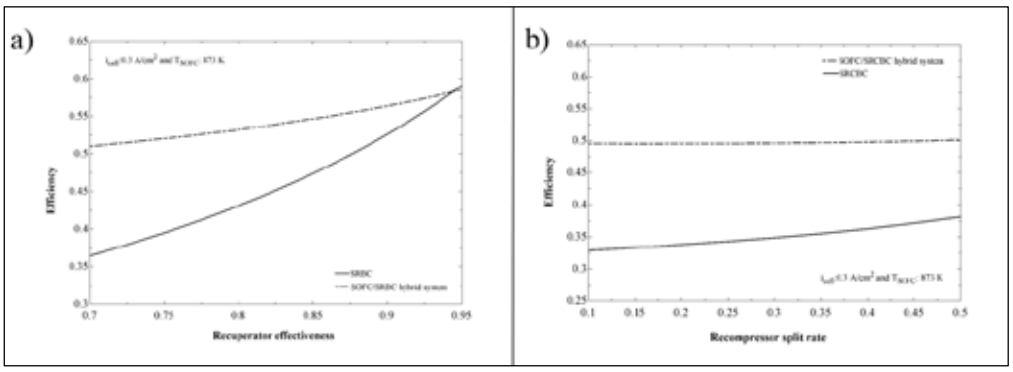

Fig. 3. a) Variation of the efficiency of SRBC and SOFC/SRBC hybrid system according to the change of recuperator effectiveness, b) Variation of SRCBC and SOFC/SRCBC hybrid system efficiency according to RC split rate change

In the SRBC, the recuperator significantly influences performance, with higher exergy destruction in heat exchangers than in turbomachinery [16]. In Fig. 3a, increasing the recuperator effectiveness from 0.7 to 0.95 boosts SRBC efficiency from 0.3646 to 0.5913—a 29.29% improvement. Similarly, in the SOFC/SRBC hybrid system, this rise in effectiveness enhances efficiency by 7.54%. The recuperator's sensitivity to temperature changes makes the SRBC more efficient at medium-high SOFC operating temperatures (>873 K). Fig. 3b. examines the effect of RC split rate on efficiency. As the

split rate increases, cycle efficiency improves, rising from 0.329 at 0.1 to 0.3814 at 0.5 [17]. Higher split rates reduce heat extraction by directing more fluid from the LTR to the RC, increasing heat retention and lowering Q_{in}. In the SOFC/SRCBC hybrid system, altering the split rate from 0.1 to 0.5 results in a modest efficiency increase, from 49.55% to 50.13%.

4. CONCLUSIONS

This study thoroughly examined the integration of IT-SOFC with different configurations of the Brayton cycle to optimize energy utilization. The analytical framework employed a metal-supported IT-SOFC cell developed by Ceres Power, which is compatible with the integration of stack and system. The tool chosen for this comprehensive analysis was EES.

- The efficiency of the SRBC, notably impacted by the recuperator, experiences a substantial enhancement with increased recuperator effectiveness.
- An intriguing observation was made regarding temperature preferences for different cycles. SRCBC exhibited optimal efficiency at lower temperatures (<600°C), while SRBC thrived at medium-high temperatures (>600°C), a trend attributed to the sensitivity of the recuperator to temperature changes.
- The power distribution of Brayton efficiencies in the total hybrid system power highlights the superiority of SOFC/SRBC in converting waste heat into useful work compared to SBBC and SRCBC.
- At the standard operating conditions of the IT-SOFC (873 K, 0.3 A/cm^2), the efficiencies stand at 43.93% for the SOFC/SBBC hybrid system, 54.66% for the SOFC/SRBC hybrid system, and 49.8% for the SOFC/SRCBC hybrid system. The SOFC/SRBC hybrid system arises as the most favorable option for harnessing the waste heat potential of IT-SOFC due to its notable increase in efficiency and simplified design, thereby making it a practical solution.

ABSTRACT

This study focuses on the effectiveness of different thermal management methods for hydrogen absorption of a metal hydride reactor. The metal hydride bed is selected as ammonia borane (NH_3BH_3). The numerical study consists of three different cases. FEM based solution method is utilized. In Case 1, the hydrogen absorption was examined in the reactor with a corrugated cooling channel. In Case 2, the absorption was examined with baffles on the corrugated cooling channel. In Case 3, the absorption was examined with a baffle combined with U-tubes. In Case 2, baffles and in Case 3, baffle were placed on the inner surface of the cooling channel in the metal hydride bed for a better cooling. The absorbed hydrogen fraction (wt. %) and the average temperature distributions in the metal hydride bed were obtained. In Case 2 and Case 3, the hydrogen absorption increased by 9.4% and 10.5%, respectively. The average bed temperature in Case 2 and Case 3 decreased by 18% and 35%, respectively.

Keywords: Metal hydride, Hydrogen storage, Reactor, FEM, Thermal Management.

1. INTRODUCTION

The ever-increasing demand for energy coupled with decreasing fossil fuel resources make the establishment of a clean and sustainable energy system an impellent need [1]. Hydrogen has a crucial place in terms of energy. Considering the historical development of the energy carriers towards more hydrogen-rich fuels and the necessity to decrease carbon dioxide emissions, hydrogen should be the energy carrier of the future [2]. The energy gain per electron is very high. The chemical energy per mass of hydrogen (39.4 $kWh \cdot kg^{-1}$) is three times larger than that of other chemical fuels, e.g. liquid hydrocarbons (13.1 $kWh \cdot kg^{-1}$). In other words, the energy content of 0.33 kg of hydrogen corresponds to the energy content of 1 kg of oil. [3]. For decades hydrogen storage has had an important place in research of most technologically progressive nations of the world. The motivation behind the move is the trust given to the fact that hydrogen can help to tackle the growing demand for energy and hold up global climate change [4-8].

A storage technology with potential for different kinds of applications is hydrogen storage through absorption in metal hydrides. This technology offers high volumetric energy densities and increased safety due to hydrogen chemically bound at lower pressures. In addition, based on the thermodynamic properties of metal hydrides, this class of materials gives the chance to improve a new hydrogen compression technology. They allow the direct conversion from thermal energy into the compression of hydrogen gas with no need of any moving parts [9]. Thermal management is an important issue in systems which consist of heat transfer phenomena. Since hydrogen absorption is an exothermic process, it's significant to control the temperature factor in the system. One of the studies related to this issue belongs to Disli et al [10]. Tong et al [11], conducted a numerical study based on complete and reduced models to examine the thermal effects on the system. Tong et al [12], performed a study with phase change material to examine the thermal effects of a metal hydride storage system. Zhu et al [13], conducted a study based on proton exchange membrane fuel cell and metal hydride hydrogen storage tank for active thermal management. Askri et al [14], performed a study for the optimization of hydrogen storage in metal hydride tanks. Nguyen et al [15], performed a study for the thermal management of metal hydride hydrogen storage using phase change materials for standalone solar hydrogen systems.

This study focuses on the development of new thermal management techniques in hydrogen storage in metal hydrides. Effect of baffle(s) on the hydrogen absorption is examined. The baffles and the baffle used in Case 2 and Case 3, respectively are placed on the inner surface of the cooling channel in the metal hydride bed for a better cooling. Thus, better hydrogen absorption process is expected. These special structures attached to the cooling channel may be promising for a better hydrogen storage in a metal hydride bed.

2. MODELLING

Each model for Case 1, Case 2 and Case 3 is shown on Fig. 1 (a), Fig. 1(b) and Fig. 1(c). For each case, the cooling channel of the metal hydride reactor has a corrugated structure based on half circle profiles. The corrugated structure is used to increase the local velocity of the coolant. For a better cooling process and a faster absorption, baffles are placed on the inner surface of the cooling channel to be present in the metal hydride bed in Case 2. The baffles are placed in equal spacing (number of baffles is 10) in contact with the metal hydride bed. The same attempt is performed in Case 3 with a different profile of the baffle. Instead of using more than one baffle, a single baffle which has a structure of a

combination of U-tubes is considered. The U-turning movements of the coolant through the baffle creates a flow profile for a faster cooling process for better hydrogen sorption.

Fig 1. Models (a) Case 1, b) Case 2, c) Case 3)

Mass conservation for hydrogen is given as [10]

$$\varepsilon \frac{\partial \rho_g}{\partial t} = -\dot{m} \tag{1}$$

The mass conservation of metal hydride bed is [10]

$$(1-\varepsilon)\frac{\partial \rho_{mhb}}{\partial t} = \dot{m} \tag{2}$$

where $m^{\cdot}$ is the volumetric mass flow rate of the hydrogen during the sorption process. It's evaluated from the common kinetics equation [11],

$$\dot{m} = Ca\, exp\left[-{}^{E_a}/_{R\,T}\right]\ln\left({}^{P_g}/_{P_{eq}}\right) = [\rho_{st} - \rho_s] \tag{3}$$

where Ca and E_a are reaction constant and activation energy respectively. P_g is the hydrogen supply pressure, ρ_{st} is the density of saturated metal hydride, ρ_s is the density of metal hydride at a particular time during sorption.

Energy conservation equation is given by [11]

$$\left(\rho C_p\right)_{eff}\left(\frac{\partial T}{\partial t}\right) + \left(\rho C_p\right)_g(\vec{u}\,\nabla \mathrm{T}) = k_{eff}\nabla^2 T + Q \tag{4}$$

$\left(\rho C_p\right)_{eff}$ and k_{eff} stand for effective heat capacity and thermal conductivity for solid and gaseous phases. These expressions are given as

$$\left(\rho C_p\right)_{eff} = (1-\varepsilon)\left(\rho C_p\right)_s + \varepsilon\left(\rho C_p\right)_g \tag{5}$$

$$k_{eff} = (1-\varepsilon)k_s + \varepsilon k_g \tag{6}$$

The momentum conservation equation is given by [16]

$$\frac{\rho}{\varepsilon}\frac{\partial \vec{v}_s}{\partial t} + \left(\frac{\mu}{K} + \frac{S_0}{\varepsilon^2}\right)\vec{v}_s = -\nabla P + \nabla.\left[\frac{\mu}{\varepsilon}\left(\nabla\vec{v}_s + \nabla\vec{v}_s{}^T\right)\right] - \nabla.\left[\left(\frac{2\mu}{3} - \eta_d\right)\left(\frac{1}{\varepsilon}\right)(\nabla.\vec{v}_s)I\right] \tag{7}$$

At the beginning of the sorption process, metal hydride bed, fins and coolant in the channel are in ambient conditions. The density of metal hydride bed is uniform.

$$P = P_{\mathrm{i}} = 10\ atm \tag{8}$$

$$T = T_0 = 288.15\ K \tag{9}$$

$$\rho_{MH} = \rho_i = 780\ {}^{kg}/_{m^3} \tag{10}$$

$$\dot{Q} = 0.5\ {}^{m^3}/_{h} \tag{11}$$

The outer wall of the reactor is considered adiabatic.

$$\left(-k\frac{\partial T}{\partial r}\right)_{r=r_w} = 0 \tag{12}$$

Finite element method (FEM) is used for the solution of the governing equations. Lagrange FEMs of different orders are used for the approximation of field variables in different domains of thermal management system coupled with hydrogen

storage. Number of tetrahedra elements used is 578111. Minimum element quality is 0.00379. COMSOL Multiphysics 6.2 is utilized for the simulation of the coupled system.

3. RESULTS AND DISCUSSION

Fig. 2 shows the hydrogen absorption fraction (wt. %) for three cases. Based on the results, the absorption process in Case 2 and Case 3 (cases in which ten baffles and one baffle in the structure of U-tubes, respectively) is improved by 9.4% and 10.5%, respectively. The best result was obtained with the usage of baffle combined with U-tubes. Models in Case 2 and Case 3 improved the sorption process with significant difference compared to the model in Case 1 as it's seen in Fig. 2.

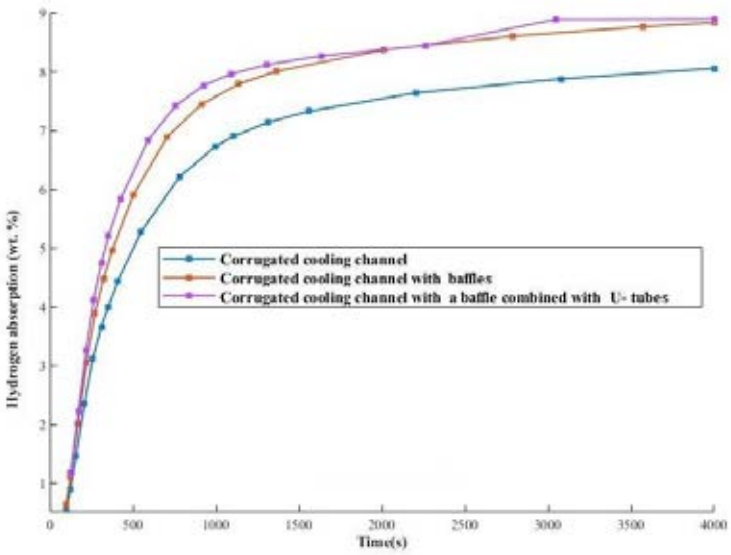

Fig 2. Hydrogen absorption (wt. %) for Case 1, Case 2 and Case 3

Fig. 3 demonstrates the average bed temperature values for three cases. The improvement in the average bed temperature in the metal hydride bed of the reactor is clearly seen in Fig. 3. The average bed temperature in Case 2 and Case 3 decreased by 18% and 35%, respectively. The best performance was shown by the model in Case 3 with an improvement of 17% compared to the model in Case 2. The wavy flow the baffle created during the cooling process caused this improvement. Fig. 4 shows the average bed temperature at 2000 s and 4000 s for each case. The wavy flow of the coolant due to the U-turns of the baffle created a remarkable acceleration in the coolant velocity. This enhancement of the coolant caused a faster absorption process for the reactor and a much better average temperature distribution in the metal hydride bed. The favorable properties of the ammonia borane metal hydride are a remarkable contribution to sorption due to its high volumetric and gravimetric capacity of hydrogen absorption. The corrugated structure of the cooling channel also improved the hydrogen sorption process in all three cases.

According to the results, it may be promising to use baffle(s) on the cooling channel surface in contact with the metal hydride bed for a faster absorption and average temperature distribution in a reactor in terms of thermal management.

4. CONCLUSIONS

Novel thermal management methods for hydrogen storage in metal hydride is developed. FEM based simulation method is utilized. Based on the data obtained from the study,

1) The best result is obtained in Case 3 (in which the cooling channel had a baffle with a structure of several U-tubes). The absorption process is improved by 10.5% compared to the model in Case 1(which had a corrugated structured cooling channel with no baffle(s) on)

2) The average bed temperature in the metal hydride in the hydrogen reactor is reduced by 35%.

3) The baffle used in Case 3 has the biggest effect on the enhancement of the hydrogen storage system.

4) The corrugated structure and the metal hydride ammonia borane are two factors which contributed to the hydrogen storage system.

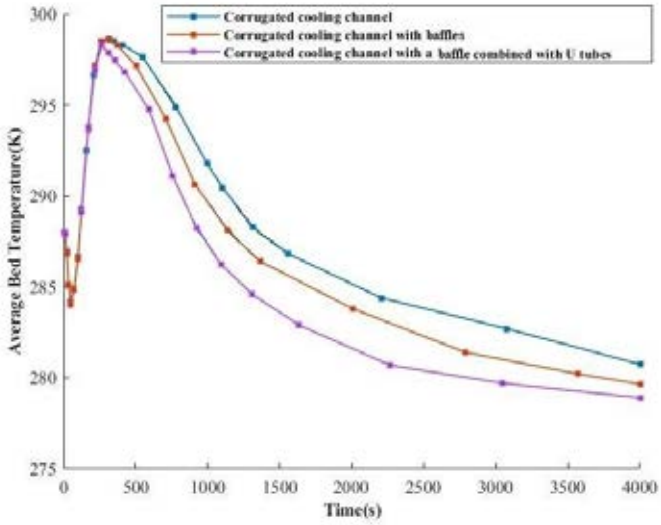

Fig 3. Average bed temperature values for Case 1, Case 2 and Case 3

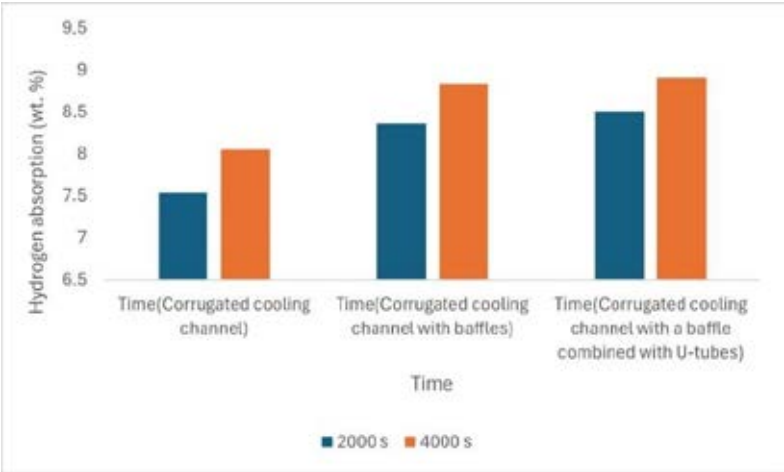

Fig. 4. Average bed temperature values at 2000 s and 4000 s for Case 1, Case 2 and Case 3

ABSTRACT

Thermochemical water splitting using two-stage REDOX processes and concentrated solar radiation as an energy source has been the focus of process engineering research for more than two decades. It is considered as a promising technology for producing green hydrogen and liquid green fuels at competitive prices in the medium term. In this process concentrated solar radiation is directly converted into storable chemical energy. The present article reports the results of an experimental campaign, which has been carried out at the research level of the Solar Tower Jülich to further demonstrate the feasibility of this technology. Based on the experience from prior tests at a large-scale solar simulator a combined receiver/reactor has been re-designed and built up. The reactor was operated at temperatures between 1200 °C and 1000 °C using radiative power of up to 780 kW generated by part of the heliostat field of the Solar Tower. As redox material ceria has been used which has been coated on a framework of a zirconia foam due to stability reasons. It could be shown that the production of hydrogen in a medium scale structured reactor is possible. The tests also revealed which improvements concerning structure, optical and thermal management as well as operational parameters are necessary to achieve satisfying efficiencies.

Keywords: thermochemical cycle, green hydrogen, redox reaction, ceria, solar hydrogen reactor

1. INTRODUCTION

Solar thermochemical water splitting has been investigated at the Institute for Future Fuels and its predecessor since 2002. Together with national and international partners such as the major research organisations CERTH (Greece) and CIEMAT (Spain) as well as industrial partners such as HELPE (Greece), ABENGOA (Spain) and ENGICER (Switzerland), this technology has been advanced to a great extent. It has high theoretical solar-to-fuel efficiency potential of up to 50% [1, 2] and provides a way to generate hydrogen directly from the sun without prior generation of electricity. A two-stage redox process is used in which a metal oxide is alternately reduced and oxidised, releasing hydrogen in the process (Fig. 1). As part of the NRW projects ASTOR and ASTOR-ST, which have been realized in co-operation with RH Cologne, Stausberg & Vosding and AWS-Technik, this technology has been demonstrated with a 250-kW solar reactor in a large-scale solar simulator [3].

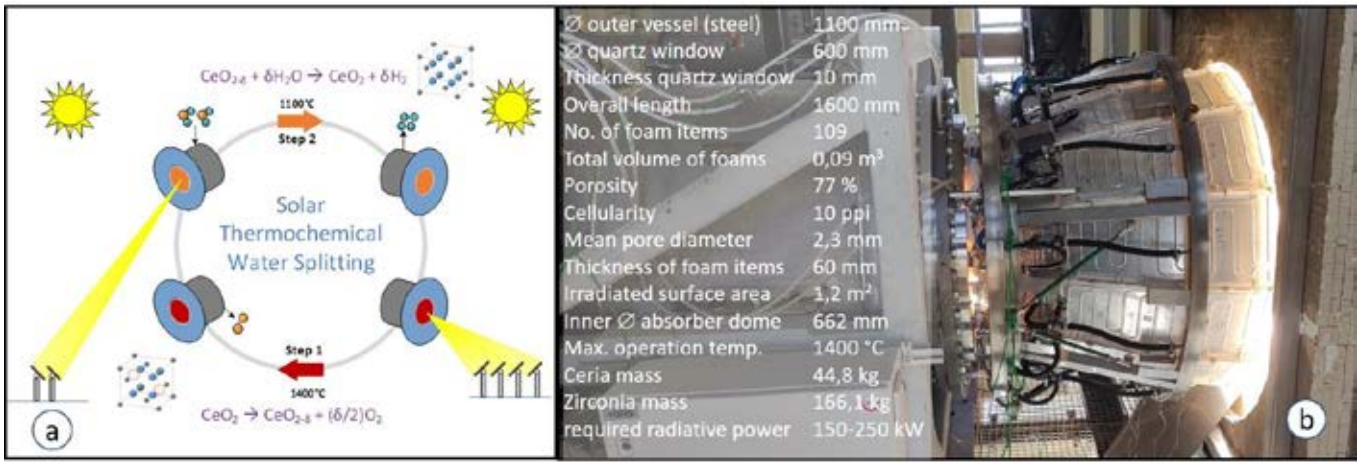

Fig. 1. The two-stage redox-process with ceria as a functional material (a). The reaction takes place to a certain extent described by the non-stoichiometry parameter δ depending on oxygen partial pressure and temperature in the reactor. (b) Reactor and secondary concentrator in operation on the research level of the Solar Tower Jülich along with some technical data of the receiver.

2. MATERIALS AND METHODS

2.1. Redox material

The redox material used was pure ceria, which appeared as a coating on a zirconia framework consisting of an RPC 10ppi foam produced by EngiCER using the classical Schwarzwalder process. A total of 44.8 kg of ceria and 166 kg of zirconia was used. 109 blocks of slightly different geometry were manufactured, which were then assembled to form the reactor dome shown in Fig. 2d. After the tests in the solar simulator, which totalled 52 operating hours, the entire redox material was replaced with the objective of improving the absorption properties of the reactor. A two-stage porosity was created in each block, in a way that the porosity was higher on the irradiated side to allow deeper penetration of solar radiation (Fig. 2c). Model calculations by RH Cologne have shown that this equalises the temperature in the receiver and thus enables higher efficiency levels.

Some of the material used in the first test campaign exhibited severe traces of degradation, which were particularly evident in strut fractures and detachment of the cerium oxide layer (Fig 2 a and b). The blue colouration at the interface between zirconia and ceria oxide was also conspicuous. X-ray analysis suggests that this is the solid solution ZrCeO2 (Fig 4a), which has been proposed in other studies to improve the reduction properties of the material [4].

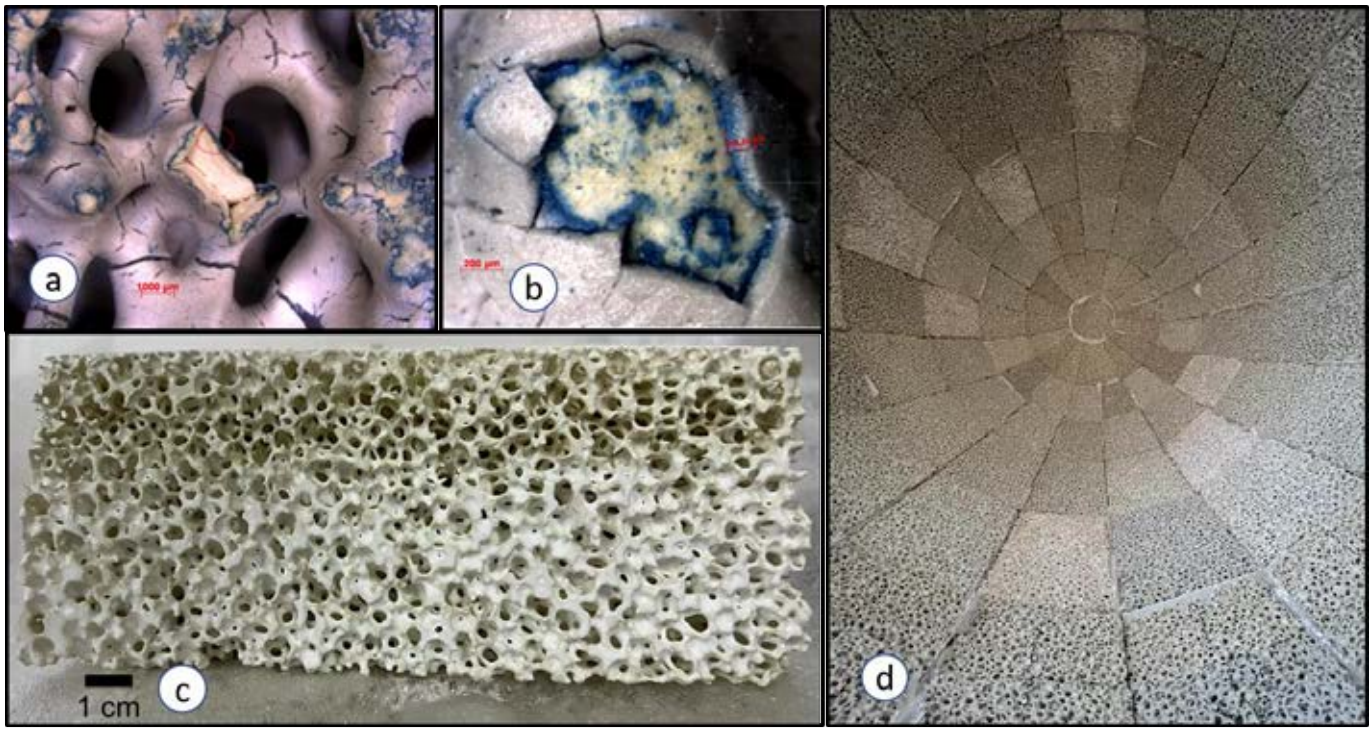

Fig. 2. 10ppi ceria coated zirconia foam used for the reactor. (a) Micrograph of the material after approx. 52 operation hours. (b) Parts of the approx. 135 µm thick ceria-layer detached from the zirconia substrate during tests of the 1st campaign. (c) One of the 109 as received modules of the reactor-dome for the 2nd campaign with two-stage porosity. (d) Front view of the reactor as a whole.

2.2. Experimental set-up

As part of the ASTOR-ST project, we developed a 250-kW reactor, the centrepiece of which was the REDOX dome described in the last section. It can be seen as a further development of the reactors built for the solar gas turbine as part of the EMPOLI and REFOS projects [5], which were also used in a modified form for the solar methane reformation demonstrated in the SOLREF project [6]. The outer vessels of these reactors as well as secondary concentrators with an optical efficiency of up to 80% have been reused, which caused some constraints concerning size and aperture geometry. The reactor is shown schematically in Fig. 3a. An inner vessel separates the incoming and outgoing fluids, which pass the wall of the redox dome from left to right before they finally leave the reactor through the gas outlet. The solar radiation enters the reactor through a flat fused silica window, which replaces the formally used dome shaped version, because the experiment was operated under close to ambient pressure conditions, thus fixing the flat window was easier and the operation safer. Fig. 3b shows a simplified map of the entire set-up. Stausberg & Vosding developed the system control. It consisted of a LabVIEW-controlled PLC that enabled real-time operation and measurement as well as automatic mode and multi reactor operation. During the reduction step the reactor is heated up and flooded with nitrogen 5.0, creating an oxygen partial pressure of 10^{-5} bar provided that the reactor is completely filled up. Only the valves v301, v400 and v500 are open and an O2-meter monitors the O2 content of N2/O2 mixture leaving the reactor.

Hereafter, v401 is opened and steam enters the reactor to introduce the oxidation step. In the same time v500 is closed, v600 is opened enabling the N2/H2 mixture to leave the system and to be analyzed by a mass spectrometer. The reactor temperature was measured from the rear using thermocouples at a depth of 1.5-3 cm. The whole set-up was put onto the research level of the Solar Tower. In the inserted photograph in Fig. 4c the irradiated reactor can be seen in the middle of the left tower from the outside. The radiative power from the Heliostat-field on the outer aperture of the secondary concentrator was estimated by creating a second similar focus on a white screen equipped with a standard high-flux radiometer.

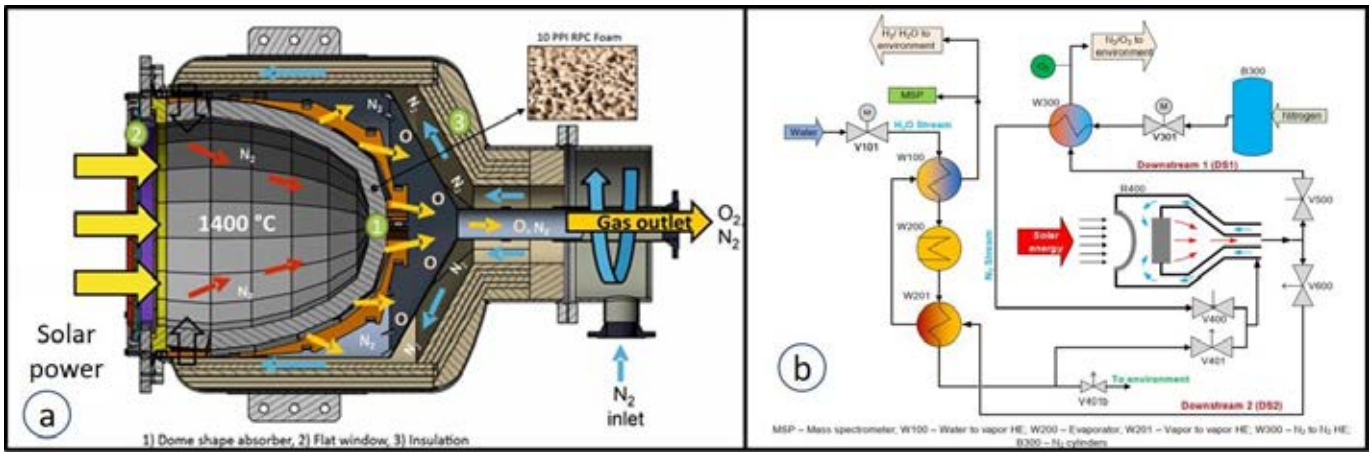

Fig. 3. Schematic representation of the reactor (a) and simplified diagram of the piping and instrumentation for the supply of the reactor with steam and nitrogen as well as the treatment of the outlet gases including three heat exchangers for heat recovery (b).

3. RESULTS AND DISCUSSION

Fig. 4 b and c show the course of an experiment on the research level of the Solar Tower Jülich. On this day, conditions were almost clear sky and up to 285 heliostats each with an aperture area of about 8 m² could be used for the experiment. The blue curve represents the power on the aperture of the secondary concentrator. Due to larger optical losses compared to the mentioned gas-turbine application, only a smaller fraction of this power reached the surface of the reactor. These additional optical losses were caused by a relatively low position of the focus, a horizontal alignment of the reactor and the use of a flat window showing less transmittance due to higher incident angles. The concentration ration was approx. 350. Additionally, reactor average and maximum temperature as well as the steam mass flow is displayed. By successively increasing the radiative power to 690 kW, the reactor was heated up to 979 °C maximum temperature at the backside. At this point a first oxidation phase was introduced resulting in a hydrogen production rate of 0.6 g/h. Once the rate of hydrogen production had fallen to almost zero, a second reduction phase was initiated. Now the maximum available power (780 kW) was put on the experiment. Consequently, the reactor temperature increased and in the subsequent second oxidation phase the hydrogen yield was correspondingly greater and a hydrogen mass flow 1.2 g/h was achieved. However, the reactor temperature did not exceed 1000 °C on the rear. We know from the previous measurement campaign in the solar simulator that the temperature on the irradiated side is significantly higher [3] but the redox foam used during this campaign had a slightly different porosity. From model calculations this effect could be estimated [7, 8] so that we assume that the temperature at the front side was approx. up to 1200 °C. Integration of the hydrogen curve from Fig. 4b provides the absolute values of hydrogen produced during the two cycles carried out. These were 0.2 g and 0.57 g respectively. This is much less then expected but simply be explained by the fact that within this experiment the lay-out temperature of 1400 °C could not be reached by far, because overheating problems with the secondary concentrator and the window flange occurred, which could not be solved in the remaining time of the project. However, the stoichiometry of the reduction equation (Fig. 1a) predicts these amounts for temperatures of 1000 °C and 1080 °C along with a ceria mass of 44.8 kg and an oxygen partial pressure of 10^{-5} bar [9]. Thus, in principle, the reactor is able to generate hydrogen according to predictions based on theoretical calculations and lab scale experimental experiences.

4. CONCLUSIONS

It has been shown that solar thermochemical hydrogen production on a medium scale is possible with the reactor concept developed. The amount of produced hydrogen per mass of redox material used, as predicted by theory, was largely achieved. However, the efficiency of the process in these first tests was relatively low. The main reasons for this are the large aperture to reactor surface area relationship and the associated low concentration ratio. Moreover, the optical efficiency of the secondary concentrator was low. Further work on the optical design of the reactor and the secondary concentrator is planned with the aim of significantly increasing the concentration ratio and thus the overall efficiency.

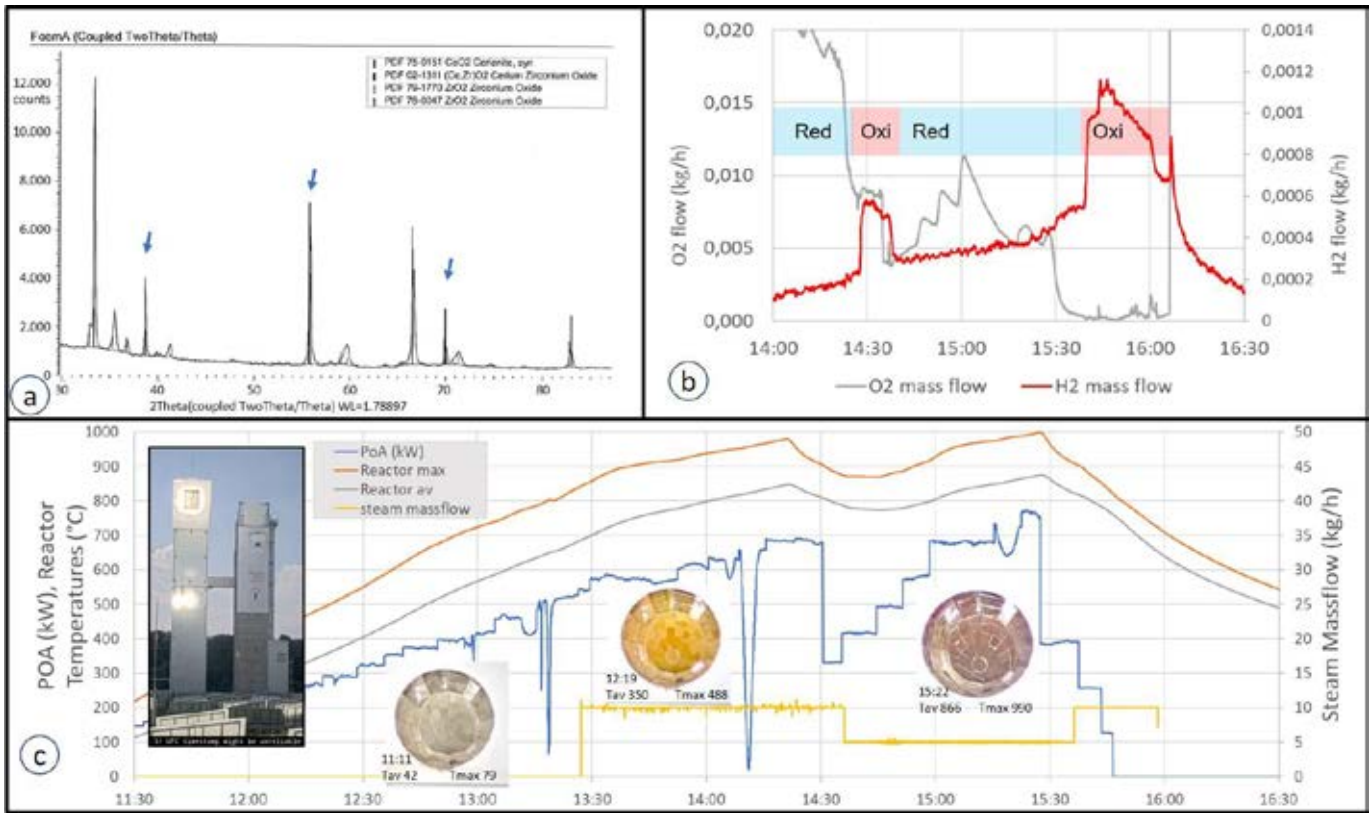

Fig. 4. An X-ray analysis (a) of the degraded material (see Fig. 2) shows the formation of a solid solution (CeZrO2, blue arrows) in the transition region between cerium oxide and zirconium oxide. (b) Oxygen and hydrogen mass flow during the reduction and oxidation phase of the experiment. (c) Related reactor temperatures, radiative power from the heliostat field and steam mass flow. Note that steam was only inserted into the reactor during the oxidation phase by opening valve V401and closing the by-pass V401-b

ACKNOWLEDGEMENT

The study has been carried out in the frame of project ASTOR-ST (EFRE-0801815). The funding of the EFRE fund and the NRW Ministry of Economic Affairs, Innovation, Digitalisation and Energy is gratefully acknowledged

ABSTRACT

Expanding the penetration of renewable energy sources to address the greenhouse gas emissions from residential heating systems is imperative. However, renewable energy sources, such as solar and wind have an intermittency issue. Hydrogen emerges as a potential energy vector to be used as a storage medium or to be directly processed for generating the required heat and power. Therefore, this study outlines a hydrogen-based heating system to decarbonize residential heating while meeting thermal demands. Furthermore, the present investigation focuses on district heating networks as they deal with central energy production plants and hold significant potential to deploy large-scale zero-emission units to decarbonize the built environment. The proposed system uses hybrid solar and wind sources as the prime movers of the system and combination of a proton exchange (PEM) electrolyzer, a stacked PEM fuel cell, and an air-source heat pump to generate the required thermal demand. In addition, a series of electrical, hydrogen, and thermal storage options exist to manage the load shifting. Two detached houses with different floor areas have been selected in Almere City, located in Flevoland province to meet their demands through the proposed system. Based on anticipated results, using hydrogen for bigger homes is more cost-effective.

Keywords: Hydrogen, Decarbonization, Residential buildings, Dynamic modeling, District heating

1. INTRODUCTION

Currently, most residential heating systems across Europe rely on non-renewable sources, including natural gas. For instance, around 85% of the required residential thermal demands are provided using natural gas boilers in houses in the Netherlands [1]. Therefore, evaluating the feasibility of sustainable heating solutions is of great importance to decarbonizing residential heating systems. Electrification, through using heat pumps is a favorable choice for Dutch stakeholders to use in newly built houses to reduce the CO_2 emissions [2]. However, electrifying all residential buildings could lead to grid congestion in the absence of sufficient grid capacity, endangering the balance between supply and demand. This underscores the need for stakeholders to adopt a mix of sustainable solutions to decarbonize buildings while maintaining grid resiliency. Therefore, hydrogen is introduced as a versatile energy vector, capable of being used directly as a fuel to generate heat or indirectly as a storage medium to mitigate the fluctuations of renewable energy sources such as wind and solar [3]. Decentralizing energy production helps decarbonize buildings, but costly microgrids remain a challenge. Using existing heating networks is a practical solution to meet thermal needs and support the energy transition. District heating networks (DHN) are connected to centralized plants to produce the required thermal energy, which is then delivered to homes through insulated pipes in the form of hot water. These heating networks hold a significant potential to boost energy efficiency within communities and mitigate greenhouse gas emissions [3].

Few studies have focused on hydrogen's potential role in heating networks in the Netherlands. Thus, this study aims to introduce a hydrogen-based heating system and perform a techno-economic analysis to assess its technical and financial characteristics using the dynamic modeling approach.

2. METHODOLOGY

The designed hydrogen-driven heating system along with the selected methodology is introduced in this section.

2.1. System description

According to Fig.1, the designed system is equipped with hybrid solar/wind sources to produce clean electricity. A lithium iron phosphate ($LiFePO_4$) battery package stores excess electricity to ensure the electrolyzer demand is met later. In this study, a proton exchange membrane electrolyzer (PEME) generates hydrogen. In fact, this electrical storage system is designed to shave the peak demand of the PEME as it leads to its longevity and decreases its wear and tear. Fig. 2 depicts the flowchart of the battery system to manage the generated power. The excess amount of produced hydrogen is then stored in a gaseous form for storage purposes. The stacked proton exchange membrane (PEM) fuel cell is used

to produce the required heat and power. The generated power by the stacked PEM is sent to an air-source heat pump to produce complimentary thermal energy. In this study, a portion of produced heat in the PEM fuel cell is used to pre-heat the heat pump to increase its coefficient of performance (COP) and consequently total energy efficiency of the system. In the end, after storing excess heat in phase change material (PCM) tanks, heating networks transfer the required thermal energy of studied houses in the form of hot water at 60°C

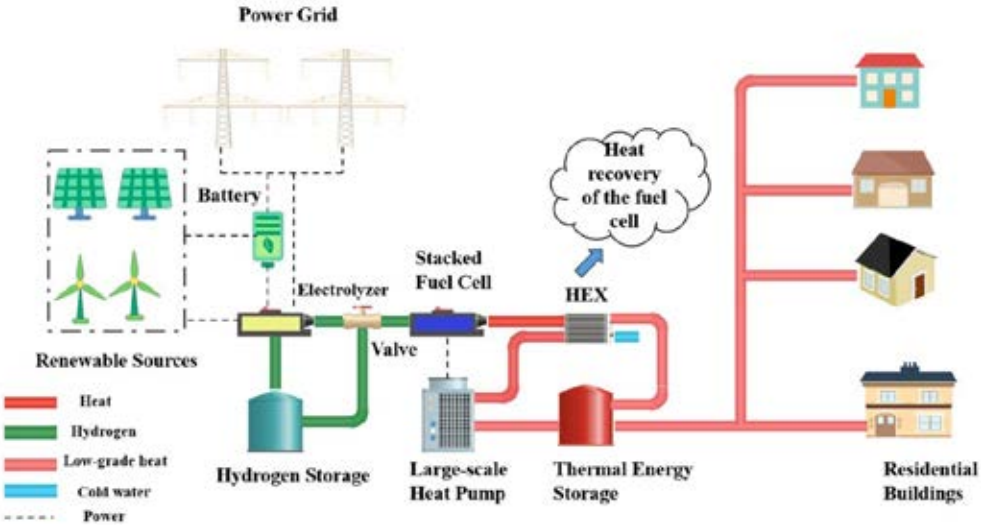

Fig. 1. Hydrogen-driven heating system

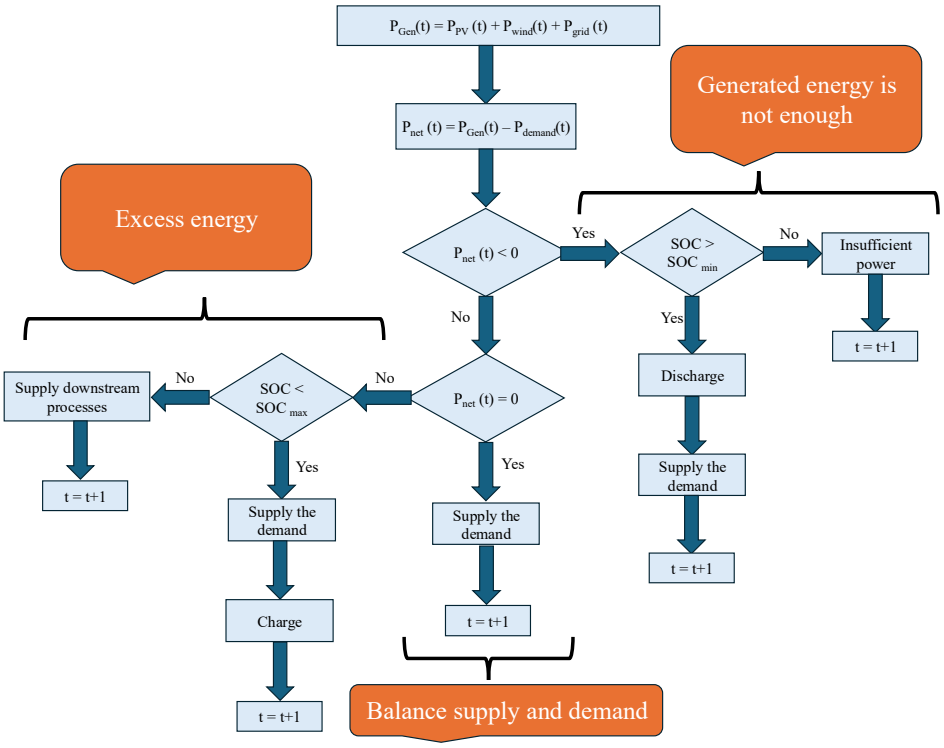

Fig. 2. Flowchart of the used electrical energy storage system

2.2. Selecting the case study location

As was mentioned earlier, around 85 % of residential houses in the Netherlands are equipped with natural gas boilers to meet their space heating and hot water demands. However, heating networks are leveraged in different locations to diversify utilized heating systems and reduce greenhouse gas emissions. As shown in Fig. 3, District heating without gas consumption accounts for 32% of the heating methods in the Flevoland province of the Netherlands in recent years which is recognized as the highest among other regions [4]. This highlights the availability of the necessary facilities from both the energy providers' and consumers' perspectives. Therefore, Almere City, located in this province, has been selected

to evaluate the incorporation of hydrogen heating technologies in their heating networks.

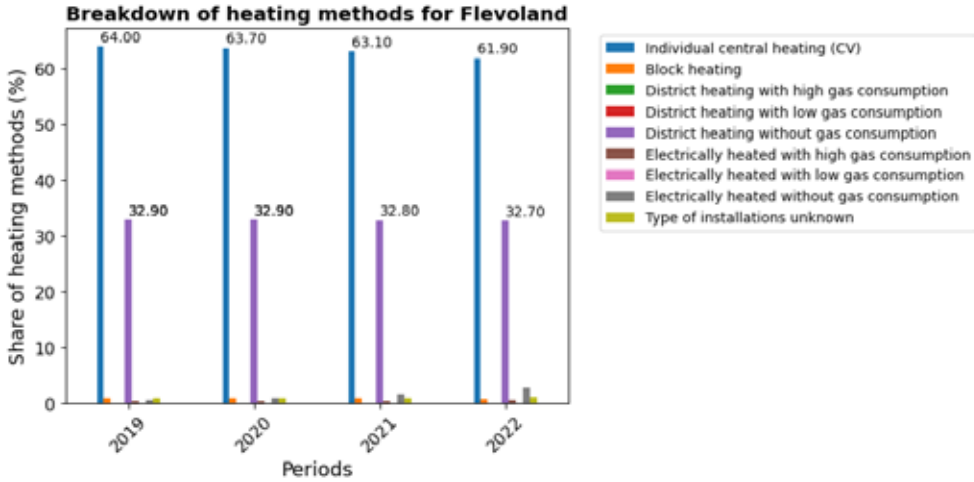

Fig. 3. Breakdown of available heating methods in Flevoland province across different years

2.3. Mathematical modeling approach

The following equations are employed to conduct dynamic system-level modeling and determine the technical and economic characteristics of the designed system [5].

$$\frac{dE}{dt} = \dot{E}_{in} - \dot{E}_{out} \tag{1}$$

$$\frac{dm}{dt} = \dot{m}_{in} - \dot{m}_{out} \tag{2}$$

$$\frac{dEx}{dt} = \dot{Ex}_{in} - \dot{Ex}_{out} - \dot{Ex}_{dest} \tag{3}$$

$$\dot{C}_{total} = \dot{C}_{fuel} + \dot{Z}_{total} \tag{4}$$

3. RESULTS AND DISCUSSION

The first step in conducting system integration is to ensure the validity of the used mathematical model for each component by comparing the results of the simulation with the prior experimental endeavors. As shown in Fig. 4, polarization curves of employed PEME and PEM fuel cells are in good agreement with experimental results [6,7]. Through polarization curves, key parameters such as operating voltage, overpotential losses, and critical characteristics of studied PEM fuel cell or electrolyzer, which are rooted in electrochemical processes can be obtained. This highlights the accuracy of the current simulation and shows that the simulation results validate the system model.

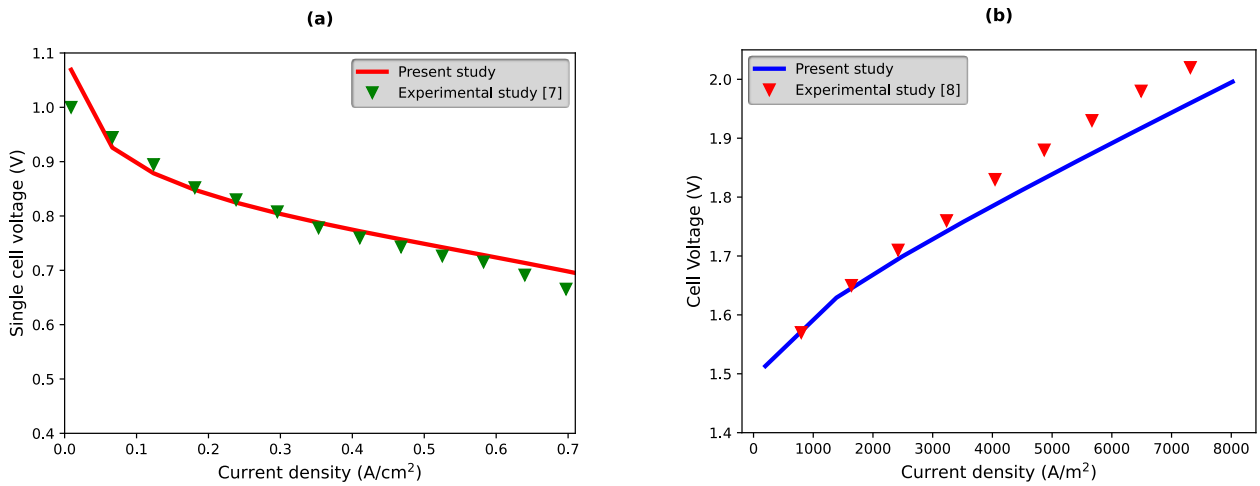

Fig. 4. Validation results for a) PEM fuel cell and for b) PEME

After carrying out the system integration, the capacity of all components is determined based on the heating demand profiles of the studied houses. In fact, their heating demand is reported as consumed natural gas in cubic meters (m^3). Afterward, considering the difference between calorific values of hydrogen and natural gas, it can be converted to demand of hydrogen which leads to calculating the appropriate sizing of components. It is expected to completely decarbonize the residential heating systems in the studied region in the Netherlands by utilizing the proposed hydrogen-driven heating option. Furthermore, grid congestion is expected to be addressed by introducing hybrid hydrogen/electricity-based heating system which enables stakeholders to manage the distribution of thermal energy. From the economic perspective, it is anticipated that hydrogen would be more cost-effective in houses with larger surface areas owing to the economy of scale notion.

4. CONCLUSIONS

The present study aims to decarbonize the residential heating systems in the Netherlands by using hydrogen in district heating systems. The proposed plan consists of a combination of photovoltaic panels and horizontal-axis wind turbines to generate clean electricity. The generated electricity is used to drive a PEME for hydrogen production which will later be used for thermal energy production through a stacked PEM fuel cell. The generated power in the fuel cell is used to drive an air-source heat pump for the generation of complimentary thermal energy. This produced heat flow is used to provide space heating and hot water for two detached houses in Almere City, located in Flevoland province. Key findings of this study show that the proposed system leads to decarbonization of the residential heating systems in the studied region. Furthermore, this enables energy providers to manage hydrogen, and electricity flows to prevent grid congestion. For future studies, it is recommended to consider a semi-decentralized system, partially decentralizing certain aspects of energy production. This approach could help evaluate its effect on improving the manageability of thermal demand distribution and achieving a better balance between production and transmission costs.

ABSTRACT

Fuel cell vehicles are studied by researchers due to their zero emission and performance. In researches of fuel cells, cost, size and hydrogen consumption can be problematic. Some methods and algorithms are required to optimize cost, size and hydrogen consumption. Metaheuristic algorithms are the algorithms that can provide the fastest response and provide the most optimum solutions on the subject. Hence, a wide variety of metaheuristic algorithms are derived. This study mainly deals with metaheuristic algorithms for fuel cell vehicles. Various studies of open literature are assessed in accordance with metaheuristic algorithms. In addition to algorithm types, input and output parameters, objectives, results, iteration and standard deviations are also discussed. According to the results, fuel cell powered locomotives are involved with metaheuristic algorithms. Particle swarm optimization is used more than other metaheuristic algorithms.

Keywords: Fuel cell, metaheuristic, algorithm, review, vehicle

1. INTRODUCTION

Metaheuristic algorithms are methods used for problem solving and optimization based on the acts of animals [1]. The term of ''metaheuristic'' is beyond concept of simple heuristics in engineering. The algorithms are stochastic based algorithms provide effective modeling and solutions [2]. Many complex and difficult engineering problems can be solved by using metaheuristic algorithms in short time [3]. Algorithms present an acceptable error in engineering problems with satisfactory results [4]. Considering that there are many animals in nature, it is inevitable that metaheuristic algorithms are quite different than each other [5]. Owl search algorithm, eagle strategy, genetic algorithm, artificial bee colony, monkey algorithm, dolphin echolocation, particle swarm optimization are some nature-inspired metaheuristic algorithms [6]. In addition to these algorithms, artificial fish swarm algorithm, bat algorithm, emperor penguin optimizer, jaguar algorithm, puma optimizer, whale optimization algorithm and grey wolf optimizer are other metaheuristic algorithms [7]. Thus, metaheuristic algorithms are also named ''animal algorithms'' [8].
Metaheuristic algorithms are widely used for fuel cells or hydrogen systems. Fuel cell vehicles are one of the most useful areas for metaheuristic algorithms. In open literature, various studies are conducted. Li et al., [9] suggested converged barnacles mating optimizer (CBMO) algorithm for fuel cell/battery vehicles. With the use of CBMO algorithm, fuel consumption, fuel cell stack lifetime and battery or stack sizes are investigated. The results exhibit that decrement in stack size causes higher fuel consumption. On the other hand, stack lifetime is affected adversely by smaller battery size. In recent studies, bald eagle search (BAS), multi-objective particle swarm optimization (CMOPSO) and genetic algorithm (GA) are preferred. Savran et al., [10] examined fuel cell electric vehicles from the viewpoint of hydrogen consumption and battery cycles. Hydrogen consumption and battery cycles of fuel cell electric vehicles are studied via BAS algorithm to optimize. It is asserted that BAS algorithm enables less hydrogen consumption about 60% in hybrid driving conditions. Liu et al., [11] employed CMOPSO algorithm to fuel cell hybrid vehicles. By using the metaheuristic algorithm, capacity investigation, vehicle durability, energy management and durability are searched. According to the results, CMOPSO presents satisfactory capacity configuration results. Furthermore, safe and efficient operation can be done with 22 kW rated power, 7 batteries in parallel and 100 batteries in series. Mazouzi et al., [12] applied GA to fuel-cell hybrid electric vehicles for energy management purposes. Fuzzy logic-based energy management system is implemented and simulations are performed via Matlab/Simulink. Proposed system with genetic algorithm is found successful in respect to fuel utilization and efficiency operation. Fuel utilization and efficiency operation increase about 30% and 14% respectively.
In this paper, studies of fuel cell vehicles are shortly reviewed in respect to metaheuristic algorithms. Studies are listed from the past to present in tables. Besides metaheuristic algorithms, parameters, error rates, objective functions and iterations are examined and results and conclusion are clarified.

2. APPLICATION OF METAHEURISTIC ALGORITHMS ON FUEL CELL VEHICLES

Applications of metaheuristic algorithms for fuel cell vehicles are challenging. Metaheuristic algorithms are used to reveal dynamic performance, predict stack lifetime, meet power demand or supply, optimize size and reduce total cost.

Additionally, decrement in hydrogen consumption and optimize speed trajectory are other purposes. Dynamic performances of fuel cell vehicles are related to operating conditions. Load conditions, air flow and pressure are significant performance parameters. Dynamic performance of fuel cell vehicles is crucial to investigate and operate [13]. Besides, dynamic performance, stack lifetime is investigated by researchers. Sudden load changes reduce stack lifetime in fuel cell vehicles. Load cycling process can't be neglected in terms of stack lifetime [14]. Power demand and supply are other factors. Power demand can be short-term or long-term. In fuel cell vehicles, it is expected to provide the necessary power at any time. Size optimization and cost reduction are important evaluation parameters. An optimal design of fuel cell vehicles includes battery, fuel cell or hydrogen tank [15].
While optimizing size, it is important to reduce total cost and hydrogen consumption as much as possible. Dynamic performance, drivability and degradation are considerably affected by fuel cell or battery size [16]. Speed planning or trajectory is compulsory for energy or power management of fuel cell vehicles. Vehicle's energy consumption is related to speed trajectory. Revealing speed trajectory is useful to reduce energy consumption of fuel cell vehicles. Therefore, speed trajectory is searched in open literature [17].
Studies of metaheuristic algorithms for fuel cell vehicles are explained. Metaheuristic algorithms for fuel cell vehicles with input, output parameters are listed and given. In addition to input and output parameters, main objective of metaheuristic algorithms are presented in Table 1.

Table 1. Metaheuristic algorithms for fuel cell vehicles

No	Citation	Metaheuristic Algorithm	Input Parameters	Output Parameters	Main Objective
1	Li et al. [13]	Effective Informed Adaptive Particle Swarm Optimization (EIA-PSO)	air flow, stack temperature, hydrogen pressure and fuel cell current	dynamic performance of locomotive	to predict the dynamic performance of locomotive
2	Macauley et al. [14]	Genetic Algorithm (GA)	humidity level, temperature, platinum, oxygen concentration, cell voltage, humidity cycling	stack lifetime	predict stack lifetime
3	Sarma and Ganguly [15]	Particle Swarm Optimization (PSO)	drive cycle, total driving time, distance, maximum speed, average speed, number of stops, maximum acceleration, average acceleration, maximum deceleration, average deceleration	size and dynamics of fuel cell with battery including fuel consumption and total cost	to conduct energy management of system in terms of power demand and supply
4	Zhang et al. [16]	Lion Optimization (LO), Modified Student Psychology Optimization (MSPO), Elephant Herd Optimization (EHO) and Student Based Psychology Optimization (SBPO)	distance, average speed, total driving time, acceleration, average speed, deceleration, state-of-charge (SOC), acceleration force, friction force, force needed for climbing slopes and force of air resistance, total power demand	sizes of fuel cell and battery, overall cost	to achieve optimum size and reduce overall cost as possible
5	Ajayan and Immanuel Selvakumar [17]	Differential Evolution (DE), Teaching Learning Based Optimization (TLBO), Particle Swarm Optimization (PSO), Firefly Algorithm (FA), Artificial Bee Colony (ABC) and Invasive Weed Optimization (IWO)	slope, number of fuel cell replacements, work-life of battery, panel unit cost, number of battery replacements, battery unit cost, motor constant cost, work-life of fuel cell, drive cycle, battery constant cost, motor unit cost, rate of interest, panel constant cost and fuel cell unit cost	cost	to minimize cost and fuel consumption

According to Table 1, metaheuristic algorithms are generally used to decrease cost and increase performance. Additionally, size optimization is other purpose. It can be seen that metaheuristic algorithms are particularly employed to fuel cell powered locomotives. PSO is applied more than other metaheuristic algorithms.

3. RESULTS AND DISCUSSION

Main results of studies are explained in Table 2. In Table 2, standard deviation, population size, iteration, run number and significant results are highlighted. Flowchart of metaheuristic algorithm for fuel cell vehicles is given in Fig. 1.

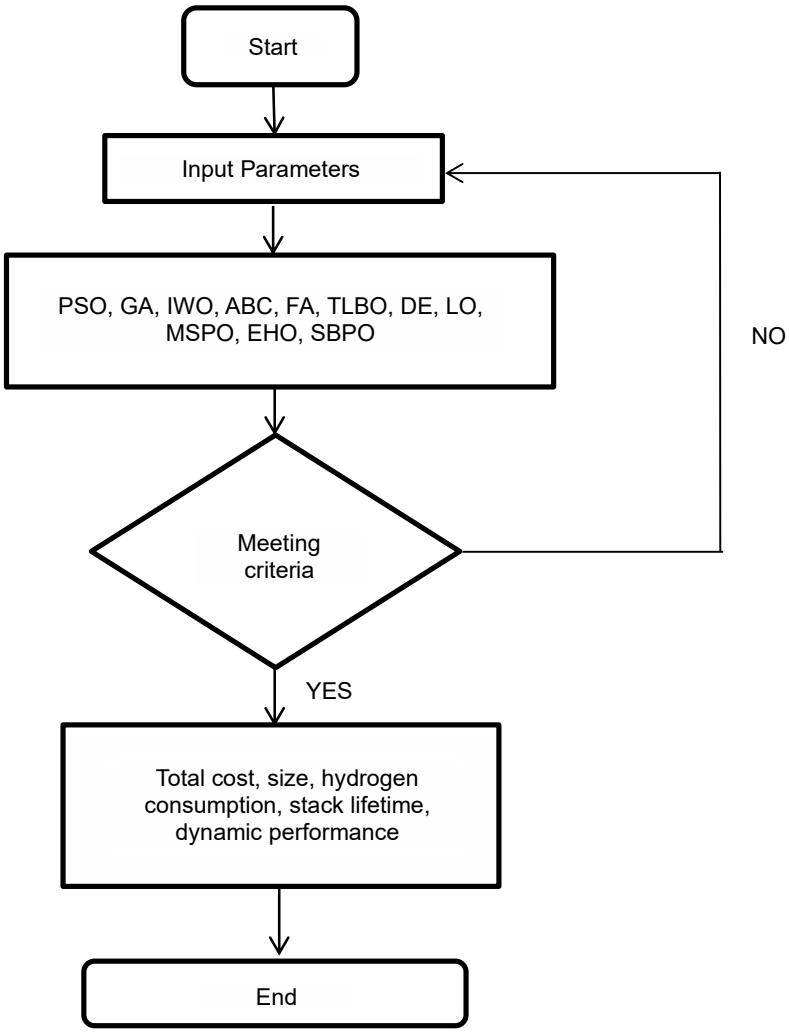

Fig. 1. Flowchart of metaheuristic algorithm for fuel cell vehicles

Table 2. Main results

No	Citation	Metaheuristic Algorithm	Standard Deviation	Population Size	Iteration	Run Number	Main results
1	Li et al. [13]	EIA-PSO	0.028	25	30 (maximum)	5	EIA-PSO exhibits optimum solutions for locomotives in respect to dynamic response
2	Macauley et al. [14]	GA	Not Available	Not Available	Not Available	Not Available	In accordance with operating time, GA is used to leak initiation and found useful to reveal membrane lifetime within 20%.
3	Sarma and Ganguly [15]	PSO	Not Available	200 (for the best results)	100 (maximum)	Not Available	PSO provides 3.93 x 10^6 $ total cost in accordance with 2% of slope.
4	Zhang et al. [16]	LO, SPO, EHO and SBPO	Not Available	Not Available	Not Available	Not Available	MSPO can be recommended in terms of minimization of total cost.
5	Ajayan and Immanuel Selvakumar [17]	DE, TLBO, PSO, FA, ABC and IWO	Not Available	50 (population of students)	Not Available	144 different case	TLBO presents better results than DE, PSO, ABC, IWO and FA.

According to Table 2 the least amount of standard deviation is noticed in EIA-PSO. Population size is also crucial for algorithms. In examined studies, general population size is taken as 25, 50 and 200. Minimum and maximum population sizes are used in EIA-PSO and PSO respectively. Besides population size, number of iterations is significant. With the use of 30 and 100 iterations, optimum solutions via PSO are obtained. Minimum and maximum number of iterations is belonged to EIA-PSO and PSO respectively.

4. CONCLUSIONS

This paper is an initial attempt to evaluate studies of fuel cell vehicles in respect to metaheuristic algorithms. Little amount of studies are reviewed based on metaheuristic algorithms. The algorithms are mainly used to minimize fuel consumption with overall cost. Additionally, metaheuristic algorithms are employed for size optimization. The findings indicate that PSO algorithm is effectively used for locomotives. PSO algorithm is expressed as useful to decrease maximum iteration number, population size, standard deviation and run number. The algorithm is practical to reveal system dynamic response. GA is utilized to predict membrane lifetime. MSPO gives satisfactory results from the viewpoint of minimization of total cost. DE, TLBO, PSO, FA, ABC and IWO enable different cases. This paper also exhibits how effectively metaheuristic algorithms can be used to fuel cell vehicles.

ABSTRACT

This article explores the concept of using offshore wind farms as hydrogen fuel stations for maritime applications. It covers site assessment and traffic analysis to estimate fuel requirements at a specific location, as well as the amount of hydrogen production needed to meet the fuel demand. The Marmara Sea has been chosen as the study area due to its strategic importance, as a significant number of ships travel between Europe and Asia through this region. The integration of a hydrogen fuel station with an offshore wind farm presents a potential solution for long-distance vessels, as it eliminates the need for ships to return to nearby ports for refuelling. This study provides a sustainable solution for the maritime industry, addressing the environmental impact of fuel emissions from cargo ships and vessels and contributing to pollution reduction efforts. The approach outlined in this research offers a promising pathway for reducing the carbon footprint of maritime transportation while promoting the use of hydrogen.

Keywords: Offshore wind farm**,** Hydrogen production**,** Offshore fuel station, Marmara Sea

1. INTRODUCTION

The maritime shipping industry is the backbone of global trade, as it handles the majority of the worldwide cargo transport [1]. However, it is responsible for approximately 3% of global greenhouse gas emissions [2]. To control global warming, it is essential to reduce these emissions and adopt more sustainable practices. Agreements like the Paris Agreement and the Glasgow Climate Pact, along with recent climate reports, are pushing the shipping industry to quickly switch to cleaner, low- or zero-carbon technologies for powering ships [2]. Cargo ships running on heavy oil fuel cause serious air and water pollution [1]. These ships also release nitrogen oxides (NOx), which can cause harmful algal blooms in coastal waters. According to the report by the Pacific Northwest National Laboratory [1], large cargo ships transport $4 trillion worth of goods annually, handling 80% of global trade by volume. These ships emit over one billion tonnes of greenhouse gases [1]. If no action is taken, these emissions are expected to increase in the coming decades. However, switching to cleaner fuels such as hydrogen can significantly reduce these pollutants, helping to protect both the air and oceans [1]. However, lack of infrastructure for their large-scale production, storage, and distribution poses a significant barrier. Despite these challenges, hydrogen presents a potential solution, offering a pathway to zero-carbon shipping if these obstacles can be addressed. This study focuses on the potential of offshore wind farms for hydrogen fuel production and their role as fuelling stations for ships. However, extensive research has already been conducted on offshore wind infrastructure, covering key aspects of hydrogen production such as site selection, wind turbines and foundations, wind electrolysis integration, desalination units, hydrogen storage, and transportation [3]. In addition, three primary models of wind electrolysis integration have also been explored: onshore (centralised), offshore (centralised), and in-turbine (decentralised) [3]. Unlike previous research, this research article aims not only to highlight hydrogen as a viable solution to maritime pollution but also to explore the use of offshore wind farms as direct fuelling stations for ships. By enabling ships to refuel directly at the wind farm, the need to transport hydrogen from offshore to port can be eliminated which can reduce the transportation costs. Additionally, this approach would allow ships to bypass ports for refuelling, thereby helping to alleviate port congestion. The Marmara Sea has been selected as the site for deploying an offshore wind farm as a fuel station. This region experiences high shipping traffic due to its strategic connectivity with sea routes linking Asia and Europe [4]. It serves as a global trade hub and supports a diverse local shipping network, making it an ideal location to study the impact of hydrogen-propelled ships on both short and long hauls. Additionally, previously available data further supports the suitability of the Marmara Sea for this type of study [4].

2. PROPOSED MODEL

2.1 Site selection for offshore wind farm

The site assessment of the Marmara Sea has been extensively explored in numerous research articles, which has proven to be beneficial for the current investigation [4]. A key consideration in this study is the shipping routes, as wind farms cannot be deployed in busy areas. To gain insights into these routes, a live map from the Marine Vessel Traffic website was utilised, as shown in Fig. 1(b) [5]. By examining areas with high traffic density, a less congested region was selected for this study, which is highlighted by the black square in the figure. The area of the selected region (526 Km^2) was then

calculated using Google Earth. Additionally, using the EMODnet Map Viewer, the average depth of the Marmara Sea at various locations was estimated [6]. As shown in Fig. 1(b), the average depth of the selected region is approximately 50 meters, and it has been reported that the wind speed in this area is around 8 m/s at 100 m elevation [4]. Further factors influencing site selection will also be assessed using Quantum Geographic Information System (QGIS) software. Based on the depth, area, and wind speed of the selected site, the appropriate wind turbine foundation will be determined, and the electricity generation will be optimised. All this analysis is under process.

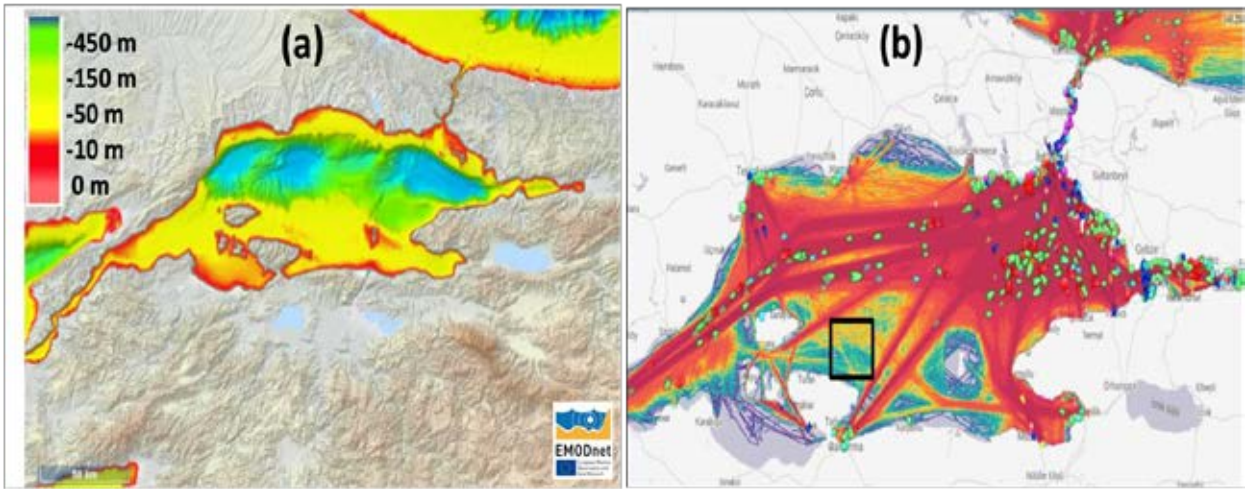

Fig. 1. AIS data and shipping routes traffic in Marmara Sea [5, 6]

2.2. Assessing the suitability of offshore wind farms as fuel stations

Figures 2 and 3 illustrate the schematic diagram and the strategic flowchart of an offshore wind farm integrated hydrogen fuel station. The flowchart provides a clear and systematic overview of the approach required for integrating a fuel station with an offshore wind farm

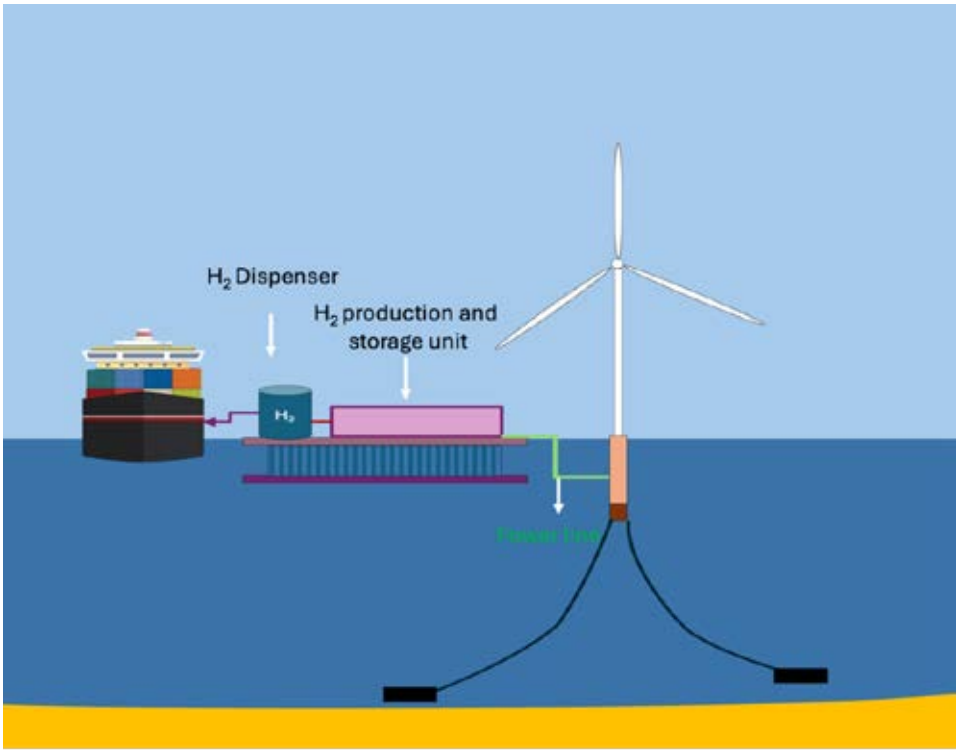

Fig. 2. Schematic diagram of an offshore hydrogen fuel station powered by an offshore wind turbine system.

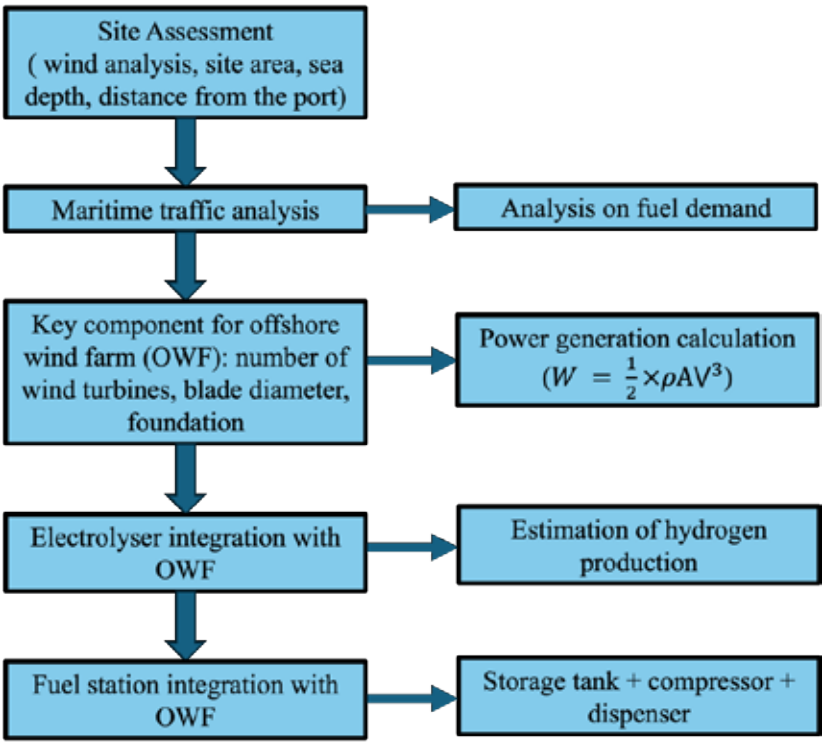

Figure 3: Flowchart of an offshore hydrogen fuel station powered by an offshore wind

In this section, an estimation of the wind farm's capacity to consistently produce sufficient electricity for hydrogen production will be conducted, ensuring that the location is suitable for ship and vessels for refuelling.
The analysis of ships, ferries, cargo vessels, or tankers passing through or near the location will help to determine the demand for fuelling services and identify peak operational periods. An assessment of energy fuel requirements help in determining whether the projected farm's capacity can meet this need and, if not, what other elements need to be changed. This data will also aid in determining whether the chosen location is appropriate for integrating a fuel station and wind farm. All the key components, such as the electrolyser, desalination unit, storage, and dispenser techniques, since we wish to combine a hydrogen fuel station with a wind farm, will be discussed.

3. CONCLUSION

This study emphasises the utilisation of offshore wind farms as hydrogen fuel stations. It provides a systematic overview, from site selection to the use of hydrogen as a fuel for maritime applications. The site assessment process includes key factors such as marine traffic, wind speed, and water depth, which are crucial for optimising the location for offshore wind farm installation. Additionally, this work highlights the role of marine traffic analysis in optimising fuel demand calculations. By doing so, it is possible to determine the number of turbines required to generate the electricity needed for hydrogen production, which can then be directly used by ships and vessels. An advantage of this study is that, by utilising offshore wind farms for hydrogen production, the need to transport hydrogen to onshore fuel stations is eliminated. Furthermore, ships can directly charge at sea without the need to return to port, thus improving efficiency and reducing operational costs. To the best of our knowledge, no existing literature has explored this type of study, making this research unique in its approach.

DEVELOPMENT OF OPERATION STRATGIES FOR IMPROVING POLYMER ELECTROLYTE MEMBRANE FUEL CELL SYSTEM WATER MANAGEMENT AND HYDROGEN CIRCULATION

[1]*Jaekwan Bae*, [1]*Haewook Park*, [1]*Ik Jae Son,* [1]*Seung Man Park*
[1] Hyundai Motor Company, Fuel Cell System Test Team, Mabuk-ro 240beon-gil 17-5, Yongin-si, 16891, Republic of Korea

ABSTRACT

In this study, we discussed methods of increasing anode water discharge and enhancing hydrogen circulation during polymer electrolyte membrane fuel cell (PEMFC) operation. Constant current measurement was performed by changing the operating conditions in three major ways: increasing the pressure difference between the inlet of hydrogen and air, increasing air stoichiometry ratio (SR), and oscillating the hydrogen pressure. As a result, it was possible to distinguish the correlation between anode water discharge rate and performance degradation. In particular, it was confirmed that hydrogen pressure oscillation using step peak pressure circulation (SPPC) control boosts anode water discharge and reduces performance degradation at low current range due to hydrogen distribution improvement in the PEMFC stacks. Ultimately, we demonstrated that the commercialization of PEMFCs can be accelerated by developing a PEMFC operation strategy with improved durability and performance.

Keywords: PEMFC System, Operation Strategy, Anode Water Discharge, Fuel Cell Performance, Performance Degradation, Hydrogen Circulation

1. INTRODUCTION

Recently, as carbon neutrality is emerging to prevent global warming, energy sources that do not emit carbon dioxide or greenhouse gases are receiving attention. Among them, hydrogen fuel cells have attracted interest as a next-generation energy source because they produce electricity through the electrochemical reaction of hydrogen and oxygen and only emit pure water. In particular, PEMFCs can be applied not only to various mobility such as vehicles, ships, railways, etc., based on their high-power density [1, 2]. However, they have problems with the physical and chemical deterioration of composition materials including electrodes, electrolyte membranes, and gas diffusion layers (GDLs) as the operating time increases [3].

One of the main causes of this degradation is related to water management within the system. In the dry-out state, ion conductivity decreases due to insufficient hydration of the membrane, which reduces the channels for proton (H^+) movement. Furthermore, sulfonic acid groups with a small amount of moisture form radicals ($OH\cdot$) to destroy the membrane, which raises the quantity of fluorine released, and creates pinholes and cracks in the membrane [4]. On the other hand, if the generated water is not expelled smoothly, the transfer of reactants to the triple phase boundary (TPB) where the electrochemical reaction occurs is obstructed, leading to issues like a decline of fuel cell performance and hydrogen utilization efficiency in the short term, as well as a diminishment in the anticipated operational lifespan due to irreversible damage in the long term [5]. Since excessive hydrogen supply is impossible, there is a limit for discharging the back-diffused water to the anode. Therefore, it is essential to develop an operating strategy that can secure PEMFC performance and durability by preventing fuel electrode flooding and ensuring hydrogen circulation.

2. EXPERIMENTAL

2.1. Fuel Cell System Test Condition

All experiments were conducted in a 100 kW system unit with balance of plants (BOP) attached to a pair of PEMFC stacks positioned one on top of the other, and the hydrogen supply was controlled by following the target pressure based on a sensor located at the inlet side. Since a recirculation system using an ejector was adopted, there is a limit to improving water discharge through excessive fuel provision in the low current section. In order to compare the degree of stack deterioration according to the operating conditions, constant current operation for more than 1 hour was performed as a test protocol. Stack temperature was maintained at 60 ℃, and the system was dried based on 20 purge cycles after the examination to minimize the influence of the previous operating conditions. In the case of exhausted anode water, the droplets within the fuel processing system (FPS) were captured and the amount was measured.

2.2. Increase hydrogen/air inlet differential pressure

This method improves the anode water discharge by increasing the base pressure of the hydrogen supply and inducing more electro-osmotic drag. It does not require large power consumption except for controlling the pressure. While maintaining the air pressure constantly, the fuel was pressurized at 0.8 A/cm^2 operation so that the inlet pressure difference satisfies 10 to 40 kPa.

2.3. Increase the amount of air supply

It is possible to prevent flooding issues on the fuel electrode by diminishing back-diffusion rate within the system in the manner of enhancing the SR of the air. As holding the air pressure at 0.8 A/cm^2 equally, air flow rates corresponding to 1.5, 1.6, and 1.8 SR were applied sequentially.

2.3. Repeated cycles of hydrogen pressure up and down

The instantaneous pressure change of the supplied hydrogen was utilized to strengthen the hydrogen flow rate in the FPS. Three control methods were proposed in this experiment, and they were named One Peak Pressure Circulation (OPPC) control, Step Peak Pressure Circulation (SPPC) control, and Slew Rate Pressure Circulation (SRPC) control, respectively. Although the management logic is different depending on the circulation method, all of them maintained the same 150 kPa during the purge. The average pressure of hydrogen was 150 kPa, and operated under a low current density condition of 0.18 A/cm^2 (small amount of hydrogen supply) so that the effect of the improvement could be confirmed clearly. OPPC had the disadvantage of generating flow noise in the FPS due to the sudden rise with a single pressure increase. To prevent this, SPPC was also applicated, which divides the same pressure enhancement into steps and maintains one step about 610 ms. Lastly, we conducted additional comparisons of the SRPC method, which allows the gradient to vary with pressure change.

3. RESULTS AND DISCUSSION

3.1. Increase hydrogen/air inlet differential pressure

The results of increasing the hydrogen pressure during constant current operation of 0.8 A/cm^2 are summarized in Fig. 1. When the hydrogen/air inlet differential pressure (ΔP) is 40 kPa, it can be confirmed that the anode water discharge amount decreases from 2.78 g/s (10 kPa) to 2.57 g/s due to the effect of reduced water back-diffusion following larger prsessure difference between electrodes. In addition, it shows that the cell performance deterioration is improved from -3.499 mV/h to -1.884 mV/h at ΔP 30 kPa. However, it demonstrates that the oversupply makes hydrogen crosse-over to the cathode, which affects the catalyst and binder leading to a negative impact on the performance as -2.084 mV/h (40 kPa). So, it is possible to minimize the fuel electrode flooding by optimizing ΔP while preventing cell degradation.

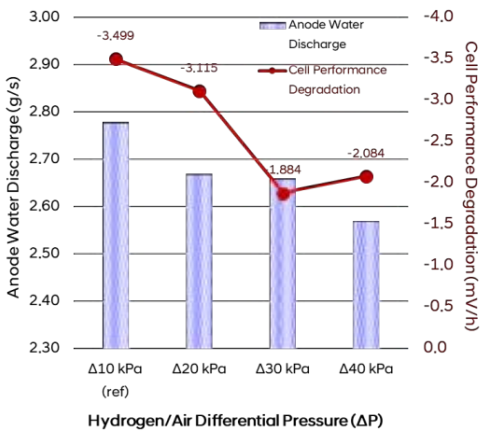

Fig. 1. Anode water discharge during 3-hour constant current operation and cell performance degradationof the last 2 hours according to the supply hydrogen/air differential pressure (0.8 A/cm^2, temperature 60 ℃)

3.2. Increase the amount of air supply

The effects of the air SR increase are analyzed in Fig. 2. In the case of operating SR at the existing ΔP 10 kPa are increased to (1.6 → 1.8), the system discharge decreases to 2.47 g/s due to the diminished amount of water back-diffusion. Furthermore, we can also find that cell voltage degradation is also evoluted from -3.499 mV/h to -2.172 mV/h. Despite the expelled water amount decreases significantly, the performance improvement is smaller than the effect of the increase in ΔP. Then, we also check the influence of the air SR change based on ΔP 30 kPa, which was the optimal condition among the ΔP control. The total amount of discharged water slightly increases (2.66 → 2.75 g/s) at SR 1.5 because of the weakness in the water discharge capacity of the cathode. It affects the deterioration of cell performance (-1.884 → -1.996 mV/h) adversely. On the contrary, the increase in air SR plays a sufficient role in removing the residual water in the stack making the anode water discharge significantly decrease (2.68 → 2.35 g/s). However, the air oversupply (1.6 → 1.8) has the potential to form a dry-out state in the system, accelerating the deterioration of cell

performance (-1.884 → -2.589 mV/h). The larger energy is consumed by the air compressor in this situation, which negatively impacts both the system efficiency and stack durability. According to these results, we can realize that the air SR not only affects the anode water removal but also is an invaluable element related to maintaining PEMFC performance.

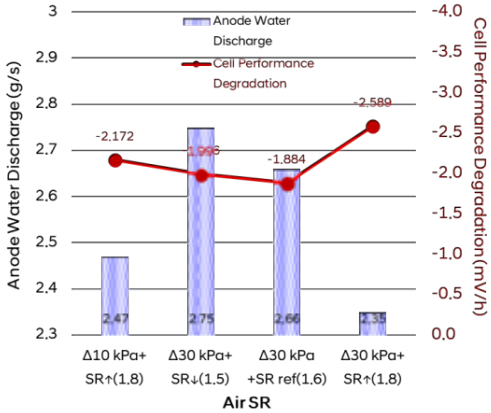

Fig. 2. Anode water discharge during 3-hour constant current operation and cell performance degradationof the last 2 hours according to the air SR (0.8 A/cm^2, temperature 60 ℃)

3.3. Repeated cycles of hydrogen pressure up and down

It is demonstrated that the repetitive hydrogen pressure oscillation cycle can effectively improve the exhaust of generated water accumulated in materials such as bipolar plates and GDLs (Fig. 3).

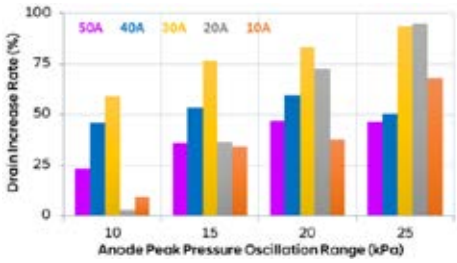

Fig. 3. Anode water discharge increase rate according to the hydrogen pressure oscillation range (0.18 A/cm^2, temperature 60 ℃ / 5 kPa reference)

Stack performance decrease change under the constant current operation according to SPPC on/off is shown in Fig. 4. It is confirmed that the performance improvement rate is 21.2% at 40 ℃ with SPPC on, and 3.5% enhancement at the temperature 60 ℃. In other words, it indicates that the irreversible deterioration caused by anode flooding is shrinked by early discharge of the generated water through SPPC control.

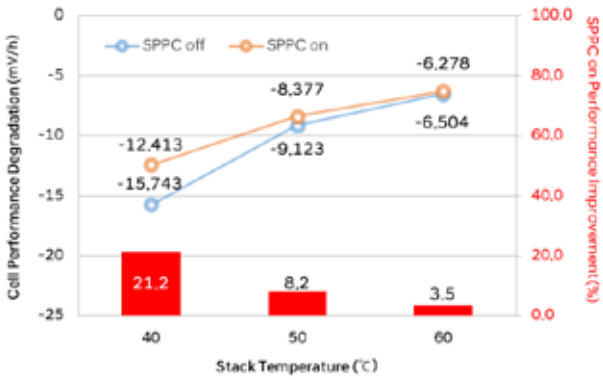

Fig. 4. Cell performance degradation data based on SPPC on/off according to stack temperature (0.18 A/cm^2)

4. CONCLUSIONS

In this study, we showed a novel approach for securing durability by increasing the anode water discharge and hydrogen circulation of the PEMFC system.

- Enhanced ability for expelling anode water and maintaining cell performance was confirmed through hydrogen/air pressure difference optimization.
- Although the discharge of generated water was improved by the air overprovision, there is a concern that the deterioration can be serious due to drying out. Furthermore, this method has a constraint because of the higher energy usage of the air compressor.
- Controlling the fuel supply pressure with appropriate steps and peaks had a positive effect on anode water exile and reducing the hydrogen concentration deviation.

According to these results, durability improvement of the fuel cell system is expected by preventing stagnation of the generated water based on the step and peak pressure control modeling. Moreover, if the water droplets inside the stack induce the irreversible deterioration of the electrode materials, an upgraded driving technique can solve this real-time dry out & flooding issue in the near future.

ABSTRACT

This study explores the potential of recycling electronic waste, particularly CPUs, for hydrogen and oxygen evolution reactions as a step towards sustainable energy generation and resource recovery. A multi-step, eco-friendly leaching protocol was developed to extract valuable metals such as gold, silver, and copper from discarded CPUs. The extracted metals were incorporated into an electrolyte, which was then subjected to electrochemical evaluation in a three-electrode setup.

Cyclic voltammetry and Tafel analysis provided insights into the electrochemical behavior of the recycled metals. The results revealed a preferential enhancement of hydrogen evolution over oxygen evolution, attributed to the lower activation energy barrier and favorable kinetics of hydrogen production. Despite the promising electrocatalytic activity for hydrogen evolution, further optimization is necessary to improve oxygen evolution efficiency.

This research underscores the dual benefits of e-waste recycling: mitigating environmental hazards and advancing renewable energy technologies. By demonstrating the feasibility of repurposing e-waste for sustainable applications, this study contributes to the development of circular economy models and supports the global transition toward greener energy solutions.

Keywords: e-waste recycling, hydrogen evolution reaction, oxygen evolution reaction, CPU recycling, sustainable energy

1. INTRODUCTION

The exponential growth of electronic waste (e-waste), driven by rapid technological advancements and increasing consumer demand, has become a critical environmental challenge. Among various e-waste components, central processing units (CPUs) represent a significant proportion due to their widespread use and short lifecycle. Effective recycling strategies for CPUs are essential not only to mitigate environmental hazards but also to recover valuable embedded resources such as gold, silver, and copper [1].

Traditional recycling methods often rely on aggressive chemical treatments, posing significant environmental risks. This study aims to address these challenges by introducing an eco-friendly multi-step leaching process for metal recovery from discarded CPUs. By utilizing the recovered metals to produce electrolytes for electrochemical hydrogen and oxygen evolution reactions, the study explores a sustainable pathway for renewable energy generation.

The production of hydrogen and oxygen through electrolysis holds immense potential as a clean energy source, contributing to global efforts to reduce carbon emissions. This research bridges the gap between resource recovery and renewable energy, demonstrating the feasibility of integrating e-waste recycling into sustainable energy applications.

2. MATERIALS AND METHODS

2.1. Sample collection and preparation

All discarded CPUs used in this study were sourced from the same brand and generation. The computers and motherboards were disassembled, and the processors were carefully removed from their sockets. A thorough cleaning process was then employed to remove contaminants such as dirt, plastic residues, and thermal paste, ensuring uniformity across all samples.

After cleaning, the CPUs were mechanically shredded and milled using an electrical mill. The resulting powder exhibited some variability in particle size, which was subsequently assessed using a lab sieve [2].

2.2. Leaching procedure

To achieve optimal leaching results, a multi-step procedure was employed to effectively separate the various metals present in the CPU powder.

The first step involved dissolving the powder in 1 M HCl at ambient temperature under an inert gas atmosphere for 5 hours. This step aimed to dissolve and segregate iron (Fe) and nickel (Ni) from the other metals present in the powder.

After dissolution, the solution was filtered, and the sediment was separated, washed, and dried until completely dry. The dry powder was then immersed in a solution consisting of $NH_3/(NH_4)_2SO_4 + H_2O_2$ at room temperature for 2 hours. This

step facilitated the dissolution and removal of copper (Cu) and silver (Ag) from the sample.
Following this leaching step, the powder underwent another round of filtration, washing, and complete drying. The final leaching step consisted of dissolution in a mixture of 4-PSH + DMF + H_2O_2 at 60 °C for 25 minutes. In this step, the metallic gold (Au) dissolved from the powder and formed a complex with 4-PSH. Finally, the solution underwent one last filtration and the relutling solution was reseved for subsequent testing [3].

2.3. Electrochemical evaluation

Electrochemical testing was conducted using a three-electrode glass cell setup. The working electrode was a pure metallic nickel electrode with a surface area of 1 cm², while high-surface-area nickel foam served as the counter electrode. An Ag/AgCl electrode was used as the reference electrode.
Electrochemical characterization involved recording and analyzing polarization curves to determine the kinetics of hydrogen and oxygen evolution reactions within the electrolyte, which was prepared from the leached powder.

3. RESULTS AND DISCUSSION

The main focus of this investigation was to explore the feasibility of employing recycled metals sourced from electronic waste, particularly CPUs, in hydrogen and oxygen evolution reactions.
Upon the examination of cyclovoltamogram (Fig 1), the peak of nickel oxidation, at approximately 0.5 V vs Ag/AgCl can be observed, but the absence of a corresponding reduction peak, expected around 0.1 V vs Ag/AgCl indicates the involvement of additional processes at the electrode surface [4].

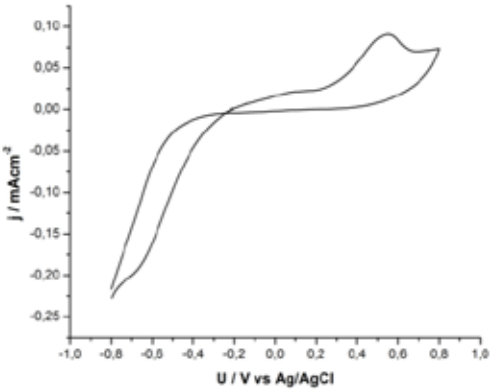

Fig. 1. Cyclic voltammogram of a pure nickel electrode in prepared solution

The next step in the activity evaluation was the recording of linear sweep polarization curves for hydrogen and oxygen evolution reactions (Fig. 2). The results presented below indicate that the metal complex, likely the Au-PSH complex, demonstrated relatively favorable electrochemical activity for the hydrogen evolution reaction. However, its performance in oxygen evolution was comparatively less effective.

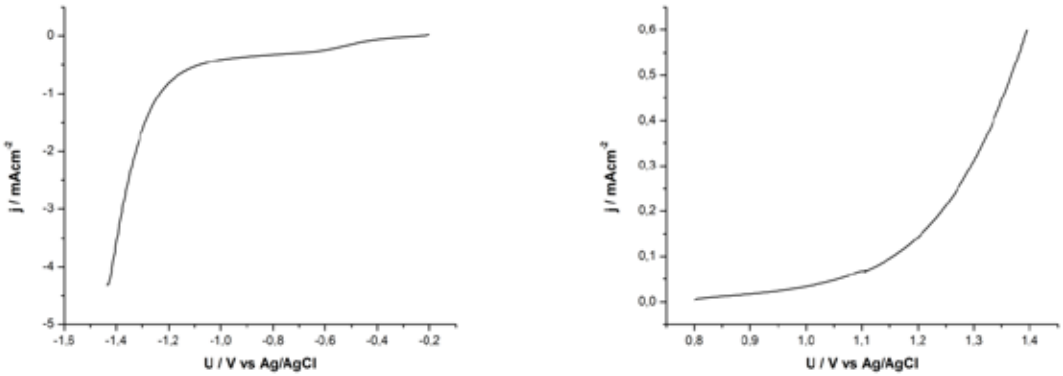

Fig. 2. Polarization curves for hydrogen (left) and oxygen (right) evolution reactions

A subsequent Tafel analysis was performed on the recorded polarization curves, with the resulting plots shown in Fig. 3. The Tafel plot reveals a linear relationship between the logarithm of the current density and the overpotential. The slope of these curves, known as the Tafel slope, offers critical insights into the reaction mechanism and activation energy.

Based on the Tafel slope values, the reactions can be classified into three primary mechanisms: activation-controlled, diffusion-controlled, or mixed-controlled.

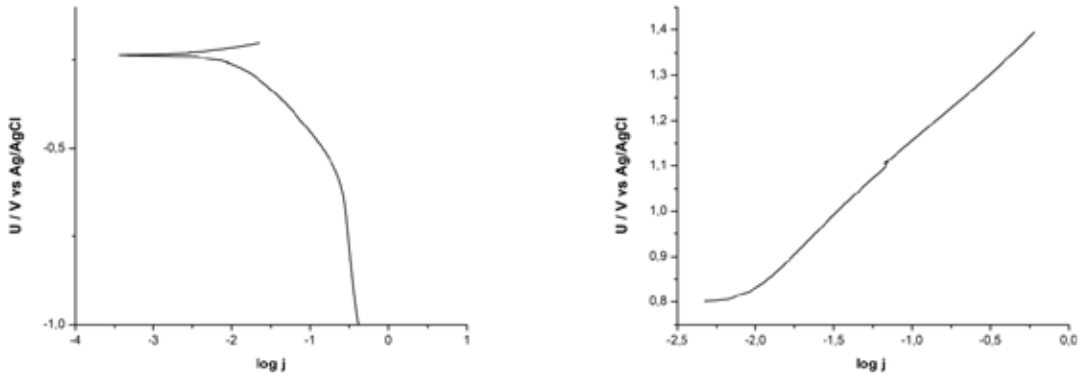

Fig. 3. Tafel plots for hydrogen (left) and oxygen (right) evolution reaction

The Tafel slope values derived from the analysis support the initial hypothesis, showing that the electrolyte prepared using this protocol demonstrates superior electrocatalytic activity for hydrogen evolution compared to oxygen evolution. This disparity in electrocatalytic performance between the two reactions highlights the complex behavior of the electrolyte and emphasizes its preferential enhancement of hydrogen evolution.

Table 1. Kinetick parameters for Ni electrode in prepared solution

Reaction	Tafel slope (mV dec^{-1})
HER	-266.8
OER	318.8

The observed variation in Tafel slope values between the hydrogen and oxygen evolution reactions suggests a lower activation energy barrier for hydrogen production, resulting in a more efficient electrochemical process. Conversely, the higher activation energy barrier for oxygen evolution signifies slower reaction kinetics, which hinder the overall rate of oxygen generation [5].

4. CONCLUSIONS

The recycling of electronic waste, particularly CPUs, for hydrogen and oxygen evolution reactions represents a complex yet impactful approach to promoting sustainability and clean energy generation. The increasing volume of e-waste emphasizes the need for effective recycling strategies, and this study highlights the potential of environmentally friendly leaching techniques for extracting valuable metals from discarded electronic components.

The multi-step leaching protocol developed in this research offers a promising pathway for recovering metals from e-waste CPUs, with the extracted solution functioning directly as an electrolyte for electrochemical evaluation. Cyclic voltammetry and Tafel analysis have provided critical insights into the electrochemical behavior of the recycled metals, demonstrating a notable preference for enhancing hydrogen evolution over oxygen evolution.

The relationship between electrolyte composition and electrochemical performance underscores the importance of tailored strategies when utilizing recycled materials for sustainable energy applications. While the electrolyte exhibits strong electrocatalytic activity for hydrogen production, further optimization may be required to improve its effectiveness for oxygen evolution reactions.

This study highlights the dual benefits of e-waste recycling: resource recovery and renewable energy generation. By advancing eco-friendly leaching methods and elucidating the electrochemical mechanisms involved, this work contributes to the development of a circular economy and supports the global transition towards sustainable energy solutions.

ABSTRACT

This study explores the impact of electrochemical surface preparation on the catalytic activity of nickel-based electrodes for the hydrogen evolution reaction (HER) in alkaline media. Two distinct forms of nickel hydroxides, α-$Ni(OH)_2$ and β-$Ni(OH)_2$, were synthesized through potential cycling within specific voltage ranges and subsequently evaluated for their catalytic performance. Carbon-based materials doped with nickel nanoparticles were used as catalytic substrates, and their suspensions were applied to glassy carbon electrode surfaces to create working electrodes. Electrochemical characterization, including polarization curve analysis and Tafel slope evaluation, was conducted to assess the catalytic efficiency and reaction kinetics.

The results indicate that both hydroxide forms exhibit comparable catalytic activity, with β-$Ni(OH)_2$ showing slightly superior performance due to lower overpotential and a more favorable Tafel slope. The kinetic analysis confirmed a diffusion-controlled reaction mechanism for both forms, with β-$Ni(OH)_2$ demonstrating subtly enhanced reaction kinetics. These findings underline the significance of surface modification in optimizing nickel-based catalysts for HER and provide insights into the role of nickel oxidation states in catalytic processes.

Keywords: hydrogen evolution reaction, nickel hydroxides, electrochemical surface modification, catalytic efficiency

1. INTRODUCTION

The growing global demand for energy, fueled by rapid industrial and technological advancements, necessitates the exploration of alternative energy sources. While fossil fuels remain the dominant energy resource, the adoption of renewable energy technologies has been steadily increasing. However, the limited efficiency of these sustainable solutions prevents a complete transition to renewable energy. Among the most promising alternatives is hydrogen energy, which offers an environmentally sustainable pathway for converting chemical energy into electricity. [1].

Despite its immense potential, the large-scale implementation of hydrogen energy systems hinges on continual advancements, particularly in the development of catalytic materials [2]. Efficient and cost-effective catalysts are crucial to enhancing hydrogen production processes. Currently, the most widely used catalysts for hydrogen evolution rely on precious metals from the platinum group, valued for their high efficiency but limited by availability and cost. Thus, identifying alternative catalytic materials that deliver comparable performance at a lower cost is an essential research priority.

Nickel has emerged as a promising candidate for catalytic applications due to its versatile properties. A silver-white metal belonging to group VIIIb of the periodic table, exhibits high thermal and electrical conductivity, ferromagnetic properties, and notable resistance to corrosion by air, water, and alkalis [3], [4]. It dissolves efficiently in diluted oxidizing acids, while the solubility of its salts varies depending on the nature of the acid.

For nickel to function effectively as a catalytic material, it must be supported on a suitable substrate. This study examines carbon-based materials doped with nickel nanoparticles as catalytic substrates. Suspensions containing a specific concentration of nickel will be prepared and applied to electrode surfaces to create working electrodes. These electrodes will undergo comprehensive electrochemical evaluations to determine their catalytic properties. Additionally, this study provides insights into the various oxidation states and forms of nickel, evaluating their potential as catalytic materials for the hydrogen evolution reaction.

2. MATERIALS AND METHODS

The catalytic material utilized in this study was commercially available 1% Nickel supported on Vulcan XC-72 (Fuel Cell Store). The ink for electrode preparation was formulated using deionized water and 1 mg/ml of catalyst, subsequently sonicated for 30 minutes. Following sonication, the ink was drop-casted onto a pre-polished glassy carbon electrode surface and left to dry for 24 hours. After the surface was completely dry, and prior to the electrochemical teasting, the 5 µl of a Isopropyl alcohol and Nafion (50:1) mixture solution was added to the surface.

Electrochemical evaluation of prepared electrodes was perfomed in a three-electrode glass cell. The working electrode was a rotating disk electrode (RDE) consisted of a glassy carbon with drop casted catalytic material. The surface area of a RDE glassy carbon electrode was 0.196 cm^2. The counter electrode was high-surface area Pt mesh, while the

reference electrode was a saturated calomel electrode (SCE). Presented potential values were converted to fit Reversible Hydrogen Electrode (RHE) scale. The conversion was perfomed using the Equation 1. Electrochemical measurements were carried out using Gamry Interface 1000 Potentiostat/Galvanostat/ZRA. The electrolyte used in this study was an analytical-grade 1 M KOH from Merck, with a pH value of 13.2. Prior to the measurements, electrolyte was purged with N_2 for 20 minutes, and the RDE was continually rotated at a rate of 1600 rpm.

$$E_{RHE} = E_{SCE} + 0.244\,V + 0.059 \cdot pH \quad (1)$$

The first part, prior to the electrochemical evaluation of activity, the electrochemical surface modification was conducted. Cycling in a specific potential range the electrode surface can oxidyze and produce different oxides and hydroxides (Fig 1). In this study, surface was modified to produce alpha and beta $Ni(OH)_2$.

Fig. 1. Representation of potential values for oxidation and reduction of NiO

Emideatly after surface modification, the linear sweep was used to determin the HER activity. Potenial was measured between 0 V and 0.65 V vs RHE.

3. RESULTS AND DISCUSSION

In order to investigate the influence of produced nickle hydroxide form on the electrode surface, two different types were produced based on the potential rage presented in Fig 1. The first produced was α – $Ni(OH)_2$ by cycling in adequant potential range (Fig 2. a). Analysis of the polarization curves for the formation of α-$Ni(OH)_2$ indicates that this hydroxide exhibits significant reduction potential, as nearly all the formed oxide can be reduced, returning the electrode surface to its original state.

a) b)

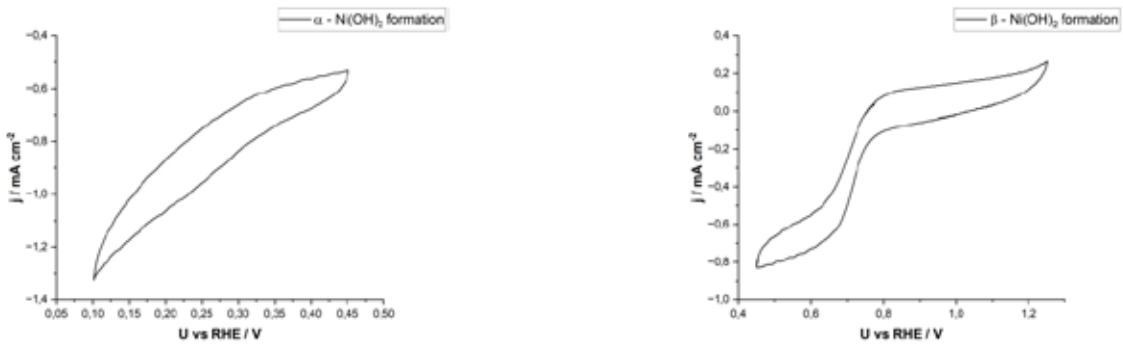

Fig. 2. Cyclovoltamograms of α (left) and β (right) $Ni(OH)_2$ oxidation

The next aspect investigated was the formation of β-$Ni(OH)_2$ and its influence on the hydrogen evolution reactions. This hydroxide form was created through potential cycling in the range of 0.45 to 1.25 V, with the polarization curve of the modified material shown in Fig. 2. b).
It was observed that, although both oxide forms are considered reducible, only alpha nickel hydroxide actively undergoes reduction under the working conditions of the hydrogen evolution reaction. After completing the experimental protocol, the electrode coated with the formed alpha hydroxide fully returned to its original state, with no traces of alpha oxide present on the surface. In contrast, the electrode with beta oxides formed on its surface retained its oxide features and formes [5].

Analysis of the polarization curve reveals that the presence of β-$Ni(OH)_2$ on the electrode surface increases the activity for the hydrogen evolution reaction, compared to the α – $Ni(OH)_2$ activitie (Fig. 4.). Several explanations for this enhanced activity have been proposed. One possibility is that the oxidation of nickel and the formation of β-$Ni(OH)_2$ result in improved development of the active surface area, directly contributing to higher catalytic performance. Additionally, the formation of this hydroxide may increase the material's electrical conductivity, further boosting its activity.

a) b)

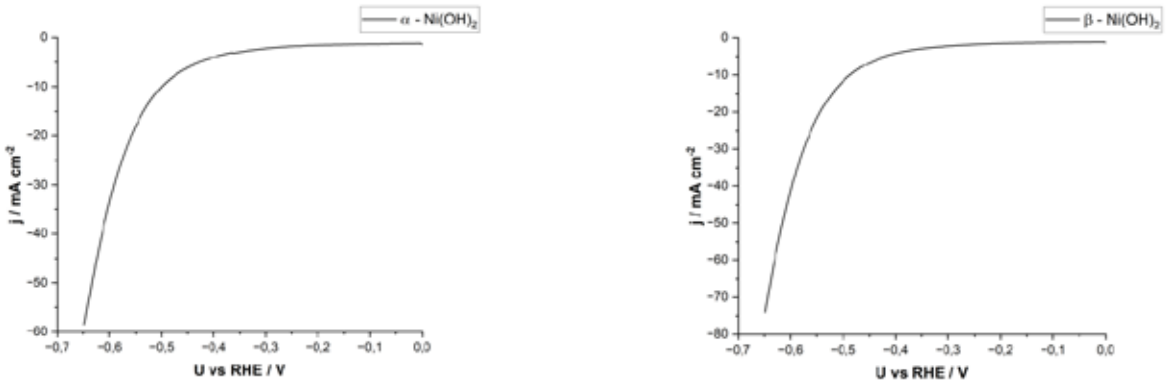

Fig. 3. Polaryzation curves for HER on α – $Ni(OH)_2$ (left) and β – $Ni(OH)_2$ (right) electrode surface

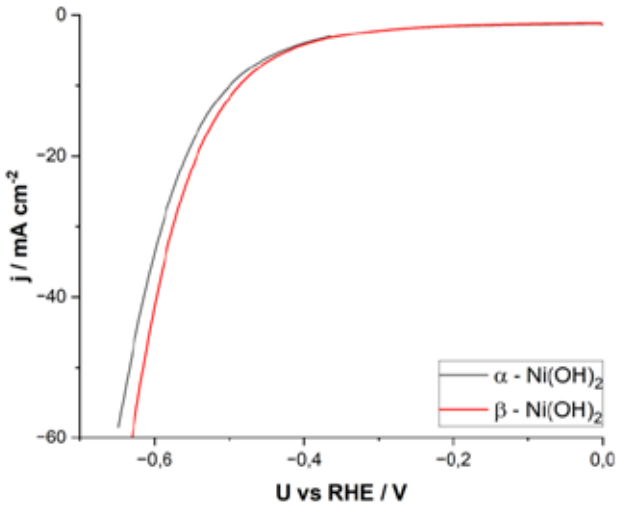

Fig. 4. Comparison of catalytic activity for hydrogen prodyction of α – $Ni(OH)_2$ and β – $Ni(OH)_2$

Based on the obtained polarization curves, the Tafel analysis was condycted to get insights on hydrogen evolution reaction mechanisms and kinetics. In the Tafel plot, a linear relationship emerges between the logarithm of the current desity and the overpotential. The curve's slope. Known as the Tafel slope, provides insight into the reactio's activation energy, implying a diminished reaction rate [6]. Broadly, three mechanisms can be categorized based on the Tafel slope value: activation – controlled, diffusion – controlled and mixed – controlled reaction mechanism [7].
The Tafel slope values are presented in Table 1. For both α – $Ni(OH)_2$ and β – $Ni(OH)_2$ slope values were between -180 and -210 mV dec^{-1}, correlating with a diffusion - controlled reaction mechanism.

Table 1. Overpotential and Tafel slope values for evaluated electrodes

	Overpotential at 10 mA cm^{-2} [mV]	**Tafel slope [mV dec^{-1}]**
α – $Ni(OH)_2$	-502	-205
β – $Ni(OH)_2$	-487	-187

4. CONCLUSIONS

This study highlights the influence of electrochemical surface preparation on the catalytic performance of nickel-based electrodes for the hydrogen evolution reaction (HER) in alkaline media. Two distinct nickel hydroxide forms, α-$Ni(OH)_2$ and β-$Ni(OH)_2$, were synthesized through potential cycling and evaluated for their catalytic properties. While both forms exhibited similar polarization curve profiles and catalytic activities, β-$Ni(OH)_2$ demonstrated slightly better performance, reflected in its lower overpotential and improved Tafel slope values.
The enhanced catalytic activity of β-$Ni(OH)_2$ is attributed to its ability to develop a more active surface area and potentially increased electrical conductivity during formation. Kinetic analysis confirmed that both hydroxides follow a

diffusion-controlled reaction mechanism, with β-$Ni(OH)_2$ exhibiting a lower Tafel slope, indicating improved reaction kinetics.
These findings emphasize the role of nickel oxidation states and structural modifications in improving catalytic efficiency for HER, offering valuable insights for designing cost-effective and high-performance nickel-based catalysts for hydrogen production in alkaline media.

ABSTRACT

The mass production and use of fuel cells are limited by the cost of components, primarily the price of catalysts. Fuel impurities lead to the degradation and poisoning of catalysts. Therefore, there is an intensive development of cheaper and more durable catalysts and their interactive supports. In this study, we synthesized non-stoichiometric tungsten oxides as supports for PtRu-based catalysts for Proton Exchange Membrane (PEM) fuel cells. The performance of obtained PtRu/WO_x+C catalysts was investigated using cyclic voltammetry and linear sweep voltammetry. Limiting diffusion currents of hydrogen oxidation reactions are reached very quickly and maintain constant values over a wide range of potentials corresponding to anodic potentials of an active PEM fuel cell. The synthesized catalysts show greater catalytic activity and CO tolerance compared to commercial catalysts. The 30% PtRu/WO_x+C catalyst, as the catalyst with the highest catalytic activity and tolerance to CO poisoning, could be a good candidate for commercial application.

Keywords: Anode catalyst, Tungsten-oxide, CO tolerance, PEM fuel cells

1. INTRODUCTION

By developing and utilizing technologies that use renewable energy sources, the emission of carbon dioxide and other harmful gases into the atmosphere will be reduced, while also increasing energy sustainability and the security of energy supply. A significant number of studies are focused on the development of smaller energy supply devices, known as fuel cell stacks, which would be located near or at the point of energy consumption [1]. Fuel cell stacks, as the name implies, are composed of a series of individual fuel cells. Each individual fuel cell represents a system that converts the chemical energy of fuel into electrical energy and heat [2]. For widespread use, the most practical option is Proton Exchange Membrane (PEM) fuel cells, which produce clean electrical energy, heat, and water while operating at low temperatures. The commercialization of PEM fuel cells faces significant challenges due to two key factors: durability and cost. Agglomeration of catalyst particles and oxidation of the catalyst support, along with high sensitivity to impurities in the fuel and oxidant, directly affect the cost-efficiency, durability, and reliability of fuel cells [3]. The high cost primarily stems from the expensive catalysts required. The platinum-group metals, though highly active as electrocatalysts for hydrogen and oxygen electrode reactions in PEM fuel cells and electrolyzer, are prohibitively expensive. Additionally, platinum-based catalysts face challenges with poisoning: impurities in the hydrogen fuel, such as small amounts of CO, can significantly degrade performance and shorten the lifespan of the PEM fuel cell [4]. Therefore, significant efforts are being made to develop longer-lasting and more affordable catalysts, as well as their interactive supports.
The research goal of this study is to develop new, efficient non-stoichiometric tungsten oxides as supports for anode catalysts for use in fuel cells with a proton-conducting membrane. The advantage of tungsten oxide as a catalyst support is primarily improved tolerance to CO poisoning. This material serves as the support for PtRu nanoparticles. The loading of PtRu on this support is varied, and the electrochemical performance of the catalysts is evaluated. Thin-film electrodes combined with (rotating disc electrode) voltammetry, are employed to examine the catalysts' activity and CO tolerance.

2. MATERIALS AND METHODS

2.1. Catalyst preparation

In the present work, tungsten oxide was synthesized by first suspending 1g of tungsten (powder, Sigma-Aldrich) in 25 cm³ of deionized water. To this suspension, 25 cm³ of 30% (by weight) hydrogen peroxide (Sigma-Aldrich) was added, and after 15 minutes, an additional 20 cm³ of 30% H_2O_2 was introduced. The suspension was then left to allow excess liquid to evaporate, followed by drying at 110ºC. A powdery sample, lemon yellow in color, was obtained and labeled as WO_x (non-stoichiometric tungsten oxide).
Anode catalysts were prepared by adding small amounts of commercial hexachloroplatinic acid (H_2PtCl_6, Merck) and ruthenium chloride ($RuCl_3$, Merck) to a 35 ml solution of 0.005 mol dm^{-3} perchloric acid ($HClO_4$, Sigma-Aldrich) with synthesized WO_x support, followed by 30 minutes of ultrasonication and magnetic stirring each. Next, 5 ml of 0.1 mol dm^{-3} sodium borohydride solution was added dropwise while stirring, continued for another 30 minutes before mixing in Vulcan XC72R carbon black. After a final 30 minutes of stirring, the mixture was left to settle, filtered, washed with

deionized water, and dried at 50ºC for 24 hours, producing PtRu/WO_x+C samples at 10%, 20%, and 30% concentrations.

2.2. Cyclic voltammetry and kinetics of HOR

After confirming the composition of all prepared catalysts, electrochemical tests were conducted using a thin film of the catalyst suspension applied to a gold rotating disk electrode (RDE) with a consistent platinum loading of 40 µg cm^{-2}. The catalysts, compared against a commercial 30% PtRu/C catalyst, were tested in a PEM fuel cell application scenario. Electrochemical measurements started with cyclic voltammetry after nitrogen purging the 0.5 mol dm^{-3} $HClO_4$ electrolyte for 30 minutes at room temperature, cycling the potential between 0.03 V and 1.2 V vs. RHE at 100 mV s^{-1}. Hydrogen oxidation reaction (HOR) kinetics were assessed by recording linear sweep voltammetry (LSV) curves at various electrode speeds (1000, 1500, 2000, and 2500 rpm) within 0 to 0.3 V vs. RHE, with calculations for kinetic and mass activity based on the Koutecky-Levich ($\frac{1}{i} = \frac{1}{i_k} + \frac{1}{i_l}$) and a specific activity equation ($i_m = \frac{i_k}{L}$) [5]. Lastly, the catalysts' carbon monoxide tolerance was tested by adsorbing CO for 2000 seconds at 50 mV vs. RHE, followed by a potential scan up to 0.9 V and cycling between 0 V and 1.2 V vs. RHE to facilitate CO oxidation.

3. RESULTS AND DISCUSSION

The elemental composition of all prepared catalysts (Table 1) was determined by EDS analysis using a JEOL JSM-6610LV microscope. This method confirmed the desired composition of the catalyst with smaller deviations from the target mass percentage for Pt and Ru.

Table 1. The elemental composition of catalysts based on Pt and Ru on WO_x supports.

Catalysts	Pt (weight %)	Ru (weight %)	W (weight %)	O (weight %)	C (weight %)
10% PtRu/WO_x-C	7,0	3,5	15,9	11,8	61,8
20% PtRu/WO_x-C	14,0	7,4	15,1	10,4	53,1
30% PtRu/WO_x-C	20,7	10,1	14,7	9,3	45,2

Figure 1 (a) shows the cycle voltammogram for a commercial PtRu/C and 30% PtRu/WO_x+C catalyst. It can be seen that in the typical hydrogen adsorption/desorption region (0.03 V < E < 0.35 V vs. RHE) the PtRu/C catalyst exhibits certain symmetrical anodic and cathodic features attributable to hydrogen adsorption/desorption.

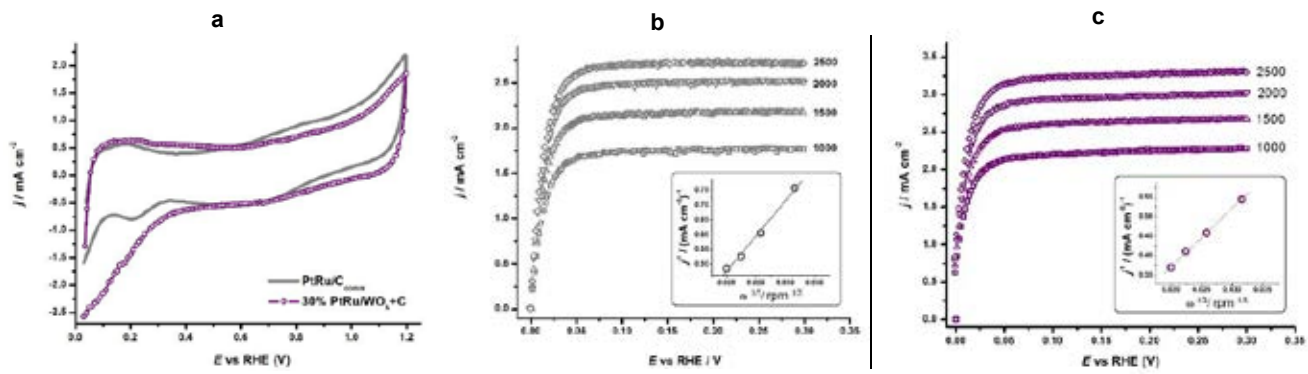

Fig. 1. Comparison of the cyclovoltammograms of the commercial and 30% PtRu/WO_x+C catalysts (a); LSV curves of H_2 oxidation at different rotation speeds with the fitted Koutecky-Levich line at 0.02 V vs. RHE for 30% PtRu/C (b) and 30% PtRu/WO_x+C (c)

H_2 oxidation curves at different rotation speeds are shown in Fig. 1 for a commercial 30% PtRu/C catalyst (b) and 30% PtRu/WO_x+C catalyst (c). For all catalyst, it can be noted that the limiting diffusion current density is reached very quickly (at an overvoltage of about 60 mV) with good definition and stability in a wide potential area (anode potential area of an active PEM fuel cell).

Table 2. Kinetic current densities and mass activities for HOR

Catalysts	j_k / mA cm^{-2}	j_m / A mg_{Pt}^{-1}	$j_{m,CO}$ / A mg_{Pt}^{-1}
30% PtRu/C	7,86	0,197	0,028
10% PtRu/WO_x-C	10,51	0,263	0,050
20% PtRu/WO_x-C	11,40	0,285	0,060
30% PtRu/WO_x-C	12,97	0,324	0,121

From the HOR curves, at different rotation speeds, the current densities are read and from them the Koutecki-Levich line is obtained (insets of Fig. 1. for 30% PtRu/C (b) and 30% PtRu/WO_x+C (c)). The kinetic current density at an overvoltage

of 20 mV (j_k) was calculated and the mass activity (j_m) for all catalysts (Table 2.) As can be seen from Table 2, all of the prepared catalysts have a higher activity for hydrogen oxidation compared to commercial catalysts (30% PtRu/C). Also, it can be seen that the most active is the 30% PtRu/WO_x+C catalyst with a kinetic activity of 12.97 mA cm^{-2} and a mass activity of 0.324 $\mathrm{A\ mg_{Pt}^{-1}}$.

Given that the prepared catalysts are synthesized for use in PEM fuel cells, it is very important that they have the highest possible tolerance to carbon monoxide poisoning. For this reason, all prepared catalysts were analyzed in a hydrogen atmosphere with a proportion of carbon monoxide (98% H_2 + 2% CO) simulating reformate which is used in real systems as fuel for PEM fuel cells. By recording and analyzing the electrooxidation curves of adsorbed CO and the HOR curves in the presence of carbon monoxide, the tolerance of the catalyst to CO poisoning can be assessed.

The first cycle of the cycle voltammogram (CO stripping) represents the CO_{ads} oxidation curve with a pronounced CO oxidation peak, and the second cycle (basic cycle voltammogram) is a curve that should match the cycle voltammogram recorded in a pure hydrogen atmosphere. From recorded cyclovoltammograms and HOR curves in the presence of CO, the following values were determined: active surfaces for COads oxidation (ESA_{CO} /cm^2) and mass activities for hydrogen oxidation ($j_{m,CO}$ /$\mathrm{A\ mg_{Pt}^{-1}}$) in a mixture (98% H_2 + 2% CO) of gases.

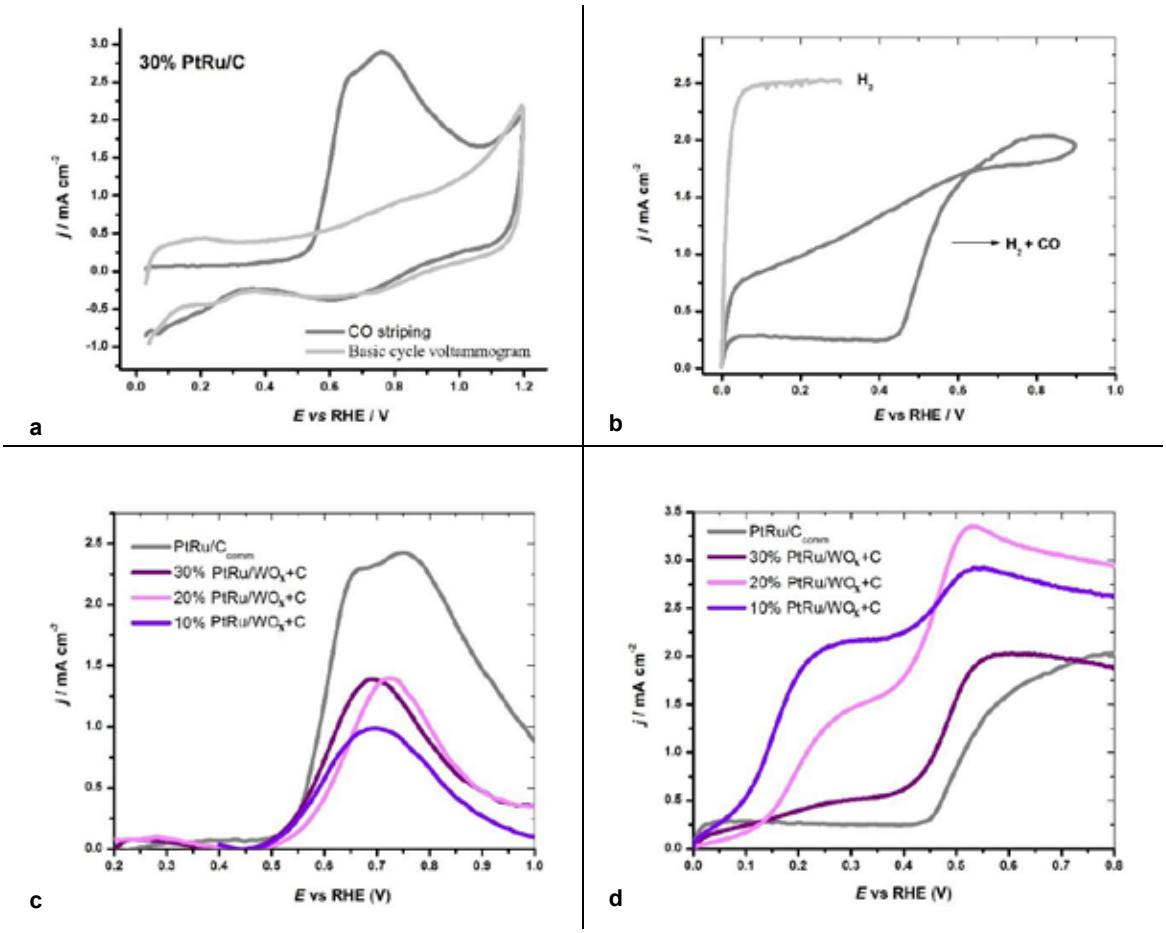

Fig. 2. Cyclovoltammogram of CO ads desorption for commercial 30% PtRu/C catalyst (a); HOR curves for commercial 30% PtRu/C catalyst recorded in pure H_2 and mixture (H_2 +2%CO) gases, at 2000 rpm (b); Cyclovoltammogram of CO_{ads} desorption - comparison of CO_{ads} oxidation peaks of commercial, 10%, 20% and 30% PtRu/WO_x+C catalyst (c) and HOR curves in H_2 + 2%CO mixture at 2000 rpm - Comparison of anode branches of commercial and PtRu/WO_x+C catalyst (d)

Figure 2.(a) shows the CO_{ads} desorption cycle voltammogram (CO stripping voltammogram) of the commercial 30% PtRu/C catalyst. The curve marked as CO stripping is the first cycle of the cyclovoltammogram and shows a pronounced, broad peak corresponding to the amount of adsorbed CO on the catalyst surface. The second cycle (basic cyclovoltammogram) was cleaned of adsorbed CO and corresponds to the cyclovoltamogram recorded in a nitrogen atmosphere. Based on the size of the CO peak area (Q in mC), ESA_{CO} was calculated according to equation $ESA=Q/q$: 0.605 cm^2. Figure 2 (b) shows HOR curves recorded in pure hydrogen and gas mixture with RDE rotation of 2000 rpm and polarization rate of 5 mV s^{-1}. From the HOR curve recorded in the gas mixture, the oxidation potential of adsorbed carbon monoxide, i.e. desorption of CO_{ads} from platinum nanoparticles (E_{onset}): 0.460 V vs. RHE. Figure 2 (b) shows that

the current recorded in the anodic direction, in a mixture of gases, is smaller than the anodic current recorded in pure hydrogen. The potential was scanned down to 0.9 V vs. RHE, during which the surface is not completely cleaned of CO_{ads}, but partially, and back to 0 V vs. RHE. In the reverse current branch (cathodic direction of current), higher current values are recorded compared to anode currents. From this part, the current at an overvoltage of 20 mV was read and the mass activity $j_{m,CO}$ was calculated: 0.028 $\mathrm{A\ mg_{Pt}^{-1}}$.
Figure 2 (c) shows the high-potential parts of the cyclovoltammogram, i.e. the CO_{ads} oxidation peaks of all prepared catalysts. By recording the cyclovoltammogram of CO_{ads} desorption for a series of PtRu/WO_x+C catalysts, differences are observed compared to the cyclovoltammogram recorded for a commercial PtRu/C catalyst, in the entire potential range. In the region of low potentials (E < 0.5 V vs. RHE), these deviations are attributed to the existence of OH species in the interfacial space that joins/separates the phases of the WO_x carrier and PtRu nanoparticles (PtRu|WO_x) [6,7].
In the region of high potentials (E > 0.5 V vs. RHE) all catalysts are rapidly cleaned of CO_{ads}. With the commercial PtRu/C catalyst, the appearance of a broad, double peak with the main peak at 0.760 V vs. RHE, while only one CO_{ads} oxidation peak occurs with the PtRu/WO_x+C series catalyst. Also, one can see a shift of these peaks by 40 to 70 mV towards more negative potentials compared to the CO_{ads} oxidation peak of the commercial catalyst. In this potential area, CO_{ads} are dominantly removed at the expense of OH species from the oxidized metal phases (Pt-OH_{ads} and Ru-OH_{ads}) in both the synthesized catalysts and the commercial catalyst. Since there is a difference in the amount of oxidized CO_{ads} species between PtRu/WO_x+C and the commercial catalyst, there is another effect that accelerates the removal of adsorbed CO from the catalyst surface. The improved CO_{ads} removal is attributed to the electronic carrier effect affecting the chemisorption properties of PtRu in PtRu/WO_x+C catalysts. This effect can also explain the less complex peaks of these catalysts compared to commercial ones. ESA_{CO} were calculated from the areas of CO_{ads} peaks of PtRu/WO_x+C catalysts. It was found that PtRu/WO_x+C catalysts have a significantly smaller ESA_{CO} surface area (from 0.204 cm^2, 270 cm^2 and 0.290 cm^2) compared to the commercial catalyst (0.604 cm^2). Mass activity $j_{m,CO}$ ($\mathrm{A\ mg_{Pt}^{-1}}$) in a mixture (98% H_2 + 2% CO) of gases of all analyzed catalysts was also determined and the obtained values are shown in Table 2.

4. CONCLUSIONS

Pt and Ru-based catalysts were prepared on a synthesized WO_x support. The performance of the obtained catalysts was investigated by cyclic voltammetry and voltammetry on a rotating disk electrode. Special attention was paid to the examination of carbon monoxide poisoning, in order to evaluate the contribution of the prepared catalysts to CO tolerance. The obtained results show significantly lower values of mass activities for HOR in the mixture (98% H_2 + 2% CO) of gases compared to the mass activities obtained for HOR in pure hydrogen. The commercial 30% PtRu/C catalyst has the lowest mass activity, while the obtained catalysts based on PtRu have significantly higher mass activities. Higher activities are explained by the formation of the interphase space PtRu|carrier, but also by the formation of Ru-CO_{ads} species, which frees Pt centers for HOR reactions. Most of the synthesized catalysts show a shift of the CO_{ads} desorption peak towards more negative potentials. This confirms that they are more tolerant to CO poisoning compared to commercial catalysts. Based on the presented conclusions, it can be said that the 30% PtRu/WO_x catalyst could be a good candidate for commercial application.

ABSTRACT

This study focuses on the hydrogen absorption of a metal hydride reactor with different cooling methods. The metal hydride bed was selected as magnesium hydride (MgH_2). The numerical study was based on four different cases by using FEM based solver. In case 1, the metal hydride reactor had a simple structured cooling channel with water as the coolant. In case 2, the coolant used in the system was pure water, but the cooling channel had a baffle with a structure of combined U-tubes. Case 3 had one difference when it was compared to Case 2. The coolant used in the metal hydride reactor was a ternary nanofluid (tnf) of Al_2O_3 nanoparticles, MWCNT cylindrical nanoparticles and platelet graphene nanoparticles in water. Case 4 was based on Case 3. Effects of different mass rates of the ternary nanofluid on the hydrogen storage were examined. For each case, the absorbed hydrogen (wt.%), average bed temperature results were obtained and comparative results were provided. According to the results, in Case 2 and Case 3, the hydrogen absorption increased by 15% and %18, respectively. The average bed temperature decreased by 8% and 10%, respectively. In Case 4 the hydrogen absorption increased by 15% when the flow rate was taken as two times of the original one and the average bed temperature decreased by 8%.

Keywords: Hydrogen storage, Ternary Nanofluid, CFD, Metal Hydride

1.INTRODUCTION

Hydrogen storage in metal hydrides has gained a significant place in hydrogen storage methods, since metal hydrides show a good performance during the sorption process due to their storage capacities. Also, they are more reliable unlike many other hydrogen storage techniques. As it's known, the vital parameters which affect the sorption process performance are hydrogen supply pressure, the coolant temperature and the porosity of the metal hydride used in the system. Despite this fact, the need for a better hydrogen sorption must be considered. One of the enhancement methods for the hydrogen storage is improving the thermophysical properties of the coolant. Nanofluids can't be ignored when this issue is considered.

In a basic way, a nanofluid is a new type of fluid based on using extremely small particles (smaller than micro-structures) and adding them into a kind of base fluid; in other words, it involves creating a suspension using nano-sized particles and a specific base fluid. The term used for this special suspension was first used by Choi et al. [1]. Depending on their nature, the researchers have focused on the improvement of nanofluids' macro-scale and mega-scale properties by controlling micro-scale features of them [2,3]. Nanofluids can be prepared by using more than one nano material. They are called as hybrid nanofluids. Ternary nanofluids are the ones which consist of three different nano material particles in the base fluid [4-8]. Researchers have performed studies which emphasize the contribution of nanofluids for hydrogen storage in metal hydrides in terms of thermal management [9-12]

This study focuses on the effect of a ternary nanofluid of Al_2O_3 nanoparticles, multiwall carbon nanotubes (MWCNT) cylindrical nanoparticles and platelet graphene nanoparticles with water considering the contribution of a baffle with a structure of combined U-tubes on the hydrogen absorption process. The baffle used in cases except for Case 1, is placed on the inner surface of the cooling channel in the metal hydride bed. Within the contribution of the ternary nanofluid used as the coolant in the system a better performance has been obtained.

2. MATHEMATICAL MODELLING

Each basic model for Case 1 (a) and Case 2 (b) are shown on Fig. 1. For Case 1, the cooling channel of the metal hydride reactor had a simple structure with no baffle. For other cases, the cooling channel had a baffle with a structure of combined U-tubes. Water was used as the coolant in Case 1 and Case 2. For Case 3 and Case 4, ternary nanofluid was used for a better sorption process. Case 4 was aimed for the effect of flow rate($\dot{Q}$) of the coolant (ternary nanofluid). Different flow rates as $0.5\dot{Q}$, $\dot{Q}$, $1.5\dot{Q}$ and $2\dot{Q}$ were taken. The ternary nanofluid had Al_2O_3 nanoparticles, MWCNT cylindrical nanoparticles and platelet graphene nanoparticles in water [13].

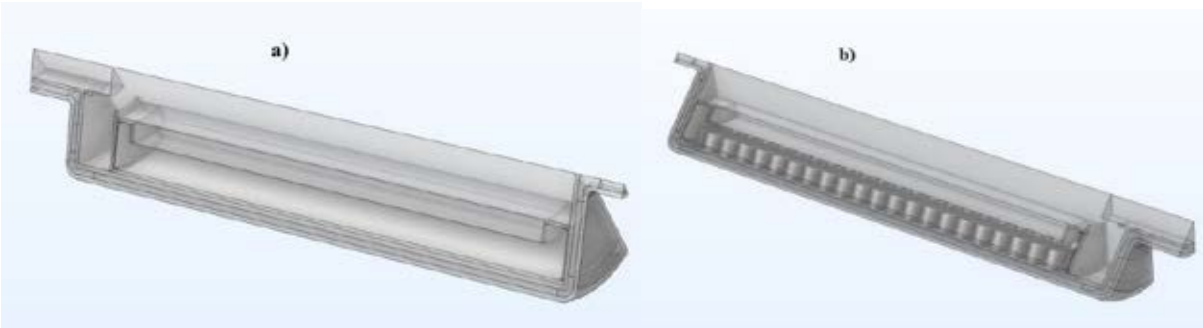

Fig. 1. Models (a) Case 1, b) Case 2

Finite element method (FEM) was used for the solution of the governing equations. Lagrange FEMs of different orders were used for the approximation of field variables in different domains of thermal management system within hydrogen storage. Number of elements and tetrahedral elements used are 987314 and 690904, respectively. Minimum element quality is 0.01008. As CFD program, COMSOL Multiphysics 6.2 is used for the simulation of the coupled system.

2.1 Governing Equations

Mass conservation for hydrogen is given as [14]:

$$\varepsilon \frac{\partial \rho_g}{\partial t} = -\acute{m} \tag{1}$$

The mass conservation of metal hydride bed is [14]:

$$(1-\varepsilon)\frac{\partial \rho_{mhb}}{\partial t} = \acute{m} \tag{2}$$

where $\acute{m}$ is the volumetric mass flow rate of the hydrogen during the sorption process. It's evaluated from the common kinetics equation [15],

$$\acute{m} = Ca\ exp\left[-{E_a}/{R\ T}\right]\ln\left({P_g}/{P_{eq}}\right) = [\rho_{st} - \rho_s] \tag{3}$$

where Ca and E_a are reaction constant and activation energy respectively. P_g is the hydrogen supply pressure, ρ_{st} is the density of saturated metal hydride, ρ_s is the density of metal hydride at a particular time during sorption.

The momentum conservation equation is given by [15, 16]:

$$\frac{\rho}{\varepsilon}\frac{\partial \vec{v}_s}{\partial t} + \left(\frac{\mu}{K} + \frac{S_0}{\varepsilon^2}\right)\vec{v}_s = -\nabla P + \nabla.\left[\frac{\mu}{\varepsilon}\left(\nabla\vec{v}_s + \nabla\vec{v}_s{}^T\right)\right] - \nabla.\left[\left(\frac{2\mu}{3} - \eta_d\right)\left(\frac{1}{\varepsilon}\right)(\nabla.\vec{v}_s)I\right] \tag{4}$$

Energy conservation equation is given by [15, 16]:

$$\left(\rho C_p\right)_{eff}\left(\frac{\partial T}{\partial t}\right) + \left(\rho C_p\right)_g(\vec{u}\,\nabla \mathrm{T}) = k_{eff}\nabla^2 T + Q \tag{5}$$

At the beginning of the sorption process, at t=0 s metal hydride bed, and the coolant in the channel were in ambient conditions. The density of metal hydride bed is uniform.

$$P = P_{\mathrm{i}} = 10\ atm \tag{6}$$

$$T = T_0 = 288.15\ K \tag{7}$$

$$\rho_{MH} = \rho_i = 1450\ {kg}/{m^3} \tag{8}$$

$$\dot{Q} = 0.4\ {m^3}/{h} \tag{9}$$

The outer wall of the reactor is considered adiabatic.

$$\left(-k\frac{\partial T}{\partial r}\right)_{r=r_w} = 0 \tag{10}$$

Equations of ternary nanofluid thermophysical properties.

The density of the composite ternary nanofluid material is [13]:

$$\rho_{tnf} = \varphi_1\rho_1 + \varphi_2\rho_2 + \varphi_3\rho_3 + (1 - \varphi_1 - \varphi_2 - \varphi_3)\rho_{bf} \quad (11)$$

where ρ_1, ρ_2, ρ_3 are the density of several nanomaterials and φ_1, φ_2, φ_3 represent volume ratio of nano particles for Al_2O_3, MWCNT and graphene nano particles, respectively. $\varphi = \varphi_1 + \varphi_2 + \varphi_3$ denotes the total number of volume ratios of the nanofluids of ternary composition. Here, ρ_{bf} is the density of the basic fluid (water).

The dynamic viscosity of the ternary composite nanofluid is [13]:

$$\mu_{tnf} = \frac{\varphi_1\mu_{nf1}+\varphi_2\mu_{nf2}+\varphi_3\varphi_{nf3}}{\varphi} \quad (12)$$

here $\mu_{nf1} = \mu_{bf}$ (1 + $2.5\,\varphi + \varphi^2$) (Al_2O_3, spherical form), $\mu_{nf2} = \mu_{bf}$ (1 + $13.5\,\varphi + 904.4\,\varphi^2$) (MWCNT, cylindrical form), and φ_{nf3}= = μ_{bf} ($1 + 37.1\,\varphi + 612.6\,\varphi^2$) (graphene, platelet form). = $\mu_{bf}$is the dynamic viscosity of the basic fluid.

The specific heat capacity of ternary composite nanofluid is [13]:

$$(\rho C_p)_{tnf} = \varphi_1(\rho C_p)_1 + \varphi_2(\rho C_p)_2 + \varphi_3(\rho C_p)_3 + (1 - \varphi_1 - \varphi_2 - \varphi_3)(\rho C_p)_{bf} \quad (13)$$

where$(\rho C_p)_1$, $(\rho C_p)_2$, $(\rho C_p)_3$ represent the specific thermal capacity and $(C_p)_1$, $(C_p)_2$, $(C_p)_3$are particular temperatures of (Al2O3) nano particles (spherical), (MWCNT) nanoparticles (cylindrical), and graphene nanoparticles (platelet) and $(\rho C_p)_{bf}$is the specific ther mal capacity of the basic fluid.

3. RESULTS AND DISCUSSION

Fig. 2 presents the hydrogen absorption fraction (wt. %) for Case 1, Case 2 and Case 3. Dynamics of absorbed hydrogen storage were found to be influenced by different thermal management methods. Fig. 3. demonstrates the average bed temperature values for Case 1, Case 2 and Case 3. Based on the results, in Case 2 and Case 3, the hydrogen sorption increased by 15% and 18%, respectively. When nanofluids are used, enhanced thermal transport features due to favorable properties of nanoparticles results in better cooling. The average bed temperature decreased by 8% and 10%, respectively. Fig. 4. shows the hydrogen absorption fraction (wt. %) for Case 4 based on different flow rates. Fig. 5 demonstrates the average bed temperature values for Case 4 based on different flow rates. Higher flow rates and nanofluid results in better cooling while lower bed temperatures were achieved. In Case 4 the hydrogen absorption increased by 15% most when the flow rate was taken as two times of the original one and the average bed temperature decreased by 8%.

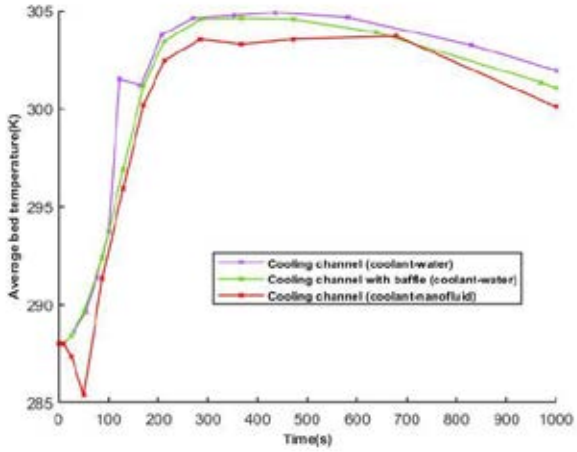

Fig. 3. Average bed temperature values for Case 1, Case 2 and Case 3

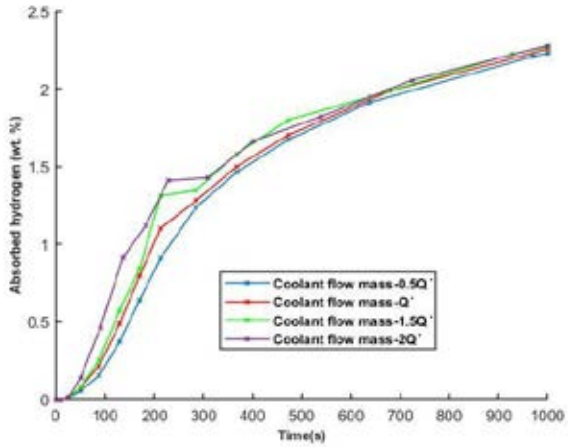

Fig. 4. The hydrogen absorption fraction (wt. %) for different flow rates

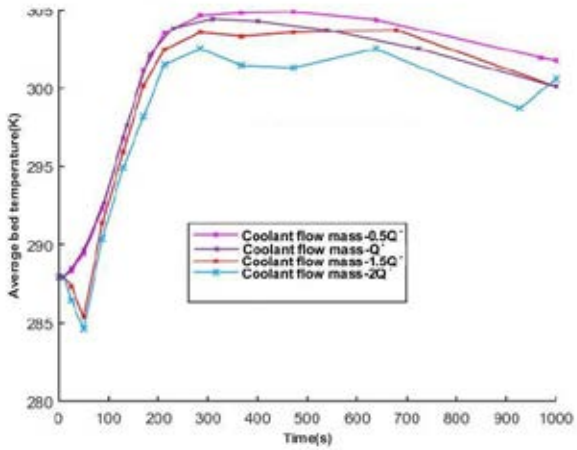

Fig. 5. Average temperature values for different flow rates

4. CONCLUSIONS

Current study proposes different thermal management methods by using ternary nanofluid for hydrogen storage in a metal hydride reactor. The best result was obtained in Case 3 (in which the cooling channel had a baffle with a structure of several U-tubes and the coolant was ternary nanofluid.). The absorption process was improved by 18% compared to the model in Case 1(which had a plain cooling channel with no baffle(s) on, with the usage of water as the coolant. The average bed temperature in the metal hydride of the hydrogen reactor was improved by 10%.The ternary nanofluid used in Case 3 had the most impact on the enhancement of the hydrogen storage system. Also, it was seen that increasing the flow rate of the ternary nanofluid in Case 4 had an extra positive effect on the metal hydride reactor, causing an improvement in sorption and average bed temperature by %15 and %8, respectively compared to the one with the reference flow rate ($\dot{Q}$).

ABSTRACT
Atomic layer deposition (ALD) was employed to fabricate Zn-doped TiO_2 nanotubes via nanolaminated stacks of binary layers of TiO_2 and ZnO. The bilayers were alternately deposited on the polycarbonate (PC) membrane template by ALD with various cyclic sequences. With a doping ratio of 0.01, the hydrogen production rate from water splitting was 6 times higher than that of commercial P25 TiO_2. Nanolamination of GaN and ZnO layers by ALD was also employed to fabricate GaN-ZnO homogeneous solid solution thin films. By varying the ALD cycle ratios of GaN:ZnO from 5:10 to 10:5, the $(GaN)_{1-x}(ZnO)_x$ films with $0.39 \leqq x \leqq 0.79$ were obtained. The density function theory (DFT) calculations are performed to understand the difference of density of states (DOS) and evaluate the bandgaps for various atomic configurations in the solid solution films. Visible-light-driven photocatalytic hydrogen evolution was conducted to confirm the applicability of the solid solution films.

Keywords: ZnO, TiO_2, GaN, Atomic layer deposition, Hydrogen evolution.

1. INTRODUCTION

Atomic layer deposition offers advantages such as atomically smooth surface, precise control of film thickness in atomic scale, and good conformality [1]. Therefore, it is widely employed as a thin film deposition technology. Moreover, ALD of two different materials layer by layer may create nanolaminates that enable formation of solid solution of the two materials, offering new physical properties. Herein, we report two examples of ALD nanolamination, i.e., ZnO/TiO_2 and GaN/ZnO, to form solid solutions which enable enhanced visible-light driven water splitting to generate hydrogen.
TiO_2 and ZnO have different crystal structures and lattice parameters. Because of their high energy gap (3.2 eV for both), they can only utilize UV light for photocatalytic reaction. Based on the phase diagram [2], there is no mutual solubility in this binary system. However, ALD nanolamination is able to dope a substantial amount of ZnO into TiO_2. On the contrary, GaN and ZnO have the same crystal structure and similar lattice parameters, but GaN has an even larger bandgap, 3.4 eV. By varying the ALD cycle ratios of GaN:ZnO, from 5:10 to 10:5, complete solid solutions of $(GaN)_{1-x}(ZnO)_x$ can be formed.

2. EXPERIMENTAL

Homogeneous Zn-doped TiO_2 nanotubes were fabricated by ALD via nanolaminated stacks of alternate layers TiO_2 and ZnO on the polycarbonate (PC) membrane template with various cyclic sequences [3,4]. The precursors for Zn and Ti were diethyl zinc ($Zn(C_2H_5)_2$) and titanium tetrachloride ($tiCl_4$), respectively. A total of 400 ALD cycles were conducted. The Zn-doped TiO_2 nanotubes in a length of 20 μm and a diameter of 220 nm were obtained after removal of the PC membrane by annealing at 450 °C. The schematic fabrication process is shown in Fig. 1 [3].
Nanolamination of GaN and ZnO layers on a Si substrate with various ratios was conducted using TMG ($Ga(CH_3)_3$) and DEZ ($Zn(C_2H_5)_2$) as the Ga and Zn precursors, respectively [5]. The substrate temperature was set at 200 °C. For the growth of GaN, an NH_3 plasma was employed to form the nitride in a direct plasma reactor by a RF generator. The solid solution films were obtained by alternating the deposition of GaN and ZnO layers with different repeated cycles. The total number of ALD cycles was fixed at 300 cycles.
The photocatalytic hydrogen generation efficiency was measured by a gas chromatograph. A 20% methanol solution was used as the sacrificial reagent, and a 150 W high-pressure Xe lamp or a 300-W Xe lamp equipped with a filter (λ≥420 nm) was employed as the visible light source [5,6].

3. RESULTS AND DISCUSSION

3.1 Zn-doped TiO_2 (ZnO/TiO_2) nanotubes

The SEM image of Zn-doped TiO_2 nanotubes is also shown in Fig. 1. The doping amount of Zn in TiO_2 could be tuned by varying the fraction of cycle number of ZnO. From the depth profiles measured by second ion mass spectrometry, Zn was uniformly distributed across the thickness, which was also supported by the analyses of X-ray diffraction, X-ray photoelectron spectroscopy (XPS), and Raman spectroscopy. Although there is no mutual solubility of these two oxides from the phase diagram, a uniform bulk solubility of ~8 at% (determined by inductively coupled plasma-mass spectroscopy (ICP-MS)) was achieved with the cycle ratio of ZnO:TiO_2 at 0.04, and the surface concentration of Zn (determined by XPS) was even higher, ~16 at%, as shown in Fig. 2. With a total of 400 cycles of ALD, the tube thickness

was measured to be ~28 nm.
The effects of doping composition on the photocatalytic and photoelectrochemical (PEC) activities were investigated. There was an optimal range of Zn doping to get enhanced photocatalytic activity and higher PEC efficiency. As shown in Fig.3 (a), with a doping ratio of 0.01, the hydrogen production rate from water splitting is 6 times higher than that of commercial P25 TiO_2 [6]..

The inset shows hydrogen evolution under visible light irradiation. (b) Comparison of visible-light-driven hydrogen evolution efficiencies of GaN, ZnO, and all solid solution films under 300-W Xe lamp irradiation with a cut-off filter of 420 nm.

3.2 GaN/ZnO solid solution films

Nanolamination of GaN and ZnO layers was conducted by varying the ALD cycle ratios of GaN:ZnO from 5:10 to 10:5. The $(GaN)_{1-x}(ZnO)_x$ solid solution films with $0.39 \leqq x \leqq 0.79$ were obtained. Figure 4 shows a cross-sectional high resolution transmission electron microscopic (HRTEM) image of the G5Z5 thin film. It clearly reveals that the film with a homogeneous polycrystalline microstructure is deposited on the Si substrate. The lattice spacing of 0.279 nm observed in Figure 4(b) is attributed to the formation of a solid solution of GaN and ZnO.

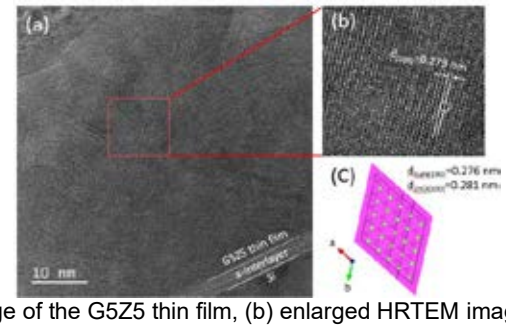

Fig. 4. (a) Cross-sectional HRTEM image of the G5Z5 thin film, (b) enlarged HRTEM image, and (c) schematic hexagonal wurtzite atomic arrangement on the (001) facet.

The DFT calculations were performed to understand the difference of DOS and evaluate the bandgaps for various atomic configurations. Figure 5(a) shows the summary of Fermi levels and positions of conduction band and valence band of GaN, ZnO, and $(GaN)_{1-x}(ZnO)_x$ solid solution films with various values of *x*. It reveals that all of the valence band positions are located at more positive potentials than that of bare ZnO. On the other hand, all of the conduction band positions of $(GaN)_{1-x}(ZnO)_x$ are very close to that of bare ZnO. Consequently, the bandgap reduction of $(GaN)_{1-x}(ZnO)_x$ is mainly attributed to the positive shift of the VBM caused by GaN. In addition, it is worthy of observing the relative band positions in the DFT calculations, as shown in Figure 5(b). The calculated values of DOS show that the positions of CBM and VBM tend to decrease systematically with increasing *x*.

The photocatalytic hydrogen evolution efficiencies of GaN, ZnO, and GaN-ZnO solid solution films under visible light irradiation are shown in Fig. 3(b). The bare GaN and ZnO exhibit nearly zero hydrogen evolution even after 4 h irradiation due to their large bandgaps. Further, G10Z5 and G10Z10 exhibit very low efficiencies, which may be attributed to their poor crystallinity. By contrast, the other GaN-ZnO solid solution films reveal significantly improved photocatalytic hydrogen evolution efficiencies. The highest value of 99.1 μmol/g for 4 h was achieved by the G5Z5 sample (*x*=0.66), and the second highest efficiency was obtained by G7Z5 (*x*=0.52) [5].

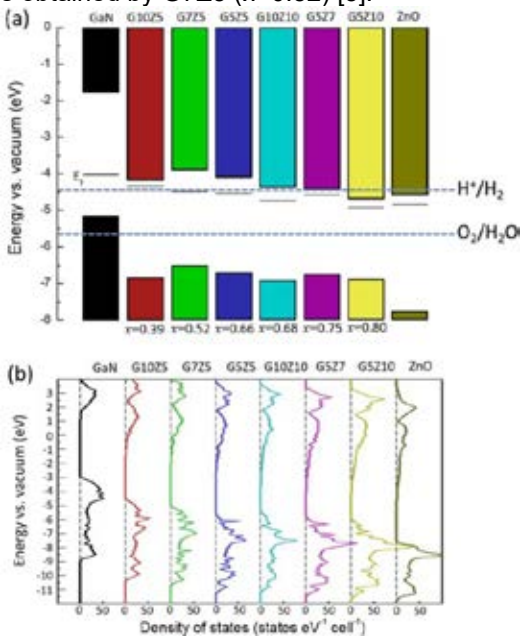

Fig. 5. Summary of (a) energies of Fermi level, conduction band, and valence band of GaN, ZnO, and $(GaN)_{1-x}(ZnO)_x$ solid solution films with various values of *x* and (b) corresponding calculated values of DOS from DFT calculations. The reduction potential of H^+/H_2 and oxidation potential of O_2/H_2O are also plotted in (a).

4. CONCLUSIONS

(1) Uniform doping of Zn ions into TiO_2 nanotubes with a bulk solubility of ~8 at% (~16 at% on the surface) was achieved by nanolamination of ALD. Compared with P25 powder, TiO_2 nanotubes with X_Z=0.01 show 6 times higher hydrogen production rate under irradiation with a 150 W Xe lamp.

(2) Nanolamination of GaN and ZnO layers with cycle ratios of GaN:ZnO from 5:10 to 10:5, the $(GaN)_{1-x}(ZnO)_x$ films with $0.39 \leqq x \leqq 0.79$ were obtained. The DFT calculations were performed. Reduction of the bandgaps to 2.19-2.67 eV was obtained from the calculations. A significant evolution of 99.1 μmol/g for 4 h was achieved by G5Z5.

ABSTRACT

This study introduces a novel electrocatalyst, iron and copper co-doped carbon (FeCu-C), derived from the carbonization of specific ionic liquids. The material's catalytic efficiency was evaluated for both the oxygen evolution reaction (OER) and the hydrogen evolution reaction (HER) in an alkaline environment. The FeCu-C demonstrated superior performance in OER with a low onset potential of -1.485 V and a peak current density of 160 mA cm^{-2} at 2 V versus RHE. In contrast, HER displayed lesser efficacy with a maximum current density of approximately 4 mA cm^{-2} at -0.4 V versus RHE. A lower charge-transfer resistance during OER, determined via electrochemical impedance spectroscopy, confirms its higher catalytic activity in comparison to HER conditions.

Keywords: HER, OER, Ionic liquid, electrocatalyst, *d* metals

1. INTRODUCTION

The growing global energy demand and the shift toward sustainable energy systems have intensified the search for efficient methods of hydrogen production. Water electrolysis has emerged as a promising solution, offering a clean route for generating hydrogen and oxygen. Central to this process are the hydrogen evolution reaction (HER) and oxygen evolution reaction (OER), which require efficient electrocatalysts to overcome high energy barriers and achieve practical performance. Platinum and iridium/ruthenium oxides are benchmark catalysts for HER and OER, respectively, but their high cost and scarcity pose significant challenges to scalability and widespread adoption [1,2].

In recent years, earth-abundant transition metals, such as iron and copper, have gained attention for their potential as cost-effective and efficient alternatives. Research has demonstrated that combining multiple transition metals can synergistically enhance catalytic activity and durability [3,4]. The incorporation of ionic liquids as precursors for catalyst synthesis has opened new possibilities, leveraging their unique chemical and physical properties to produce high-performance carbon-based materials [5].

This study focuses on developing a dual-doped iron-copper carbon material (FeCu-C) using a simple and scalable method of ionic liquid carbonization. Unlike previous studies that primarily explore single-metal doping or more complex synthesis routes, this work investigates the synergistic effects of iron and copper in a carbon matrix for improving OER and HER performance. The specific objectives are to evaluate the electrocatalytic activity of FeCu-C in alkaline media, analyze the kinetic parameters, and identify factors influencing its performance under anodic and cathodic conditions. This approach provides valuable insights into designing cost-effective electrocatalysts for sustainable hydrogen production.

2. MATERIALS AND METHODS

In this study, a FeCu-dual doped carbon material was synthesized through the direct carbonization of two ionic liquids, $[Bmim]_2[CuCl_4]$ and $[Bmim]_2[FeCl_4]$, at 800 °C in a nitrogen atmosphere for one hour, followed by cooling to room temperature. For electrochemical evaluation, a working electrode was fabricated by evenly spreading a catalytic ink—composed of FeCu-C electrocatalyst powder mixed with polyvinylidene fluoride binder in N-methyl-2-pyrrolidone—onto a glassy carbon electrode. Electrochemical properties were assessed using an Ivium V01107 potentiostat/galvanostat in a 40 cm^3 glass cell equipped with a three-electrode system, where a saturated calomel electrode and a graphite rod served as the reference and counter electrodes, respectively. Measurements relative to the reversible hydrogen electrode (RHE) were conducted in 8 M KOH at 25 °C, using linear cyclic voltammetry with scan rates of 2 mV s^{-1} for the hydrogen evolution reaction (HER) and 5 mV s^{-1} for the oxygen evolution reaction (OER), and electrochemical impedance spectroscopy across the frequency range of 100 kHz to 0.1 Hz.

3. RESULTS AND DISCUSSION

The electrocatalytic properties of FeCu-C were initially assessed for the oxygen evolution reaction (OER) in an alkaline medium, given the critical role of OER in determining the rate and efficiency of electrolytic water splitting. The activity was measured in 8 M KOH, mirroring the electrolyte concentration predominant in industrial alkaline electrolyzers. Linear sweep voltammetry (LSV) was performed from the open circuit potential (OCP) to 2 V at a scan rate of 5 mV s^{-1}, as depicted in Figure 1. The onset potential for OER, defined as the potential at which a current density of 1 mA cm^{-2} is achieved, was recorded at a notably low 1.485 V. The material exhibited robust activity, reaching current densities around 160 mA cm^{-2} at 2 V during OER polarization. Subsequent Tafel analysis utilized the polarization curve to construct a Tafel plot, analyzed via the relationship $\eta = a + b \times \log j$, where '*a*' represents the intercept correlating to the exchange current density j_0 and '*b*' the Tafel slope. This slope was calculated to be 134 mV dec^{-1}, indicating the kinetic favorability of the reaction under study.

Furthermore, the activity of FeCu-C for the hydrogen evolution reaction (HER) was evaluated under similar conditions. As shown in Fig. 1, voltammograms recorded from OCP to -0.4 V at a scan rate of 2 mV s^{-1} revealed HER activity with a current density reaching - 4.2 mA cm^{-2} at -0.4 V. The onset potential for HER was observed at -0.335 V, and the Tafel slope was measured at -151 mV dec^{-1}, suggesting that the HER process on FeCu-C likely follows the Volmer-Heyrovsky mechanism. This mechanism encompasses electrochemical hydrogen adsorption on the electrode surface (MH_{ads}) as the initial step (Volmer reaction, (1)), followed by either electrochemical desorption (Heyrovsky reaction, (2)) or catalytic recombination (Tafel reaction, (3)), with the equations:

$$M + H_2O + e^- \leftrightarrow MH_{ads} + OH^- \quad \text{(Volmer reaction)} \quad (1)$$
$$MH_{ads} + H_2O + e^- \leftrightarrow H_2 + M + OH^- \quad \text{(Heyrovsky reaction)} \quad (2)$$
$$MH_{ads} + MH_{ads} \leftrightarrow H_2 + 2M \quad \text{(Tafel reaction)} \quad (3)$$

These reactions collectively facilitate hydrogen evolution through two potential pathways: Volmer-Heyrovsky or Volmer-Tafel, with Tafel slopes typically observed at 120, 40, or 30 mV dec^-1 at 25 °C, depending on the rate-determining step.

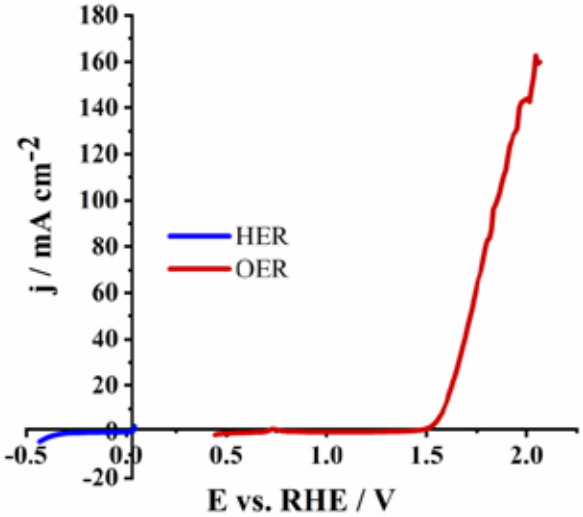

Fig. 1. Linear Sweep Voltammetry Profiles of FeCu-C in 8 M KOH for Hydrogen and Oxygen Evolution Reactions at 25 °C.

Table 1 presents the kinetic parameters obtained for the HER and OER activities of FeCu-C in 8 M KOH at 25 °C. The current density (j_{400}) measured at an overpotential of 400 mV was significantly higher for OER compared to HER, highlighting the superior activity of FeCu-C under anodic polarization. Similarly, the exchange current density (j_0), an indicator of the material's intrinsic catalytic activity and efficiency in charge transfer, was greater for OER than HER, further demonstrating the material's enhanced performance in oxygen evolution.

Electrochemical impedance spectroscopy (EIS) measurements provided additional insights into the charge-transfer resistance (R_{ct}) of FeCu-C under both HER and OER conditions. Nyquist plots (Fig. 2) revealed that R_{ct} during OER at 0.6 V was approximately 35 Ω, while under HER conditions at -1.4 V, it was higher at around 50 Ω. The lower R_{ct} observed during OER correlates with the higher current densities and greater catalytic activity for oxygen evolution, emphasizing the material's suitability for anodic processes in water splitting applications.

Table 1. Summary of HER and OER Kinetic Parameters for FeCu-C in 8 M KOH at 25 °C.

Reaction	E_{onset} / V	j_{400} / mAcm^{-2}	b /mV dec^{-1}	j_0 /10^{-2} mA cm^{-2}
HER	-0.335	2.73	-151	1.42
OER	1.485	24.78	134	2.50

**E_{onset}: Onset potential; j_{400}: Current density at an overpotential of 400 mV; b: Tafel slope; j_0: Exchange current density.*

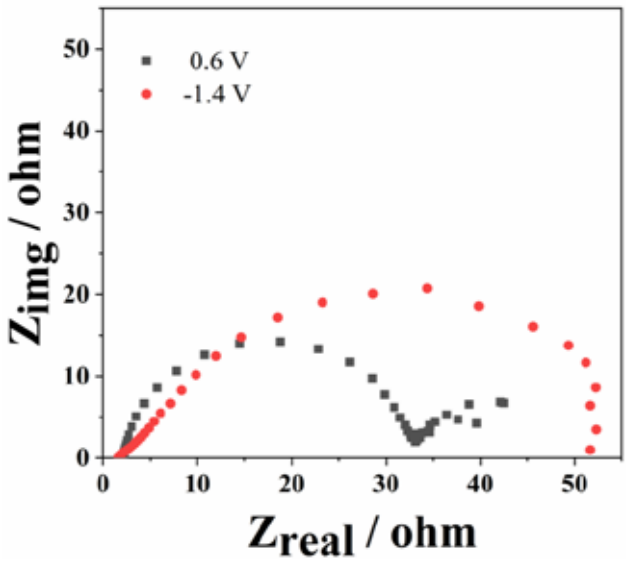

Fig. 2 Nyquist plots at potential of -1.4 V and at potential of 0.6 V at temperature of 25 °C

4. CONCLUSIONS

This study highlights the successful synthesis and characterization of FeCu-dual doped carbon (FeCu-C) as an electrocatalyst for water splitting in alkaline media. The synthesized FeCu-C material, through the innovative approach of ionic liquid carbonization, displays excellent catalytic properties for OER and moderate performance for HER. This differential activity could be partially attributed to the variances in charge-transfer resistance observed under different polarization conditions. These findings position FeCu-C as a promising non-precious metal catalyst for water electrolysis, particularly for applications emphasizing oxygen evolution. Future work may focus on optimizing the material's structure and composition to enhance HER performance, as well as long-term stability testing to assess its practical viability in industrial electrolyzers.

ABSTRACT

The pressing need for sustainable and cost-effective energy solutions drives the exploration of innovative materials for clean energy technologies. This study introduces a novel approach to synthesizing electrocatalysts from waste materials, specifically recycled central processing units (CPUs) and carbonized lemon peel. By repurposing these abundant waste sources, we developed a dual-function catalyst that facilitates both the hydrogen evolution reaction (HER) and oxygen evolution reaction (OER) in water splitting. Our catalyst showcases promising electrochemical properties, including low overpotential and decent catalytic activity, particularly for HER. Additionally, the synthesized material exhibits potential for use in supercapacitors, demonstrating significant charge storage capabilities. This research not only presents a viable strategy for reducing reliance on rare and expensive metals but also contributes to waste reduction and resource recovery
Keywords: e-waste, activated carbon, electrocatalyst, HER, alkaline electrolysis.

1. INTRODUCTION

Clean energy technologies, such as water splitting via electrolysis, are more important than ever because our energy consumption relies on sources that cause serious environmental pollution.HER and OER are essential reactions in the electrocatalysis of water splitting and play a leading role in clean energy technologies [1]. However, the widely adoption of these technologies is hindered by the high cost and scarcity of effective catalysts, typically made from precious metals such as platinum and iridium. Addressing this challenge, our research explores the potential of synthesizing electrocatalysts from recycled materials, thus not only mitigating the issue of waste but also reducing reliance on expensive, rare metals. Discarded electronic components such as computer processors, are an abundant source of valuable metals that can be repurposed into catalytic materials. Simultaneously, organic waste, like lemon peel, offers a carbon-rich matrix that can be utilized for catalyst support. By integrating these two forms of waste, we aim to create a novel, cost-effective catalyst for HER and OER [2]. Our goal in this study is to connect two kinds of waste and use it instead of expensive metals and coatings. We investigated the efficacy of carbon-based materials doped with metals extracted from computer processing units (CPUs). Dried lemon peels were immersed in aqua regia, enriched with dissolved metals from CPUs, facilitating the formation of a metal-doped carbon matrix upon subsequent carbonization. The resulting composite is then applied to electrode surfaces, forming a working electrode that undergoes extensive electrochemical testing to evaluate its catalytic properties and potential applications in clean energy technologies.

2. MATERIALS AND METHODS

2.1. Material preparation

Lemon peel was collected and dried in sunlight for 24 hours. After that, it was shredded into small pieces and used in the next step. For the recycling of the e-waste, specifically the CPUs, aqua regia was used to dissolve it [3].
Finally, the dried lemon peel was immersed into this solution for 24 hours, then washed with deionized water and dried at room temperature. The carbonization was conducted at 600°C in an inert nitrogen atmosphere. The heating rate for the carbonization was 5°C per minute, and the furnace was held at the final temperature for 1 hour. After carbonization, the sample was powdered and used for following phases.
The ink was prepared in this manner: 1 mg/mL of catalys, 20 µL of 5 wt% Nafion, deionized water and sonication for 30 minutes. The following step was ink drop-casting onto a pre-polished glassy carbon electrode surface, which was dried for 1 hour.

2.2. Electrochemical testing

The electrochemical properties of the catalyst we made were evaluated using cyclic voltammetry (CV) and linear sweep voltammetry (LSV) in 6 M KOH at room temperature using the three-electrode method. Electrochemical evaluation of the prepared electrodes was performed in a three electrode glass cell. The working electrode was a rotating disk electrode

(RDE) with the surface area of 0.196 cm². The counter electrode was a carbon rod, while the reference electrode was a saturated calomel electrode (SCE). The presented potential values were converted to the Reversible Hydrogen Electrode (RHE) scale.
Electrochemical measurements were carried out using a Gamry Interface 1000 Potentiostat/Galvanostat/ZRA. The electrolyte used in this study was analytical-grade 6 M KOH from Merck. Prior to the measurements, the electrolyte was purged with N_2 for 20 minutes, and the RDE was continually rotated at a rate of 1600 rpm.

3. RESULTS AND DISCUSSION

Prior to electrochemical characterization, the synthesized material was analyzed using X-ray diffraction (XRD) to investigate its crystal structure and phase composition. This versatile, non-destructive analytical technique provided insights into the material's structural properties.
The newly synthesized material, produced by combining recycled CPU waste with carbonized lemon peel, was then electrochemically evaluated for various potential applications, including hydrogen and oxygen evolution reactions as well as supercapacitor functionality.

3.1. Material characterization

The X-ray diffraction pattern of sample is shown in Figure A. The pattern is characterized by one broad diffraction peak and several crystalline peaks. The broad peak can be assigned to (002) plane of graphite-2H (PDF# 41-1487), while the crystalline peaks are assigned to Cu (PDF# 2-1225) and Cu_2O (PDF# 5-667) crystal phases. When we refer to Cu here, since the diffractogram reflects the structure, it is possible that, in addition to Cu atoms, there are other atoms present in the crystal lattice, like nickel and chromium. This means that the possibility of an alloy with nickel or chromium cannot be excluded; however, structurally, they are equivalent and cannot be distinguished.

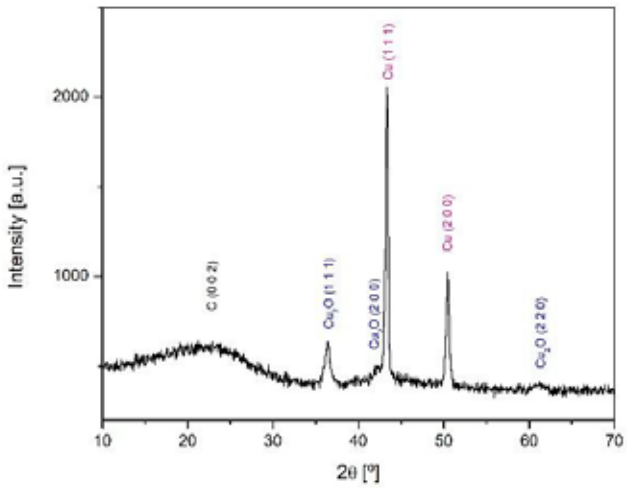

Fig. 1. XRD spectra of synthesized material with corresponding peak deconvolution

3.2. Electrochemical characterization

The initial phase of the electrochemical investigation focused on evaluating the material's activity for hydrogen and oxygen production. The prepared material was tested in a three-electrode cell for separate electrolytic reactions.
Before recording the polarization curves, the material underwent comprehensive evaluation by potential cycling over a broad range. This process provided valuable insights into the various structures and oxidation/reduction processes occurring on the electrode surface (Fig. 2).
The polarization curve exhibits a distinct structure, characterized by three oxidation peaks. The seddle-like peaks at approximately 0.5 V and 0.8 V vs. RHE correspond to the oxidation of $Cu(OH)_2^{2-}$ & $Cu(OH)_2$ and $Cu(OH)_2$ & CuO consequatlivy [4]. The third peak, in terms of both its intensity and position, correlate to the oxidation peak of nickel hydroxide ($Ni(OH)_2$) converting into nickel oxyhydroxide (NiOOH) [5].

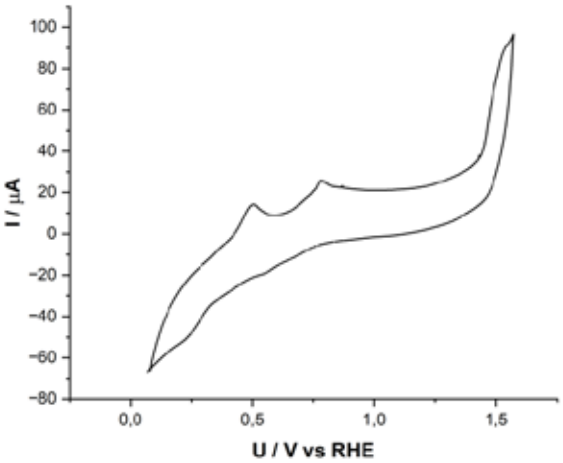

Fig. 2. Cyclic voltammogram of prepared material

The next step in the electrochemical investigation involved evaluating the material's catalytic activity for HER and OER. Polarization curves were recorded and are presented in Fig. 3.

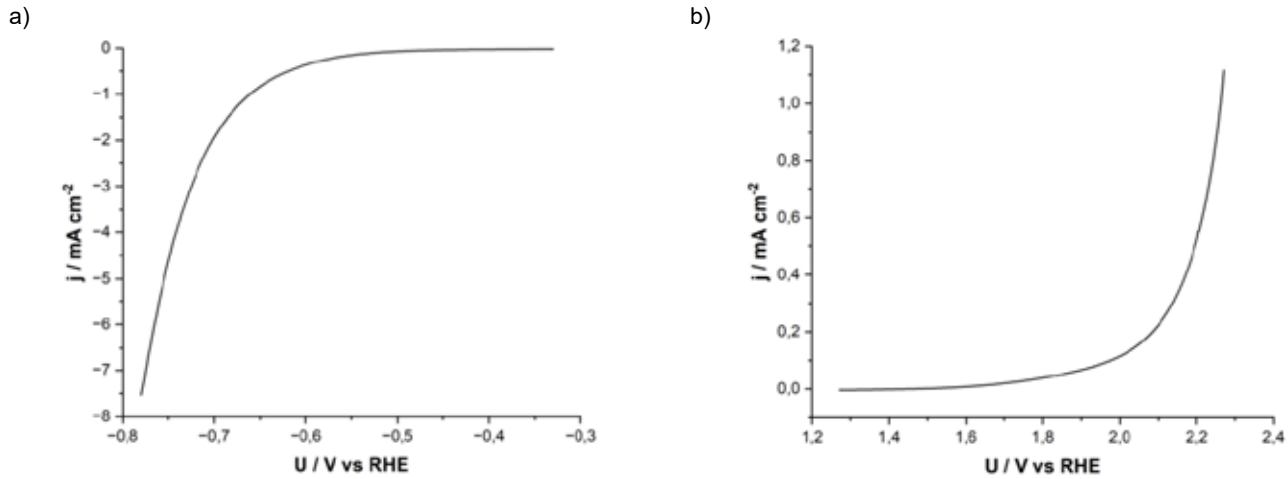

Fig. 3. Polaryzation curves for HER (a) and OER (b)

Additionally, Tafel analysis was conducted to gain insights into the reaction mechanisms and kinetics. Reaction mechanisms can be categorized into three types based on the Tafel slope: activation-controlled, diffusion-controlled, and mixed-controlled.

The synthesized material demonstrated higher activity for hydrogen evolution, exhibiting a lower overpotential and Tafel slope value (Table 1). For oxygen evolution, the overall activity was relatively low, characterized by a high overpotential and Tafel slope. This suggests that the kinetics of the oxygen evolution reaction (OER) are diffusion-controlled. In contrast, the hydrogen evolution reaction (HER), with a Tafel slope value of 137 mV dec $^{-1}$, follows mixed-controlled kinetics [6].

Table 1. Summary of IHTEC2025 formatting details

Reaction	Overpotential at 1 mA cm^{-2} [V]	Tafel slope values [mV dec^{-1}]
HER	-0.661	137
OER	2.264	405

The next phase of the electrochemical characterization focused on evaluating the synthesized material's capacitance and its potential application in energy storage devices such as supercapacitors. Supercapacitors, known for their high power density and excellent charge-discharge cycling stability, require materials with superior charge storage capabilities. To assess the material's charge storage behavior, cyclic voltammetry was performed within an appropriate potential

range (Fig. 4). The analysis revealed that the material demonstrated its highest specific capacitance of 99.767 F g^{-1} at a scan rate of 20 mV s^{-1}.

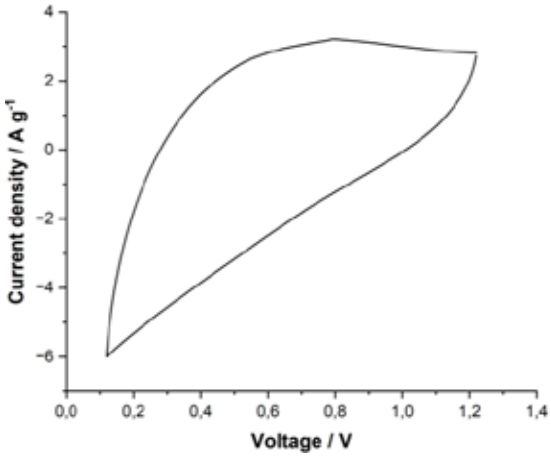

Fig. 4. Cyclic voltammogram of synthesized material for capacitance analysis

4. CONCLUSIONS

The main conclusions can be defined as follows:
Demonstration of the potential of utilizing recycled CPUs and carbonated lemon peel which present new electrocatalytic materials made of different waste.
The synthetized material exhibited promising catalytic activity, particulary for HER, with good Tafel slope values, and mixed controlled reaction mechanism. Also, electrochemical testing for OER showed lower materials performance with higher Tafel slope and overpotential, and diffusion-controlled reaction mechanism.
The XRD analysis confirmed the presence of crystalline phases which oxidation was also noticed in cyclic voltammogram. Beyond electrolytical investigation, the material demonstrated potential in energy storage applications. Cyclic voltammetry revealed a high specific capacitance of 99.767 F $g^{-1.}$
By developing eco-friendly synthesis methods and utilizing waste derived material, this research contributes to sustainable resource utilization and advances the transition toward renewable energy solution.

ABSTRACT

The increasing global energy demand necessitates a transition to sustainable and low-carbon energy systems. Hydrogen, as a versatile energy carrier, holds a significant promise for communities to achieve carbon neutrality goals. Among various hydrogen production methods, green hydrogen production through water electrolysis from renewable electricity by minimizing carbon emissions stands out as an environmentally friendly and sustainable method. However, challenges such as efficiency, cost and production capacity prevent its widespread adoption.
This paper performs a life cycle assessment (LCA) of green hydrogen production by evaluating greenhouse gas emissions, energy consumption and resource utilization under different renewable and non-renewable energy scenarios. The results highlight the importance of renewable energy integration and electrolyser efficiency in minimising environmental impacts. Green hydrogen achieves up to 90% lower greenhouse gas emissions compared to conventional methods, highlighting its potential as a sustainable energy solution.

Keywords: Green hydrogen, Electrolysis, Life Cycle Assessment, Sustainability, Hydrogen Production

1. INTRODUCTION

Energy has been one of the key determinants of social welfare and development throughout history. The discovery and utilisation of fossil fuels during the Industrial Revolution enabled rapid economic growth and improved living standards. However, concerns such as increasing energy demand and climate change have necessitated a transition to sustainable energy systems. In this regard, hydrogen has emerged as a promising energy carrier for the future due to its versatility and potential to enable a clean economy.
Hydrogen, which is abundant in nature as compounds, is not a natural primary energy source because it does not exist in free form. Therefore, hydrogen is an energy carrier produced from other energy sources. Hydrogen has great potential as a clean and renewable energy carrier depending on the method of production. However, today hydrogen is mainly used in the refining and chemical sectors and is produced using fossil fuels such as coal and natural gas and is therefore responsible for significant annual greenhouse gas emissions [1]. Therefore, for green hydrogen to be widely adopted, it needs to overcome challenges such as high production costs, efficiency limitations and the need for infrastructure development.
This study aims to perform a life cycle assessment of green hydrogen production through water electrolysis. The paper describes the importance of renewable energy integration and optimisation strategies to minimise the environmental footprint of hydrogen production systems.

2. THEORETICAL STUDY AND METHODOLOGY

In this section, theoretical study results for hydrogen are presented in general terms under the following headings:

- Hydrogen Production
- Hydrogen Colouring
- Life Cycle Assessment (LCA) Methodology

2.1. Hydrogen Production

Hydrogen can be produced using various methods, broadly categorized into fossil fuel based and renewable source based.

- **Fossil Fuels Based Methods:** The most widely used fossil fuel-based methods are steam methane reforming (SMR), partial oxidation (POX) and coal gasification (CG). SMR produces grey hydrogen, causing significant CO_2 emissions, but can produce blue hydrogen when combined with carbon capture and storage (CCS). POX involves reacting hydrocarbons with limited oxygen to produce hydrogen and CO, often used in combination with other processes. CG converts coal into syngas, a mixture of hydrogen and CO, but needs CCS to address high carbon emissions. In addition, other methods such as autothermal reforming (ATR), dry reforming (DR) and chemical loop reforming (CLR) are being developed to increase efficiency and minimise environmental impact [2], [3], [4].

- **Renewable Sources Based Methods:** Renewable-based hydrogen production includes water splitting, biological, and thermochemical process methods. The most common renewable-based method is water electrolysis, the water splitting method. Powered by solar or wind energy, water electrolysis produces green hydrogen with virtually no greenhouse gas emissions. On the other hand, biological processes and thermochemical processes offer a sustainable way to utilize hydrogen by converting organic matter into hydrogen. These renewable methods are important for the future, with ongoing research focussed on improving efficiency and scalability [2], [3].

2.2. Hydrogen Colouring

The environmental impacts of hydrogen production vary depending on the methods used. These methods are usually expressed with colours. These colours represent the environmental footprints of production processes, not the visible properties of hydrogen. In general, technical articles can be separated into those that discuss various hydrogen production methods (colours) and specific technological elements. Of course, hydrogen itself is colourless. Still, there is no universal agreement on the colour coding for hydrogen. A summary of the colours defined below [5]:

- Black/Brown Hydrogen: It is produced through coal gasification. It refers to bituminous coal (black) and lignite (brown) types of coal.
- Grey Hydrogen: It is produced from natural gas through SMR.
- Blue Hydrogen: It is produced similarly to grey hydrogen, but CO_2 emissions are captured using CCS technology.
- Turquoise Hydrogen: It is produced from natural gas using methane pyrolysis, with solid carbon as a byproduct and no CO_2 emissions.
- Green Hydrogen: It is produced by the electrolysis of water using renewable energy, resulting in nearly zero emissions.
- Yellow Hydrogen: It is produced through the electrolysis of water like green hydrogen but uses grid electricity as the power source.
- Pink Hydrogen: It is obtained from the electrolysis of water using nuclear energy.
- White Hydrogen: It refers to hydrogen found naturally in its elemental form.

2.3. Life Cycle Assessment (LCA) Methodology

The LCA methodology was employed to evaluate the environmental impacts of green hydrogen production. The study followed the ISO 14040 standard, encompassing four phases [6]: goal and scope definition, life cycle inventory analysis (LCI), life cycle impact assessment (LCIA), and life cycle interpretation. The life cycle boundaries of this study adopted a cradle-to-grave approach, considering all stages from raw material extraction to hydrogen utilisation and disposal. Key performance indicators such as greenhouse gas emissions, energy consumption and resource utilisation were quantified using specialised LCA software. In addition, sensitivity analysis was performed to assess the impact of variables such as electrolyser efficiency and electricity sources on the results.
A review of existing LCA studies on hydrogen production was conducted to contextualise and evaluate the findings. Table 1 summarises the key parameters from the literature, including life cycle boundaries, LCA programmes and main impact categories.

Table 1. Literature Review on LCA of Hydrogen Production

Study	Life Cycle Boundary	Main LCA Program	Main LCIA method	Functional unit	Main Impact Category (midpoint - endpoint)	Ref no

Global Warming Potential (GWP), Acidification Potential (AP), Eutrophication Potential (EP), Photochemical Ozone Creation Potential (POCP), Human Toxicity Potential (HTP), Single Score (SS), Abiotic Depletion Potential (ADP), Ozone Layer Depletion Potential (ODP), Cumulative Energy Demand (CED), Solid Waste (SW), Air Emissions (AE), Capacity Factor (CF), Energy Use (EU), Particulate Matter (PM), Winter Smog (WS), Ecotoxicity Potential (ETP), Water Consumption Potential (WCP)

3. RESULTS AND DISCUSSION

Three renewable energy integration scenarios were analysed to assess the environmental performance of hydrogen production through electrolysis:

1. Full renewable energy supply
2. Grid electricity dominated by fossil fuels.
3. Partial renewable and grid electricity mix.

3.1. Global Warming Potential (GWP) Performance

- **Renewable Energy Systems**: Electrolysis powered by wind and hydroelectric energy emerged as the most environmentally friendly options, achieving the lowest GWP values (e.g., 0.97–4.45 kg CO_2-e/kg H_2 for wind). Solar energy (PV and thermal) and biomass-based systems exhibited moderately higher GWP values compared to wind and hydroelectric systems.
- **Grid Electricity**: Electrolysis relying on grid electricity showed the highest GWP values due to the predominant use of fossil fuels in electricity generation. For instance, a PEM water electrolyser (PEMWE) using the German grid mix emitted 34 kg CO_2-e/kg H_2, which could be reduced by 89% to 3.45 kg CO_2-e/kg H_2 with a fully decarbonized energy system.
- **Partial Renewable and Grid Electricity**: Electrolysis operated with a combination of renewable energy and grid electricity resulted in intermediate GWP values reflecting the proportional contribution of renewable energy. The results indicate that increasing the share of renewable energy in the mix significantly reduces the environmental impact. A more detailed analysis of this scenario will be conducted in future studies.

3.2. Acidification Potential (AP) Performance

Nuclear based systems exhibited the best AP performance, followed by wind energy. However, there are significant environmental and social concerns related to nuclear waste disposal and safety, which should be included in a more comprehensive LCA. On the other hand, biomass and PV-based electrolysis showed the worst performances in this category.

3.3. Comparison of Electrolysis Technologies

- **Alkaline Electrolysis (AEL)**: It is an old technology with low cost and long life. However, it exhibited high environmental impacts due to the use of materials such as nickel and steel.
- **Proton Exchange Membrane (PEM)**: It produces hydrogen efficiently and with high purity, is suitable for renewable energy integration and has been the recommended electrolyser method in many studies. However, its cost is high due to expensive catalysts.
- **Solid Oxide Electrolysis Cell (SOEC)**: It has high efficiency and showed lower and more consistent GWP values in the long term. However, it has short lived components and high emissions during installation.
- **Anion Exchange Membrane (AEM)**: More efficient than AEL, but with lower performance compared to PEM. As it is a new technology, it needs extensive analyses and has limited capacity.

4. CONCLUSIONS

Green hydrogen production through electrolysis represents a sustainable solution to global energy needs, with renewable energy integration and advancements in electrolyser efficiency playing pivotal roles in reducing environmental impacts. Wind-based systems achieved the lowest GWP (0.97–4.45 kg CO_2-e/kg H_2) but require infrastructure scaling to overcome production limitations. Balancing environmental performance with cost, scalability and operational challenges is key to optimising hydrogen production pathways.
Policymakers and industry should invest in renewable energy and innovative technologies to accelerate the hydrogen transition, while future research should address economic viability and integration with existing energy systems to unlock its full potential for a low-carbon future.

ABSTRACT

In this study, unsupported (Fe-S) and activated carbon supported (Fe-S@AC) iron-sulfide catalysts were prepared and tested green H_2 production via H_2S decomposition. Activated carbon (AC) was prepared using a one-step method with sawdust as a starting material. The unsupported iron-sulfide catalyst was prepared using the solvothermal method and added into the support by the wet-impregnation. H_2S decomposition catalytic activity tests were performed in a conventionally heated packed-bed reactor system at 800°C using 1% H_2S-N_2 gas mixture. The catalysts were characterized using XRD, SEM-EDS and N_2-physisorption techniques. The results of the activity tests showed H_2S conversion values of 12% and 18% over the Fe-S and the Fe-S@AC catalysts, respectively. The activity test results, conducted over 60 minutes, indicated that Fe-S@AC exhibited higher activity in hydrogen production through H_2S decomposition. Synthesis, characterization and activity test studies are ongoing as part of this research.

Keywords: Hydrogen, H_2S decomposition, iron-sulfide, activated carbon.

1. INTRODUCTION

Globally, oil refineries and natural gas plants produce more than 40 million tons of hydrogen sulfide (H_2S) each year, and this amount is expected to increase in the future. Nowadays, H_2S is converted to elemental sulfur and water vapor by commercial Claus process, resulting in a large loss of hydrogen. The increasing demand for green hydrogen requires the evaluation of low-cost hydrogen sources other than hydrocarbon steam reforming. Hydrogen production from H_2S is an attractive issue because it can significantly reduce CO_2 emissions [1,2].

Hydrogen sulfide decomposes into hydrogen and sulfur vapor at high temperatures (≥600°C). At temperatures between 200-1000°C, sulfur vapor may includes different type of sulfur species from S_2 to S_8. Therefore, the reaction mixture may contain different species of sulfur (such as S_2-S_4) together with H_2. In the literature, equilibrium mixture estimation have been made using free energy minimization and the results have been confirmed experimentally. In general, since the decomposition reaction requires high temperatures to obtain significant conversion, the sulfur will be produced as diatomic. Therefore, the thermal decomposition reaction can be considered the following (R1; [3]):

$$2H_2S_{(g)} \leftrightarrow 2H_{2(g)} + S_{2(g)} \qquad (R1)$$

Several mechanisms have been proposed in the literature to understand the behaviour of metal-sulfide catalysts in H_2S decomposition. The interaction of hydrogen sulfide with metal-sulfide leads to the formation of hydrogen and “higher” sulfide (R2). This 'higher' sulfide then decomposes to form elemental sulfur and “lower” sulfide (M_xS_y) (R3) [4,5].

$$M_xS_y + zH_2S \rightarrow M_xS_{y+z} + zH_2 \qquad (R2)$$

$$M_xS_{y+z} \rightarrow M_xS_y + zS^0 \qquad (R3)$$

The H_2S decomposition reaction requires high energy due to its highly endothermic nature. To overcome this problem, various approaches have been adopted including use of catalysts to achieve higher conversions at relatively low temperatures, separation of products from reactor effluent gas stream [6]. Development of highly active catalyst is key to reducing the reaction temperature by lowering the apparent activation energy of H_2S decomposition. Transition metal-oxides and their sulfides (Mo, Cr, Fe, Co, Cu, Ni, V, and W) have been studied as catalysts for H_2S decomposition. Sulfides appear to be more active and more stable than their oxide counterparts [1,7]. For this purpose, unsupported iron-sulfide and activated carbon supported iron-sulfide catalysts were prepared and tested in a conventional heated reactor system for the thermal and catalytic decomposition reaction of H_2S to produce COx-free H_2.

2. EXPERIMENTAL

2.1. Synthesis of Unsupported Iron-Sulfide

In this study, unsupported iron-sulfide particles were prepared by solvothermal method. In this method, iron (III) chloride and thiourea were weighed in such a way that the Fe/S molar ratio is ¼, dissolved in deionized water and stirred for 15 minutes at ambient temperature under vigorous stirring. At the end of the stirring process, the solution was taken into a Teflon coated stainless steel autoclave and kept in an oven at 160°C for 10 hours and solvothermal treatment was carried out. Then, the autoclave was cooled to room temperature and the suspension was filtered and washed with deionized water for 4-times. The catalyst obtained after washing was dried in an oven at 60°C for 24-hours. The dried catalyst was calcined in a tube furnace under He gas flow at 800°C for 6-hours.

2.2. Synthesis of Activated Carbon Support Material

Activated carbon with mesoporous properties was prepared in a single step using sawdust as a precursor material and phosphoric acid (H_3PO_4) as an activating agent [8]. Initially, the raw material was sieved to obtain particles approximately 3 mm in size and treated with a 10% H_2SO_4 solution for 24-hour to remove impurities. Afterwards, it was washed with deionized water until the pH reached 6–7, filtered, and dried at 120°C until a constant weight was achieved. The dried material mixed with a 15% H_3PO_4 solution at a phosphoric acid to raw material weight ratio of 1.25 and stirred at room temperature for 24-hour. The suspension was filtered, and the residue was dried at 120°C to achieve a stable weight. Carbonization was carried out under a high-purity helium atmosphere, at 800°C for 45 minutes with a heating rate of 10°C/min. The resulting material was washed with 0.1 M HCl and hot distilled water until the pH stabilized between 6 and 7, followed by drying at 120°C to achieve a constant weight.

2.3. Synthesis of Supported Iron-Sulfide Catalysts

The support material and deionized water were mixed in a beaker with a magnetic stirrer until the temperature reached to 40°C. Iron-sulfide particles were weighted and dissolved in some deionized water. The solution containing iron-sulfide particles was added dropwise to the suspension of the support material mixed at 40°C. The suspension is allowed to dry under these conditions until the water is evaporated. The dried supported catalysts were calcined in a tube furnace under He gas flow at 800°C for 6 hours.

2.4. Evaluation of Catalytic Performances of Catalysts

In this study, supported and unsupported iron-sulfide catalysts were tested in a conventionally heated packed-bed flow reactor using a gas mixture containing 1% H_2S (with N_2 balance) with a total flow rate of 100 mL/min at 800°C and atmospheric pressure for thermal and catalytic decomposition of H_2S reaction. The product gas mixture obtained as a result of catalytic activity test studies was analysed with SRI-8610C gas chromatography equipment with Chromosil-310 column, thermal conductivity detector and N_2 gas as carrier.

2.5. Characterization Studies

QuantaChrome Autosorb 1C/MS instrument was used to perform N_2-physisorption analysis to measure the BET surface area of the spent catalysts. The X-ray diffraction (XRD) analysis was carried out using Rigaku MiniFlex X-ray diffractometer with Cu Kα radiation source to identify the crystal structures of the fresh and spent catalysts. For SEM-EDS analysis, by using a QUANTA 400F Field Emission microscope, morphological structure and elemental composition of the catalysts were determined.

3. RESULTS AND DISCUSSION

H_2S gas is a by-product released in large quantities in coal gasification, natural gas refining plants and oil refineries. Since it is a corrosive and toxic gas, it must be safely removed from the processes. The unwanted H_2S gas can be converted into green H_2, a valuable product, by thermal and catalytic decomposition reaction. In this study, the catalytic activities of new Fe-sulfide catalysts were investigated for the production of green H_2 from H_2S. Within the scope of the study, activated carbon prepared from sawdust was used as catalyst support.

In order to identify the structural/physical properties of fresh and spent catalysts, XRD, SEM-EDS and N_2-physisorption studies were performed. XRD patterns of fresh and spent unsupported Fe-S and activated carbon supported Fe-S@AC catalysts were presented in Figure 1. In the XRD pattern of the unsupported fresh Fe-S catalyst prepared by solvothermal method, only the FeS (troilite, Card No.: 01-089-1950) characteristic diffraction peaks were observed. However, fresh Fe-S@AC catalyst has more complex structure. In the XRD pattern of fresh Fe-S@AC showed that different crystalline structures such as Fe-P ($Fe_2(P_2O_7)$ (iron diphosphate, Card No.: 04-009-1838), Fe_2P (barringerite, Card No.: 01-078-6747), $Fe_3(PO_4)_2$ (graftonite, Card No.: 00-049-1087)) and Fe-S (FeS (troilite, Card No.: 01-089-1950)). The presence of P-containing species in the catalyst structure is probably due to the use of phosphoric acid as an activation agent during the preparation of activated carbon.

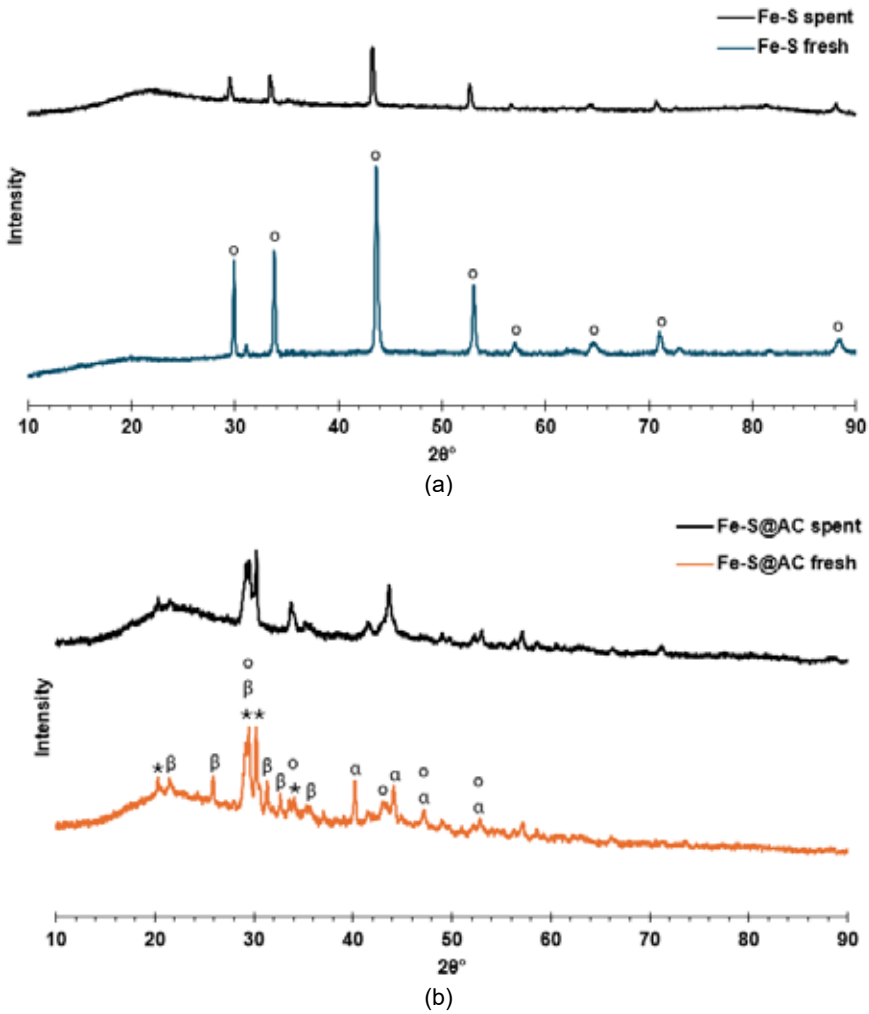

Fig. 1. XRD patterns of fresh and spent (a) Fe-S and (b) Fe-S@AC catalysts (o: FeS, *: $Fe_2(P_2O_7)$, α: Fe_2P, β: $Fe_3(PO_4)_2$)

The activity test results of the catalysts obtained in conventional heated reactor system are given in Fig. 2. Fe-S catalyst prepared by solvothermal method as unsupported bulk phase showed the lowest activity. The average H_2S conversion obtained in the 60 min test was 12% and the catalyst showed a relatively stable behaviour. Approximately 18% H_2S conversion was obtained with activated carbon supported Fe catalyst. The H_2S conversion estimated by "Gaseq Chemical Equilibrium" software under catalytic activity test conditions (1% H_2S with N_2 balance and 800°C) was 28%. Among the catalysts prepared from the study, 65% of the equilibrium conversion value was approached using the activated carbon supported Fe catalyst (Fe-S@AC).

In order to see structural change of both catalyts, XRD patterns of spent catalyts were also presented in Fig. 1. Fe-S catalyst retained its FeS structure after activity test. However, there was a structural change in the case of Fe-S@AC catalyst. The XRD peaks belonging to Fe_2P and $Fe_3(PO_4)_2$ structures disappeared while FeS and $Fe_2(P_2O_7)$ phases were still present in the Fe-S@AC catalyst. The surface area of spent Fe-S@AC (892 m^2/g) was considerably higher than the surface area of spent Fe-S catalyst (6 m^2/g) as expected. It is thought that there might be two possible reasons for the high activity of Fe-S@AC catalyst in this reaction: Fe-P structures showing activity in addition to FeS and/or the high surface area due to presence of activated carbon support material. The results obtained in this study indicate that the activated carbon supported Fe-S catalyst is worth further investigation for the production of green H_2 by H_2S decomposition.

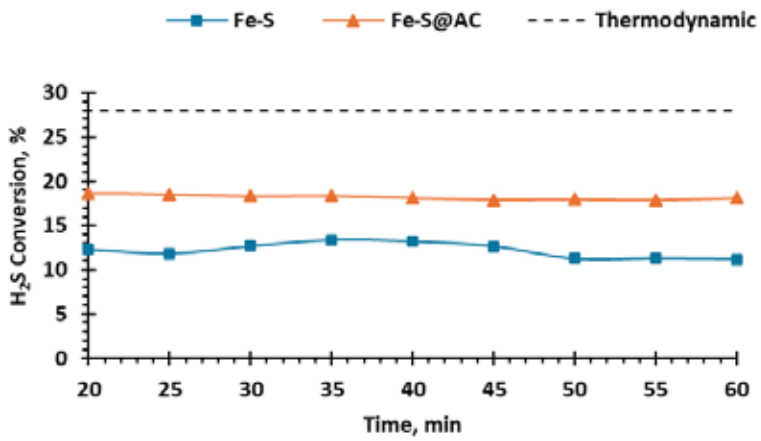

Fig. 2. H_2S conversions over iron-sulfide catalysts (800°C, 1%H_2S with N_2 balance)

4. CONCLUSIONS

In this study, unsupported Fe-S and activated carbon supported Fe-S@AC catalysts were synthesized and tested in a conventionally heated reactor system to produce green-H_2 via H_2S decomposition. The activity test results showed that the activated carbon supported catalyst showed higher activity than the unsupported catalyst and is a promising catalyst for this reaction. A conversion close to 65% of the equilibrium conversion of H_2S was achieved with the Fe-S@AC catalyst. This study investigates the utilization/conversion of wastes such as H_2S and sawdust into valuable products. As part of this research, catalyst preparation, characterization, and activity test studies are still being conducted.

ACKNOWLEDGEMENT

The valuable contributions of Prof. Dr. Gülşen DOĞU of Gazi University are gratefully acknowledged. ABSTRACT

In this study, activated carbon (DAC) supported iron (Fe@DAC & Fe-C@DAC) and unsupported iron carbide (Fe-C) catalysts were prepared to determine their activities in the decomposition reaction of H_2S. Support material activated carbon was synthesized from sawdust using a two-step synthesis method. While the Fe@DAC catalyst was prepared using the wet impregnation method, the Fe-C@DAC catalyst was obtained by applying the carburization process to Fe@DAC catalyst. BET, XRD, and TGA/DTA techniques were used to determine the physical and structural properties of the catalysts. While the XRD analysis of DAC showed amorphous graphitic carbon in the structure, it was determined that the supported catalysts had metallic Fe, Fe_3C, and graphitic carbon structures. Catalytic activity tests were performed in a continuous-flow packed-bed reactor system with %1H_2S-N_2 gas mixture, using a microwave-heated reactor at an average temperature of 600°C and as well as in conventional heated reactor at 800°C. In the microwave heated reactor system, it was observed that the thermodynamic equilibrium conversion was exceeded. Fe-C@DAC catalyst exhibited the best activity with 32% H_2S conversion. The catalysts have shown promising results in H_2S decomposition reaction in both microwave and conventionally heated reactor systems. This study is ongoing, presented the primary results obtained in the microwave heated reactor system.

Keywords: Microwave Heated, Activated Carbon, Iron, H_2 Production, H_2S Decomposition

1. INTRODUCTION

Hydrogen, as a clean energy carrier, has the potential to meet future energy demands while reducing COx emissions. It plays a critical role in technologies like hydrogen-powered vehicles and fuel cells, paving the way for a sustainable, low-carbon energy future. Hydrogen sulfide (H_2S), a toxic by-product of industries like oil refining, is a promising alternative for hydrogen production. While the Claus process efficiently removes H_2S, it fails to recover hydrogen. Conventional methods like reforming rely on fossil fuels and emit CO_2, highlighting the need for cleaner alternatives. The direct decomposition of H_2S into hydrogen and sulfur (R1) is a more efficient and sustainable solution.

$$H_2S(g) \leftrightarrow H_2(g) + 1/n\ S_n(g) \qquad \Delta H^o_{298} = 21\ kJ/mol;\ \Delta G^o_{298} = 33\ kJ/mol \qquad (R1)$$

However, achieving highly effective direct decomposition of H_2S into CO_x-free hydrogen and sulfur remains a significant challenge due to the equilibrium limitations [1, 2, 3]. For this reaction to be an effective hydrogen production method, it is essential to develop active and stable catalysts. Biomass-derived activated carbons are promising materials for improving H_2S decomposition due to their low cost, high surface area, and reversible kinetic properties [4]. Their catalytic reactions and adsorption efficiency can be enhanced through surface functionalization or metal impregnation, making them ideal for hydrogen production [5].

In this study, sawdust-based activated carbon (DAC) and activated carbon-supported catalysts (Fe, Fe-C) were prepared. The use of microwave heated reactors is being investigated to increase the production of COx-free H_2 from H_2S and to do so with less energy requirement. In order to compare, catalytic activity tests were conducted using both a conventionally heated reactor system and a microwave-heated reactor system.

2. MATERIALS AND METHOD

Preparation of Activated Carbon (DAC): Activated carbon was prepared using a two-step method with sawdust as the starting material. The starting material is sieved to obtain particles approximately 3 mm in size. The sieved material is mixed with 10% H_2SO_4 for 24 hours and then washed with deionized water until the pH reaches 6-7. After filtration, the material is dried at 120°C until a constant weight is achieved. The carbonization process is carried out at 500°C for 120 minutes under a helium flow of 100 mL/min, producing semi-coke. In the activation step, NaOH is mixed with semi-coke at 1:1 NaOH/semi-coke mass ratios using 30 mL of water and left to rest for 24 hours. The NaOH/semi-coke mixture is

then filtered, and the obtained material is dried at 120°C until a constant weight is reached. A second carbonization is performed at a heating rate of 10°C/min, reaching 800°C, and maintained for 45 minutes. The material is then stirred with 0.1 M HCl for 20 minutes and washed with warm distilled water until the pH reaches 6-7. Finally, the resulting activated carbon is dried at 120°C until a constant weight is obtained.

Preparation of Activated Carbon Supported Iron (Fe@DAC) Catalyst: Fe@DAC catalyst containing 10% iron by mass was prepared using the wet impregnation method. Iron (III) nitrate nanohydrate ($Fe(NO_3)_3 \cdot 9H_2O$) is used as the iron source. A suspension is prepared using activated carbon and deionized water, and its temperature is kept at 40°C. A certain amount of metal salt is weighed and dissolved in a small amount of deionized water. This solution is added drop by drop into the suspension. The final solution is then left to dry under these conditions. The dried supported catalyst is calcined in a tube furnace under He gas flow at 800°C for 5 hours.

Preparation of Activated Carbon Supported Iron Carbide (Fe-C@DAC) Catalyst: Carburization process was used to obtain Fe-C@DAC catalyst. In this process, the activated carbon-supported iron catalyst (Fe@DAC) obtained using the wet impregnation method is exposed to a He gas flow to remove impurities at 500°C for 30 minutes in a tube furnace. Then, the catalyst undergoes carburization in a gas mixture, including H_2 and CH_4 gases (CH_4:H_2 = 1:4) with a total volumetric flow rate of 50 mL/min at 900°C for 2 hours.

Preparation of Iron Carbide (Fe-C) Catalyst: Fe-C catalyst was prepared using Fe-O catalyst synthesized using the complexation method. In the complexation method, Iron (III) nitrate nanohydrate ($Fe(NO_3)_3 \cdot 9H_2O$) is used as the iron source and ethanol (99.9%) as the solvent. Metal salt and citric acid solutions are mixed in an equimolar ratio at 60°C, forming organo-metallic complexes. The solution is allowed to become viscous, poured into thin layers, and dried at 80°C to form solid foams. These foams are crushed, ground, and calcined at 800°C for 6 hours in a muffle furnace to obtain the metal oxide catalyst. The Fe-O catalysts are carburized under a gas mixture comprising 80% CH_4 and 20% H_2 with a controlled gas flow rate of 50 mL/min at 900°C for 6 hours.

Catalyst Characterization: N_2 adsorption–desorption (Quantachrome Autosorb1), XRD (Rigaku D/MAX 2200), SEM-EDS (QUANTA 400F Field Emission SEM), and TGA-DTA (Netzsch/STA 449 F3 Jupiter) analysis were performed for the characterization of the samples.

Catalytic Activity Test Studies: Catalytic activity test was performed in a conventional continuous flow-packed bed reactor system at 800°C and in a microwave-heated reactor system at average temperature of 600°C. Details of the experimental work was reported in [4].

3. RESULT AND DISCUSSION

The study aims to prepare highly active and stable iron-based catalysts to produce CO_x-free H_2 from thermal catalytic H_2S decomposition. The H_2S decomposition reaction is highly endothermic, requiring significant energy to achieve high conversions. Compared to conventional heated reactors, microwave heated reactors can accelerate reaction kinetics by enabling inside-out heating of particles, enhancing catalytic activity through localized hot spots and selective heating effects. Additionally, the potential of microwave heating to reduce energy consumption and shorten reaction times has attracted significant attention from researchers. Due to carbon's strong microwave energy absorption, catalysts containing activated carbon and metal carbides were prepared, and their activities in this reaction were investigated. N_2-adsorption-desorption analysis was performed to determine the surface areas and pore distribution of the catalysts. The BET surface area values to be found as 409 m^2/g, 606 m^2/g and 347 m^2/g for DAC, Fe@DAC and Fe-C@DAC, respectively. Using X-ray diffraction (XRD) analysis, the crystal structures of the materials were examined.

Fig. 1(a) displays the XRD patterns of activated carbons made from waste sawdust (DAC). The diffraction patterns of amorphous graphitic carbon were represented by two broad peaks that were centered at $2\theta \approx 23^o$ and 44° [6].Structures belonging to metallic Fe ($2\theta=43.58^o$, $2\theta=50.8^o$, $2\theta=64.94^o$, $2\theta=74.72^o$), Fe_3C($2\theta=37.67^o$, $2\theta=43.58^o$, $2\theta=44,6^o$, $2\theta=45^o$, $2\theta=82.26^o$), and graphitic carbon($2\theta=26.08^o$) were observed in the XRD patterns of Fe@DAC and Fe-C@DAC catalysts [7, 8]. Interestingly, a slight increase was observed in the characteristic XRD peaks belonging to metallic iron as well as the Fe-C structures attempted to be formed by the carburization process.

To observe thermal stability, structural changes, and carbon type of DAC under heat flow, TGA-DTA analysis was conducted in a dry air atmosphere within a temperature range of 25–950 °C (not shown here). 94 % weight loss was determined as a result of TGA. DTA analysis gives information about carbon species. It was reported that amorphous carbon up to 600 °C can be removed under dry air flow. The DAC sample exhibited the highest intensity at approximately 600 °C, suggesting the formation of amorphous carbon during the preparation [4]. The time-dependent variations in H_2S conversion values obtained with the synthesized catalysts at a reaction temperature of 800°C in the conventional system are presented in Fig. 2a, while the H_2S conversion at 600°C in the microwave reactor system is shown in Fig. 2(b). 26%, 17%, 25%, and 23% H_2S conversion values were obtained over the DAC, Fe-C, Fe@DAC, and Fe-C@DAC catalysts, respectively in the conventional heating system. In the microwave heated reactor system, the Fe-C@DAC catalyst exhibited the best activity with 32% H_2S conversion. The literature reported thermodynamic equilibrium values as %8 at

600°C and %28 at 800 °C [1, 9, 10]. In the conventional heated system, H_2S conversions very close to the equilibrium conversion were obtained with other catalysts except the Fe-C catalyst. The situation is quite different in the microwave heated reactor system. The highest conversion was obtained with the Fe-C@DAC catalyst and the thermodynamic conversion was exceeded, as expected. In the microwave heated reactor system, the catalytic activity order is Fe-C@DAC>Fe-C>Fe@DAC>DAC. Possible explanations for achieving high H_2S conversion are; the formation of hot spots during microwave irradiations and the polar property of H_2S (selective catalytic effect) in the microwave-heated reactor system [3].

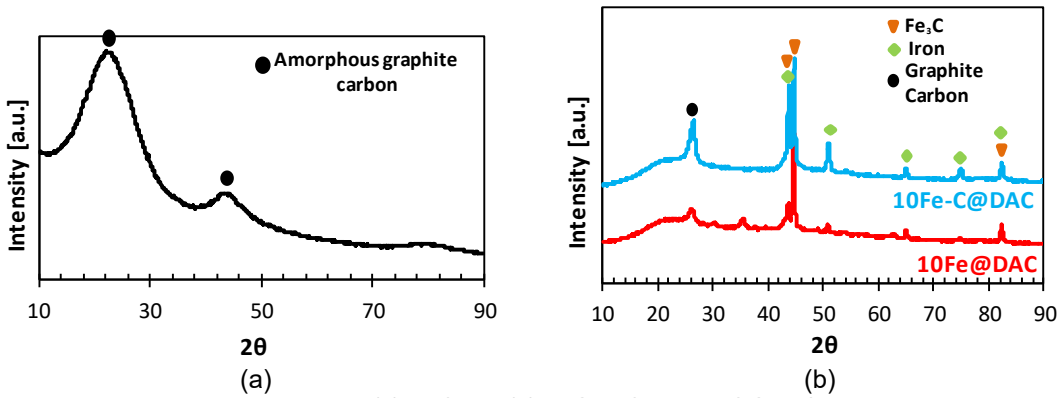

Fig. 1. XRD patterns (a) DAC and (b) Fe@DAC and Fe-C@DAC catalysts

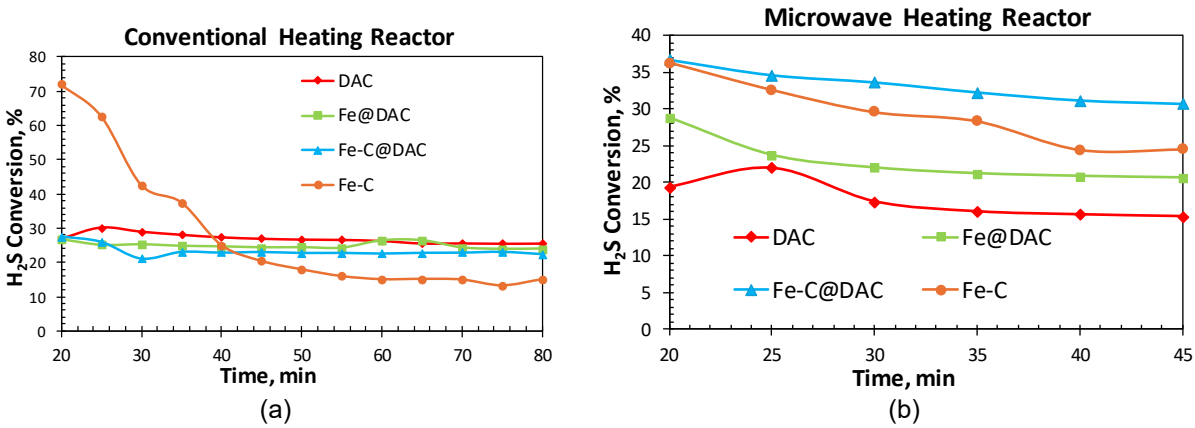

Fig. 2. (a) Catalytic Activities in a) Conventional Heating Reactor (800°C) b) Microwave Heating Reactor (~600°C) (%1H_2S-N_2, Catalyst: 0.1 g; Total gas flow rate: 100 mL/min)

4. CONCLUSION

The catalytic thermal decomposition of H_2S plays a crucial role in the producing CO_x-free hydrogen and might be a key process for sustainable energy applications. In this study, activated carbon (DAC), activated carbon-supported iron (Fe@DAC and Fe-C@DAC) catalysts, and unsupported Fe-C catalysts were successfully synthesized and tested in microwave and conventional heated reactor systems. While characteristic peaks belonging to amorphous graphitic carbon were observed in the XRD patterns of the DAC material, peaks belonging to metallic iron, Fe_3C, and graphitic carbon were observed in the XRD patterns of the Fe@DAC and Fe-C@DAC catalysts. As a result of the activity test carried out at approximately 600°C in the microwave reactor system with the Fe-C@DAC catalyst, the highest H_2S conversion value (32%) was obtained among other catalysts. This conversion value exceeds the thermodynamic equilibrium conversion (7%) at 600 °C. The results show that the Fe-C@DAC catalyst is quite promising for the microwave heated reactor system.

ABSTRACT

An electrocatalyst with good stability and superior activity for oxygen reduction reaction (ORR) is the essential criterion for fuel cell application. Intensive research has been dedicated to minimizing the Pt loading while boosting the dispersion and utilization of nanoparticles and overcome the sluggish reaction kinetic of ORR. In the present report, we prepared A-site deficient $La_{0.4}Ca_{0.4}Ti_{0.995}Pt_{0.005}O_3$ based perovskite oxides with minimal Pt substitution synthesized using solid-state and sol-gel methods and assessed ORR activity of electrocatalyst in alkaline electrolyte. The experimental findings show that Pt exsolved $La_{0.4}Ca_{0.4}Ti_{0.995}Pt_{0.005}O_{3-x}$ perovskite oxides delivered superior mass activity of 3.6 mA/μg_{Pt} and good stability in alkaline electrolyte.

Keywords: Perovskite oxide, Pt nanoparticles, electrocatalyst, oxygen reduction reaction

1. INTRODUCTION

The main challenge with the oxygen reduction reaction (ORR) in fuel cells is slow reaction kinetics, low product yield towards water formation and poor catalyst stability due to poor catalyst-support interaction. The interaction between Pt and carbon is weak compared to the interaction between Pt and oxide supports [1], which deteriorates the longevity of the catalyst by inducing dissolution, detachment, and agglomeration of Pt nanoparticles during fuel cell operation. Besides, the oxidation of the carbon support during electrocatalytic tests introduces oxygen-containing groups on the support surface, which further weakens the support-particle interaction and increases the resistance [2].
In the current research work, we used perovskite oxide as catalyst support and employ exsolution method [3] for the decoration of catalytically active nanoparticles (in this work Pt nanoparticles). The exsolution process—first incorporating catalytically active component into B-site of the ABO_3 perovskite lattice in oxidizing conditions and then releasing it under reducing atmosphere—provides highly dispersed, chemically stable, and catalytically active nanoparticles anchored onto the oxide support [4,5]. Once, B-site ions are reduced to metallic state, the nature of the bond is physical-mechanical, and they are embedded into the oxide up to 30%. These provide a larger area to interact with the support, facilitate three-phase junction/contact, enhance the adhesion, inhibits the agglomeration and growth of nanoparticles during fuel cell operation, all of which contribute to the catalytic activity and stability [6,7]. Besides the reduction process improves the electronic properties and electrocatalytic activity of perovskite oxide by forming oxygen vacancies, Ti^{3+} ions, and crystal defects in $LaTiO_3$ [8,9].
In the current research work, we compared electrocatalytic activity of Pt-substituted $La_{0.4}Ca_{0.4}Ti_{0.995}Pt_{0.005}O_3$ (LCPTO) and $La_{0.4}Ca_{0.3925}Ba_{0.0075}Ti_{0.995}Pt_{0.005}O_3$ (LCBPTO) perovskite oxides prepared using two different methods, sol-gel (pechini) and solid-state reaction methods. We evaluated electrocatalytic oxygen reduction reaction (ORR) activity of perovskite oxides in alkaline (0.1 M KOH) electrolyte.

2. MATERIALS AND METHODS

The following chemicals were used to synthesise perovskite oxide by using sol-gel method $Ca(NO_3)_2.4H_20$, $La(NO_3)_3.6H_2O$, titanium(IV) bis(ammonium lactato) dihydroxide solution, $H_2[Pt(NO_3)_6]$, citric acid ($C_6H_8O_7$), ethylene glycol ($C_2H_6O_2$). To prepare perovskite oxide by using solid-state reaction, we used high purity La_2O_3, TiO_2, $CaCO_3$, PtO_2 and $BaCO_3$ supplied from Sigma Aldrich, Alfa Aesar.
The perovskite oxide was prepared by solid-state reaction method reported previously in the following manuscript.[10] As a Pt precursor, house developed $Ba_3Pt_2O_7$ perovskite oxide prepared by solid-state reaction was used. The reason of using $Ba_3Pt_2O_7$ instead PtO_2 is that PtO_2 tends to volatilize or to be reduced to metallic form, due to poor phase stability of the compound at high temperatures [11]. The as-prepared perovskite oxide ground for an hour and fired under pure oxygen atmosphere (100 ml/min) as a pellet at 1200 °C for 12 h. The prepared pellet was fractured and reduced in 5% H_2/N_2 between 700 to 900 °C for 12 h. $La_{0.4}Ca_{0.4}TiO_3$ and $La_{0.4}Ca_{0.4}Ti_{0.95}Pt_{0.05}O_3$ were prepared using solgel technique. First, citric acid and EG with the ratio of 2:1 dissolved in 200 ml water under continuous stirring. After the dissolution of the substances, other chemicals (analytic grade titanium (IV) bis (ammonium lactato) dihydroxide solution (50 wt. % in H_2O), calcium nitrate, platinum nitrate and lanthanum nitrate, respectively, were added. When the transparent solution was obtained, the temperature was increased to 80-100 °C to evaporate water and form a gel. The gel formation was followed by a combustion at 300-400 °C resulting in black powder. The black powder was ground prior to calcination at 800 °C for 6 h with a heating/cooling rate of 4 °C/min and then reduced in 5% H_2/N_2. Perovskite oxide powders reduced

at 700°C for 12h to exsolve Pt nanoparticles.
To confirm the phase purity and crystallinity, oxidized and reduced samples were analysed by using a PANalytical Empyrean X-ray diffractometer (XRD) operated in reflection mode. The collected XRD data was further analysed using WinXPOW software. The morphology of the perovskite oxides was investigated using JSM-IT800 Schottky Field Emission Scanning Electron Microscope (SEM). The electrochemical activity of the perovskite oxide samples was probed using rotating ring disc electrode (RRDE) assembly manufactured by Pine Research.

3. RESULTS AND DISCUSSION

Fig. 1 a-f illustrates SEM images of oxidized (as-prepared) and reduced perovskite oxides prepared using solid-state reaction and sol-gel pechini methods. The sample prepared using solid-state method has large grains (~1 µm) with low porosity. The particles exsolved from reduced $La_{0.4}Ca_{0.3925}Ba_{0.0075}Ti_{0.995}Pt_{0.005}O_{3-x}$ at 700°C in H_2/N_2 are around 4-6 nm and finely dispersed on perovskite oxide as demonstrated in Figure 1b-c.

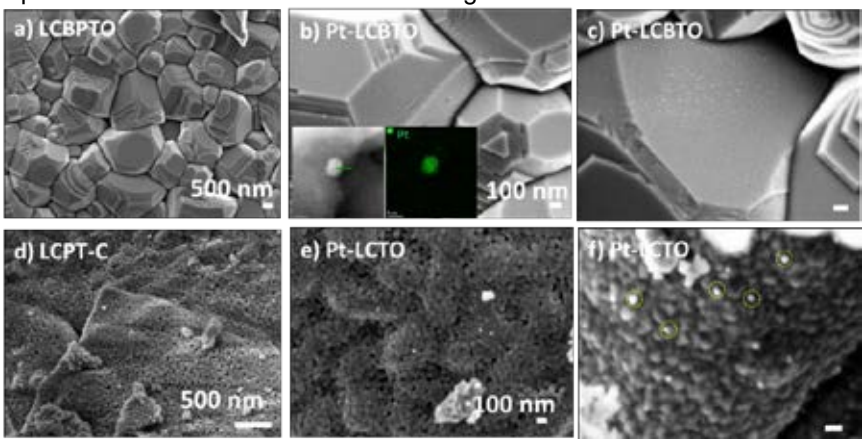

Fig. 1. a-b illustrate SEM images of perovskite oxides before and after reduction heat treatment. a) As-prepared $La_{0.4}Ca_{0.3925}Ba_{0.0075}Ti_{0.995}Pt_{0.005}O_3$-ref doped with 0.5% Pt, b-c) reduced $La_{0.4}Ca_{0.3925}Ba_{0.0075}Ti_{0.995}Pt_{0.005}O_{3-x}$ (reduced at 700 °C, inset image shows the exsolved Pt nanoparticle). c) As-prepared $La_{0.4}Ca_{0.4}Ti_{0.995}Pt_{0.005}O_3$- ref doped with 0.5% Pt, d-f) reduced $La_{0.4}Ca_{0.4}Ti_{0.995}Pt_{0.005}O_{3-x}$ (at 700 °C).

For comparison, we prepared 0.5 % Pt substituted $La_{0.4}Ca_{0.4}Ti_{0.995}Pt_{0.005}O_3$ by sol-gel method, see Figure 1d-f. The solgel-derived Pt doped LCPTO powders with ~50 nm grain size exhibit mesoporous morphology with the BET surface area of 19 m^2/g, approximately eighteen times larger surface area than solid-state derived sample. Reduction heat treatment in H_2/N_2 results in Pt exsolution on $La_{0.4}Ca_{0.4}Ti_{0.995}O_{3-x}$, as indicated with yellow circles in Figure 1f.

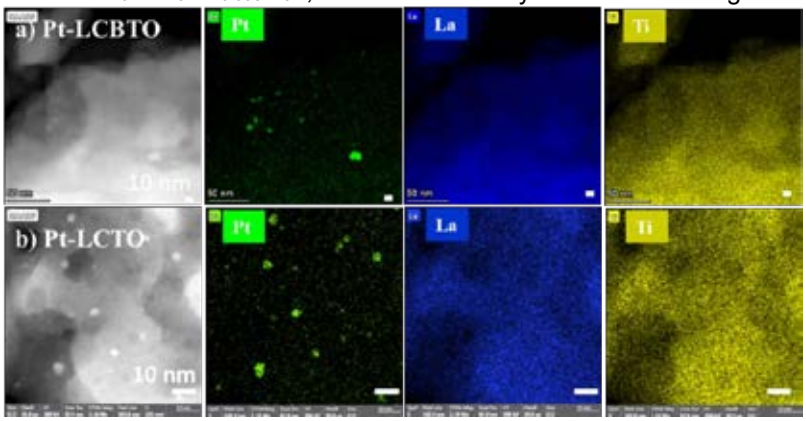

Fig. 2. HRTEM of exsolved nanoparticles on reduced $La_{0.4}Ca_{0.3925}Ba_{0.0075}Ti_{0.995}Pt_{0.005}O_{3-x}$, $La_{0.4}Ca_{0.4}Ti_{0.995}Pt_{0.005}O_{3-x}$ and elemental mapping. HRTEM image and EDX mapping of (Ti, La, Pt) reduced a) $La_{0.4}Ca_{0.3925}Ba_{0.0075}Ti_{0.995}Pt_{0.005}O_{3-x}$ and b) $La_{0.4}Ca_{0.4}Ti_{0.995}Pt_{0.005}O_{3-x}$.

We investigated the microstructure and chemical composition of exsolved nanoparticles using HRTEM as shown in Figure 2. HRTEM images show the exsolved Pt nanoparticles with the size of 16±4 nm on $La_{0.4}Ca_{0.4}Ti_{0.995}Pt_{0.005}O_{3-x}$.and 4.5±2 nm on $La_{0.4}Ca_{0.3925}Ba_{0.0075}Ti_{0.995}Pt_{0.005}O_{3-x}$. The elemental distribution of Pt, O provides evidence of exsolution of metallic Pt. In all cases, we detected unreacted Pt chunks in the bulk structure of perovskite oxide. The presence of unreacted Pt/PtO_2 in (only) calcined on $La_{0.4}Ca_{0.4}Ti_{0.995}Pt_{0.005}O_3$ can be explained by two probabilities *i)* PtO_2 is not fully

decomposed in $LaTiO_3$-based perovskite oxide, *ii)* PtO_2 displays poor stability at elevated temperatures, and is reduced to metallic Pt at earlier steps of synthesis. The formation of Pt chunks was also observed by other researchers in $CaTiO_3$- and $LaTiO_3$-based perovskite oxides [12,13].

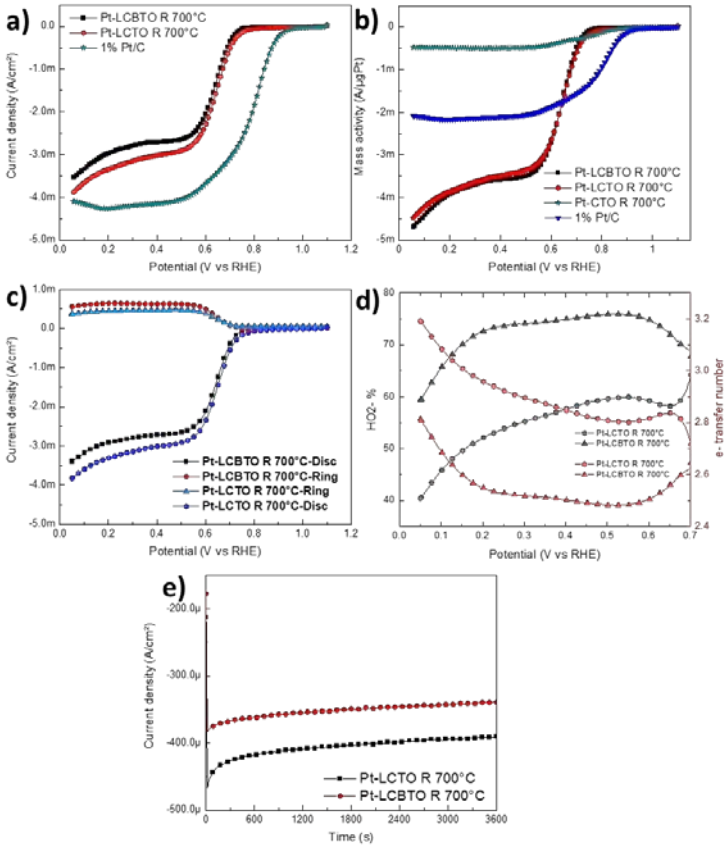

Fig. 3. Electrocatalytic activity of reduced $La_{0.4}Ca_{0.3925}Ba_{0.0075}Ti_{0.995}Pt_{0.005}O_{3-x}$ and $La_{0.4}Ca_{0.4}Ti_{0.995}Pt_{0.005}O_{3-x}$ in 0.1 M KOH. a) Comparisons of specific activity and b) the mass activity of samples in oxygen reduction region. c) RRDV profile showing the ring and disc voltammetry. d) Graph showing the $HO2^-$ yield and electron transfer number at different voltages. e) Chronoamperometric measurement of samples at 0.7 V vs RHE.

We assessed Pt exsolved perovskite oxides as ORR electrocatalysts in 0.1 M KOH. The onset potentials and diffusion limiting current densities are 0.82, 0.92 V and 2.7, 3.05 mA/cm^2 for reduced $La_{0.4}Ca_{0.3925}Ba_{0.0075}Ti_{0.995}Pt_{0.005}O_{3-x}$ and $La_{0.4}Ca_{0.4}Ti_{0.995}Pt_{0.005}O_{3-x}$, respectively. (For the commercial reference material, 1wt% Pt on C, onset potential and limiting current density values are 1.034 V, 4.14 mA/cm^2, respectively.) When the plot was converted to mass activity, the onset potential and limiting current density values are 3.48 and 3.6 mA/cm^2 for reduced $La_{0.4}Ca_{0.3925}Ba_{0.0075}Ti_{0.995}Pt_{0.005}O_{3-x}$ and $La_{0.4}Ca_{0.4}Ti_{0.995}Pt_{0.005}O_{3-x}$, respectively. We observe comparable electrocatalytic activity for perovskite oxide with Pt/C reference electrode. It is worth mentioning that the exsolution behaviour of reduced $La_{0.4}Ca_{0.3925}Ba_{0.0075}Ti_{0.995}Pt_{0.005}O_{3-x}$ is not uniform, not all Pt exsolved and the hidden Pt in the agglomerated Pt chunks (observed under TEM, data not shown) is not active for catalytic reactions and considered as an inactive catalyst. This finding indicates the importance of the uniform dispersion of fine (1-6 nm) Pt nanoparticles for effective utilization of the active material, as we previously reported [5].

The RRDE profiles of perovskite oxides are recorded in 0.1 M KOH electrolyte to understand the reaction mechanism, we estimated the HO^-_2 % yield and electron transfer numbers (n) for each sample, see Figure 5c-d. The highest HO_2^- % yield (60 %) and lowest electron transfer number (app. 2.6) within the voltage range of interest were observed for reduced $La_{0.4}Ca_{0.3925}Ba_{0.0075}Ti_{0.995}Pt_{0.005}O_{3-x}$. Overall, the perovskite oxide was prepared by solid-state reaction is more active for a sluggish two-electron reaction pathway in two steps to complete the reduction of O_2 molecules to OH^- ions. The superior activity of solid-state derived sample for two-electron reactions in alkaline media can be explained by the surface termination-segregation, structure, and poor catalytic activity towards four-electron reactions. The surface termination of the perovskite oxide might affect the binding sites of ions, OH^-, H^+, and O_2, and facilitate two-electron reactions.

We assessed the stability of reduced $La_{0.4}Ca_{0.3925}Ba_{0.0075}Ti_{0.995}Pt_{0.005}O_{3-x}$ and $La_{0.4}Ca_{0.4}Ti_{0.995}Pt_{0.005}O_{3-x}$ for 4 h by polarizing at 0.7 V vs RHE. We monitored 27 % and 9 % decay in performance for reduced $La_{0.4}Ca_{0.3925}Ba_{0.0075}Ti_{0.995}Pt_{0.005}O_{3-x}$ and $La_{0.4}Ca_{0.4}Ti_{0.995}Pt_{0.005}O_{3-x}$, respectively.

4. CONCLUSIONS

Overall, reduced $La_{0.4}Ca_{0.4}Ti_{0.995}Pt_{0.005}O_{3-x}$ prepared by sol-gel technique exhibits good electrocatalytic stability and superior mass ORR activity. Superior electrocatalytic activity of solgel derived sample is attributed to the better exsolution behaviour of Pt nanoparticles, higher surface area and better accessibility of electrocatalytically active sites compared to perovskite oxides synthesised by solid-state reaction method.

ABSTRACT

Hydrogen has gained considerable attention as a zero-emission fuel due to its potential to significantly reduce the environmental impacts of fossil fuel usage and contribute to decarbonization efforts. However, the development of safe, efficient, and environmentally friendly hydrogen storage technologies remains a significant challenge to its widespread adoption. Sodium borohydride has emerged as a key material for hydrogen storage and production due to its high hydrogen content and controllable release properties. This study investigates the potential of graphitic carbon nitride (g-C3N4) as a support material for enhancing the performance of Co-B catalysts in NaBH4 hydrolysis. The catalysts were synthesised using a chemical reduction method, and the effect of different g-C3N4 concentrations was thoroughly analysed. Experimental results demonstrated that the optimal addition of g-C3N4 to the Co-B catalyst increased the hydrogen generation rate by approximately 2.6 times compared to the Co-B catalyst. Additionally, the activation energy of the hydrolysis reaction was found to be 72.07 $kJ \cdot mol^{-1}$. These findings underscore the necessity for precise catalyst composition to optimize performance and underscore the value of further research into reaction kinetics and structural optimization. These findings highlight the potential of g-C3N4 as an effective material in NaBH4 hydrolysis, offering a pathway to more efficient and sustainable hydrogen production.

Keywords: Hydrogen storage, Sodium borohydride, g-C3N4, Co-B catalysts

1. INTRODUCTION

The global energy crisis has given rise to a significant increase in interest in clean, economic and sustainable energy alternatives [1]. Hydrogen stands out as a promising energy source due to its high calorific value, which makes it an efficient fuel, and its environmentally friendly combustion products, which contribute to reducing pollution and greenhouse gas emissions. Additionally, hydrogen is considered a sustainable energy carrier, as it can be produced from renewable resources, making it an attractive alternative to fossil fuels. However, despite these advantages, several challenges remain in the widespread adoption of hydrogen as a mainstream energy source. The safe production, storage, and transportation of hydrogen are critical issues that hinder its large-scale deployment. In this context, sodium boron hydride (NaBH4) is an attractive candidate for hydrogen storage and production due to its impressive hydrogen storage capacity, which reaches up to 10.8% [2]. The hydrolysis of $NaBH_4$ under ambient conditions proceeds slowly, with a low conversion rate. Catalysts play a crucial role in enhancing the conversion rates, accelerating the reaction kinetics, and facilitating the reaction under these conditions. Catalysts used in the hydrolysis reaction face significant challenges, primarily due to deactivation caused by the formation of polyborates. These polyborates can form on the catalyst surface, leading to a reduction in catalytic efficiency. To address this issue, it is crucial to design and develop effective support materials that can not only prevent the agglomeration of metal particles but also enhance the overall surface area of the catalyst [3]. The utilisation of support materials has been shown to enhance catalytic performance and stability by increasing the surface area of the catalyst and improving the dispersion of nanoparticles. Materials such as carbon-based supports, metal oxides and zeolites play a critical role in hydrogen production processes by providing structural stability and optimising mass transfer [4]. In this context, graphitic carbon nitride (g-C3N4) is a particularly noteworthy support material due to its high chemical stability, non-toxicity and low cost [5,6]. Its planar structure facilitates electron conduction, ensuring effective performance in catalytic processes. It also increases catalytic efficiency and provides long-term stability through complexation with pyridine-like nitrogen atoms and metal ions [7]. The catalytic potential of g-C3N4 is being explored through various modification strategies, including the incorporation of different elemental dopants to form composite catalysts. The incorporation of non-metallic elements, including N, O, S, B, and P, into g-C3N4 has been identified as a highly effective modification strategy [8–10]. The superior properties of Co-B catalysts in $NaBH_4$ hydrolysis have been emphasized by numerous researchers [11–13]. The present study aims to explore the hydrogen production efficiency derived from the hydrolysis of $NaBH_4$ by investigating the superior properties of Co-B and g-C3N4 components. In this context, the effect of adding varying amounts of g-C3N4 to the Co-B catalyst will be experimentally investigated. By systematically varying the composition of the g-C3N4 content on the Co-B catalyst, the study seeks to evaluate the impact of this modification on the overall catalytic performance.

2. MATERIALS AND METHODS

In this section, details of catalyst preparation and hydrogen releasing processes have been summarized. All the chemicals used in this study were of analytical grade and employed directly without any additional purification steps.

2.1. Catalyst Preparation

In this study, pure Co-B and g-C3N4 supported Co-B-g-C3N4 catalysts were synthesised by chemical reduction method. A specific amount of g-C3N4 was added to an ethanol solution and placed in an ultrasonic bath for 1 hour to ensure a homogeneous mixture. Subsequently, a 0.02 M CoCl2 solution was prepared and added to the mixture, which was then stirred continuously using a magnetic stirrer. The initial pH value of the solution was recorded using a WTW Multi 3420 pH meter. The final pH of the solution was adjusted to 4 using NaOH and HCl. Subsequently, the solution was cooled to 6°C in a circulating water bath, and the reduction process was achieved by the dropwise addition of 10 mL of aqueous sodium borohydride solution under vigorous stirring. The obtained black precipitate exhibited magnetic properties, allowing it to be separated magnetically. The resulting black precipitate was washed with distillate water and ethanol to remove residual ions. The precipitate were then dried in an oven at 105°C for a minimum of 8 hours and then pulverised in a mortar and pestle to yield a fine powder.

2.2. Hydrogen Releasing Tests

An important parameter for evaluating the performance of catalysts in the sodium borohydride hydrolysis process is the hydrogen generation rate (HGR). This parameter is expressed as the volume of hydrogen generated (in milliliters) per minute per gram of catalyst. The amount of hydrogen was quantified using a water displacement method in a temperature-controlled reactor, which maintained a constant temperature within an accuracy of ±0.5 ℃. The HGR tests were conducted using the experimental setup schematically depicted in Fig. 1.

The experimental procedure involved the amalgamation of sodium borohydride, sodium hydroxide pellets, and distilled water within a small beaker. This mixture was then placed in a heater, with the temperature set to 65°C. The precise mass of the catalyst, near 6 mg, was measured using an analytical balance. The heated fuel was then transferred to a volumetric flask. The mouth of the flask was sealed with a flexible hose connected to a bubbler and a gas burette to direct the gas outlet. It is imperative to note that the reaction temperature was maintained at a constant level throughout the duration of the experiment.

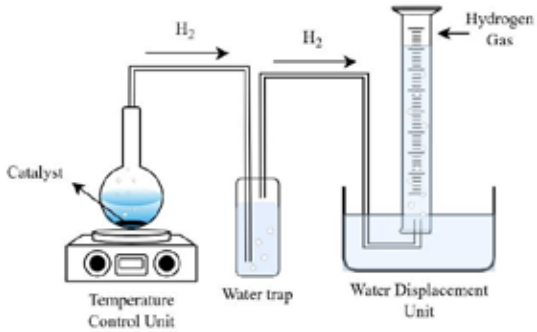

Fig. 1. Schematic representation of the experimental setup.

Total released hydrogen per gram catalyst and minute ($Lg^{-1}min^{-1}$) is defined as hydrogen generation rate:

$$HGR = L_H2/(g_cat * min) \quad (1)$$

3. RESULTS AND DISCUSSION

The performance of pure Co-B and modified Co-B with g-C3N4 catalysts was systematically evaluated based on their hydrogen generation rates (HGR). The proportion of the g-C3N4 precursor in the synthesized catalyst was optimized to maximize hydrogen production. Fig. 2 shows that incorporating different quantities of g-C3N4 into the Co-B catalyst, ranging from 1 to 30 mg, notably influences the hydrogen production rate. It has been observed that increasing the loading of g-C3N4 beyond 10 mg leads to a decline in catalytic activity. As a result, the optimal amount of g-C3N4 precursor in the Co-B catalyst composition has been identified as 10 mg. This result is clearly supported by the HGR results presented in Fig. 2b. The addition of g-C3N4 has led to achieving a maximum hydrogen production rate of 37.26 $L \cdot g_{cat}^{-1} \cdot min^{-1}$, which signifies an impressive enhancement compared to the Co-B (14.01 $L \cdot g_{cat}^{-1} \cdot min^{-1}$) catalyst. This substantial increase in activity indicates the considerable potential of g-C3N4 in enhancing catalytic activity, likely attributable to its capacity to provide a high surface area, enhanced dispersion of active sites, and improved interaction with the Co-B alloy. The observed decrease following the addition of a certain amount of g-C3N4 can likely be attributed to the excessive loading of g-C3N4, which may result in several issues. These include steric hindrance, which can

obstruct the interaction between the catalyst and the reactants, and the saturation of active sites, reducing the availability of catalytic sites for the reaction. Furthermore, the excessive amount of g-C3N4 might cause increased particle aggregation, which in turn can hinder the efficiency of mass transfer. This reduced mass transfer efficiency, coupled with the other factors, ultimately limits the overall performance.

Under the optimum reaction conditions, the hydrogen production rate of the identified catalyst was determined at different temperatures. The temperature range was controlled and tested between 65°C and 45°C with a 5°C temperature gradient. This study was also conducted to determine the activation energy associated with the hydrogen production process. The experimental results demonstrate that high temperatures have a significant impact on the catalytic hydrogen production performance of the catalyst, in line with expectations. To investigate the reaction kinetics of the catalyst, the apparent activation energy of the catalyst, which catalyzes the reaction of sodium borohydride, was determined based on experimental data collected at various temperatures. The activation energy (Ea) of the catalyst was calculated using the Arrhenius equation as follows.

$$lnk = lnk_0 - \frac{E_a}{R}\left(\frac{1}{T}\right) \quad (2)$$

The equation represents the rate of hydrogen production (k) in terms of several key parameters: k_0, the frequency factor; E_a, the activation energy (measured in kJ·mol^{-1}); R, the ideal gas constant (8.314 kJ·mol^{-1}·K^{-1}); and T, the temperature of the reaction (in Kelvin).

The activation energy of the catalyst reaction, calculated from the slope of the ln(k) versus 1/T curve presented in Fig. 3, was found to be 72.07 kJ·mol^{-1}. This value is lower than the activation energy of 75 kJ·mol^{-1} reported by Kaufman and Sen [14] for cobalt-based catalysts. The reaction was completed within four minutes and forty-four seconds at the 65°C temperature, producing a total of 1000 ml. However, at a lower temperature of 300 K, the same reaction took approximately 20 minutes to reach completion.

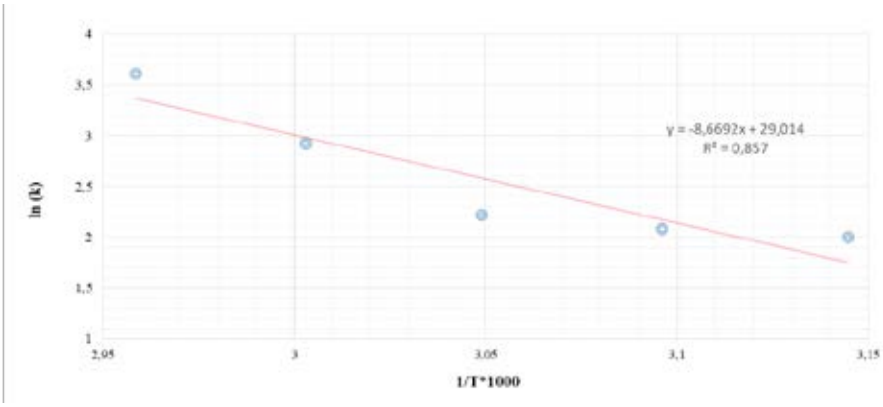

Fig. 3. Kinetic curves of hydrogen production at different temperatures.

4. CONCLUSIONS

In present study, the addition of various g-C3N4 to the Co-B catalyst under the given experimental conditions has demonstrated a significant improvement in hydrogen production rate. The results show that the incorporation of g-C3N4 leads to a maximum hydrogen production rate of 37.26 $L \cdot g_{cat}^{-1} \cdot min^{-1}$, which is notably higher than the rate observed for the Co-B catalyst (14.01 $L \cdot g_{cat}^{-1} \cdot min^{-1}$). Furthermore, the activation energy of the catalytic reaction, calculated to be 72.07 $kJ \cdot mol^{-1}$, suggests that the modified catalyst exhibits favorable catalytic efficiency. These findings indicate that g-C3N4 is a promising material for enhancing the performance of Co-B catalysts in $NaBH_4$ hydrolysis, providing a pathway for more efficient and sustainable hydrogen production systems.

ABSTRACT

Domestic heating contributes to 10% of the total Dutch CO_2 emissions. Heat pumps are a sustainable way to produce heat efficiently. However, in winter, their performance reduces, renewable energy supply is low, and heat demand is high, resulting in high electricity prices. Adding a fuel cell to the system enables the utilization of waste heat produced during the conversion of hydrogen to electricity. The integration improves both the overall system efficiency and fuel cell's heat utilization. We assess the economic viability through system simulation of different energy system configurations with a zero-dimensional model controlled by a model predictive controller as an energy management system. Under current market conditions, adding a heat pump-fuel cell system has a low marginal gain compared to a stand-alone heat pump or solar panels. However, the fuel cell dynamics mitigate the heat pump shortcomings during periods of high heat demand and/or price peaks, making it an interesting solution for certain applications.

Keywords: low temperature proton exchange membrane fuel cell, air-source heat pump, model predictive control, combined heating and power system, techno-economic analysis

1. INTRODUCTION

Currently, domestic heating contributes to approximately 10% of the total CO_2 emissions in the Netherlands [1], and more than 85% of the family houses rely on the combustion of natural gas to produce heat [2]. A new generation of energy systems is required to reduce this dependency on fossil fuels, which achieve better or comparable efficiencies and comfort levels as conventional methods. Air-source heat pumps (HP) are gaining interest due to their operation on low-emissions electricity [3]. They extract energy from their surroundings to transfer heat inside a building [4], and they produce multiple times more heat per unit of electricity input than conventional heaters, making them very efficient heating devices [5]. However, in winter, their performance reduces, renewable energy supply is low, and heat demand is high, resulting in high electricity prices. These periods are called dark doldrums. Here, Fuel Cells (FC) come into the picture.

Integrated systems of hydrogen fuel cells and heat pumps simultaneous generate power and heat. This system potentially reduces grid dependency and greenhouse gas emissions [3]. FCs produce a substantial quantity of heat in addition to electricity. This heat improves the total system efficiency to 76%-90% (HHV) [6]. Furthermore, FC systems with solar power are already comparable in price to fossil fuel alternatives for remote off-grid applications [7]. Despite the low quality of the heat recovered from an FC, the heat in the coolant stream is sufficient to be captured and utilized for a wide range of heating applications [8]. Heat recovery from proton exchange membrane FCs has multiple advantages, although it is not always cost-effective. Therefore, there is a need to investigate the combination of a hydrogen fuel cell and heat pump to cover heat demand [9].

This study evaluates the performance of the fuel cell-heat pump system in a typical residential family building in the Netherlands to determine the economic viability and required system dimensions. Since many buildings have already installed solar panels [2] and the presence of lithium-ion battery energy storage is increasing, adding more energy systems will change the marginal payback time of the overall system. Which conditions have a positive business case for utilizing an integrated fuel cell-heat pump system for domestic applications?

This short paper is structured as follows: Section 2 describes the model and energy management system to simulate the system behavior and costs. Section 3 presents the results and discussion of the simulations. Finally, Section 4 concludes the paper.

2. MODELING

In this section, the model inputs, energy systems, energy management system and various system configurations are explained together with their assumptions to evaluate the energy consumption and system behavior.

2.1 Energy demand

We consider the energy demand of a residential building to assess the marginal gain of a heat pump-fuel cell system. The energy demand consists of electricity, space heating, and hot water consumption, which fluctuate throughout the

day and year. Furthermore, building size and occupancy also influence the energy demand. Heating demand profiles are retrieved from Staffel et al., which utilize weather data and the heat capacity of a building to determine the heat demand [10]. The hot water consumption profiles are retrieved from the European energy labeling standard [11]. Waiting times for hot water are neglected because of the presence of the buffer tank. The heat demand is highly seasonal, while hot water consumption remains constant throughout the year. The yearly heat demand is equivalent to 1722 m^3 of natural gas. The annual electricity demand is set equivalent to 3650 kWh. The daily and seasonal patterns in electricity consumption are implemented, using the variation factors described by Melo et al. [12].

2.2 Energy systems

Energy systems are present in domestic buildings to satisfy their heat and power demand, schematically represented in Figure 1. The system is evaluated as a zero-dimensional model, describing the energy flows through the system. The FC and solar panels (PV) produce electricity to meet the demand. In case of an electricity deficit or surplus, electricity is exchanged with the electricity grid or stored in a battery energy storage system (BESS). The water circulation through the heat pump and the cooling circuit of the fuel cell provides heat to the buffer tank. The hot water is then distributed to the heating system and hot water consumers, after which the cooled-down water flows back to the buffer tank. A connected gas pipeline supplies the fuel to the fuel cell.

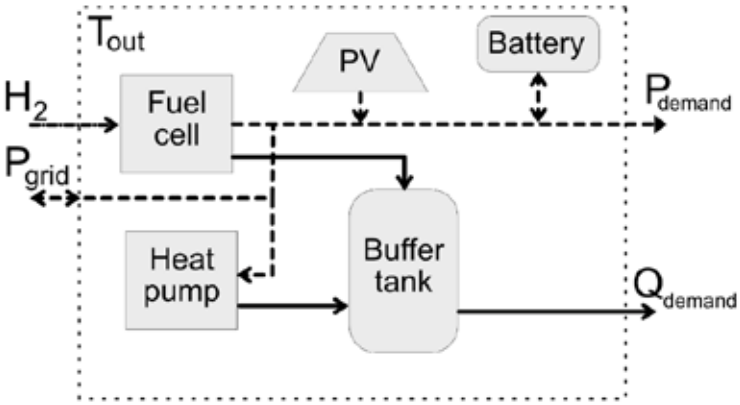

Fig. 1. Schematic representation of the energy systems

2.2.1 Fuel cell

The fuel cell produces both power and heat as the conversion from hydrogen to electricity is not fully reversible. This is described in equation 1. The fuel cell is assumed to operate with a constant efficiency.

$$\begin{bmatrix} P_{FC}[k] \\ Q_{FC}[k] \end{bmatrix} = \begin{bmatrix} \eta_{FC} t_s h_{HHV} \dot{m}_{H_2}[k] \\ (1-\eta_{FC}) t_s h_{HHV} \dot{m}_{H_2}[k] \end{bmatrix} = \begin{bmatrix} \eta_{FC} u_{FC}[k] \\ (1-\eta_{FC}) u_{FC}[k] \end{bmatrix} \quad (1)$$

2.2.2 Heat pump

The HP's heat output is a function of the input power and the coefficient of performance (COP), shown in equation 2.

$$Q_{\mathrm{hp}}[k] = \mathrm{COP}[\Delta T[k]] * P_{\mathrm{hp}}[k] \quad (2)$$

The COP is temperature dependent. The larger the difference between the source and the sink, the lower the COP. defines a relation for the COP in equation 3 between the difference in sink and source temperature $\Delta T = T_{\mathrm{tank}} - T_{\mathrm{out}}$ [13].

$$\mathrm{COP}(\Delta T) = 6.08 - 0.0941\Delta T + 0.000464\Delta T^2 \quad (3)$$

2.2.3 Other systems

The state of charge describes the energy content in the battery. Electricity cannot be stored in its original form and must be converted into other forms of energy. Batteries, consisting of chemical cell arrays, store the electrical energy in chemical bonds. However, the charging and discharging processes are irreversible, resulting in energy losses.
The solar panels are sized according to the yearly power demand of the home appliances. The power output of the photovoltaic panels was determined with the model of [10]. This model combines the geographic location, solar radiation,

panel efficiency, outside temperature, angle with the sky, and peak power to determine the output power.
We model the buffer tank as a large tank filled with water. Its state describes its average temperature. Over time, the tank loses energy to its surroundings. The fuel cell and heat pump heated the water inside the buffer tank, and the heating and hot water utilized this water. The temperature range is between 50°C and 70°C.

2.2.4 Grid inputs

Hydrogen pipelines and a low-voltage electric power grid connect the residential building to power and hydrogen utilities. The electricity grid is regarded as an inexhaustible energy source that provides and receives power. Domestic buildings buy and sell energy from this grid. Electricity prices are considered dynamic and change on an hourly basis. The fluctuation is based on current market conditions, described by the day-ahead prices. Another price component is the grid fees and taxes for charging energy from the grid. The hydrogen price is assumed to be equal to natural gas prices.

2.3 Energy management system

An energy management system determines which energy systems are addressed to meet the energy demand. Since there is no trivial solution to decide on the control action, we implement a Model Predictive Controller (MPC) to determine the most appropriate control action at each time step. This type of control uses a dynamic model to predict future system behavior for a specific control horizon. The advantage of MPC is its usability for a large variety of problems and guarantee of optimum [14]. The dynamic of the house's energy systems are combined in a linear time-varying model, shown in equation 4.

$$\begin{bmatrix} E_{\mathrm{BESS}}[k+1] \\ P_{\mathrm{grid}}[k+1] \\ T_{\mathrm{BT}}[k+1] \end{bmatrix} = \begin{bmatrix} \eta_{\mathrm{selfdis}} & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & \eta_{\mathrm{loss}} \end{bmatrix} \begin{bmatrix} E_{\mathrm{BESS}}[k] \\ P_{\mathrm{grid}}[k] \\ T_{\mathrm{BT}}[k] \end{bmatrix} + \begin{bmatrix} 0 & 0 & -1 \\ -\eta_{\mathrm{FC}} & 1 & -1 \\ c_p * \eta_{\mathrm{FC}} & c_p * \mathrm{COP}[\Delta T] & 0 \end{bmatrix} \begin{bmatrix} u_{\mathrm{FC}} \\ P_{\mathrm{HP}} \\ P_{\mathrm{BESS}} \end{bmatrix} + \begin{bmatrix} 0 & 0 & 0 \\ -1 & 0 & 1 \\ 0 & -c_p & 0 \end{bmatrix} \begin{bmatrix} P_{\mathrm{PV}}[k] \\ Q_{\mathrm{demand}}[k] \\ P_{\mathrm{demand}}[k] \end{bmatrix} \quad (4)$$

2.4 Optimal control

The MPC finds the optimal control action to match the current heat and power demand, minimizing the operation cost and penalizing excessive output switching of the fuel cell and heat pump. This optimization problem is quantified in a linear cost function, shown in Equation 5. The stage cost has a control horizon of N=12 hours. The MPC calculates the optimal control action for the entire control horizon in each time step. However, we only implement the control action for the next time step, and then the optimal control horizon is calculated again in the next iteration. Since most physical systems are bounded, a set of constraints defines the feasibility domain of the cost function. The energy systems' power outputs are unbounded to estimate maximum system sizes.

$$J[k] = \sum_{j=0}^{N-1} C_{\mathrm{grid}}[k+j] P_{\mathrm{grid}}[k+j] + \sum_{j=0}^{N-1} C_{\mathrm{H_2}} P_{\mathrm{FC}}[k+j] + W_{\mathrm{FC}} \sum_{j=0}^{N} |P_{\mathrm{FC}}[j] - P_{\mathrm{FC}}[j-1]| + W_{\mathrm{HP}} \sum_{j=0}^{N} |P_{\mathrm{HP}}[j] - P_{\mathrm{HP}}[j-1]| \quad (5)$$

2.5 System configurations

To assess the added value of an integrated heat pump-fuel cell system, we analyzed various energy system configurations to determine the impact of additional energy systems on the marginal gain and payback time. The considered configurations are the following:

1. Electric heater
2. HP
3. PV + HP
4. PV + HP + FC
5. PV + BESS + HP + FC

In the first scenario, only an electric heater was considered because it is a simple and cheap method for heat production. Despite its electric efficiency being 100%, heat pumps exhibit significantly higher efficiencies. Therefore, in the second scenario, a heat pump replaced the electric heater. Thereafter, an additional energy system is added in each scenario.

We simulate the various configurations for an entire year to evaluate the system's behavior and determine the energy consumption. The Total Cost of Ownership (TCO) quantifies the overall system costs by combining the initial capital expenditures and the yearly operation costs. The initial capital expenditures depend on the energy systems' size. The marginal gain is calculated by determining the reduction in operation costs compared to the additional investment costs.

3. RESULTS AND DISCUSSION

Simulating the various configurations shows that heat pumps and solar panels cover a significant portion of the annual energy demand. The fuel cell operates during the morning and evening price peaks when electricity is more expensive than natural gas, typically in winter due to low renewable energy inflow, low outdoor temperatures, and high demand. In

those hours, operating the heat pump is less effective. In certain cold periods with high heat demand, the EMS operates the fuel cell continuously. In those periods, the fuel cell provided enough electricity that the building was not required to import electricity from the grid. The EMS minimizes power export by prioritizing the more economically advantageous options of using the energy, charging the battery, or buffer tank. In summer, the low electricity price results from a substantial inflow of renewable energy, making fuel cell operations less cost-effective. Also, adding batteries to the energy system reduces the fuel cell operation hours. The battery cycles daily, charging during periods with low electricity prices and discharging in the evening hours.

The economic results of the various configurations are shown in Table 1. Heat pumps and solar panels in scenarios 2 and 3 are the most cost-effective measures to reduce the energy bill with a reasonable payback time compared to the electric heaters in scenario 1. Adding a fuel cell to the system in scenario 4 had no significant effect on the operation costs. They were even higher due to losses caused by the unused buffer tank during fuel cell operations. Furthermore, this configuration required high initial capital. However, this configuration required a smaller heat pump. The addition of a battery system in scenario 5 had a minor effect on the operation cost, but the high initial cost resulted in a long payback time.

Table 1. Energy system operation costs, additional investment costs and payback time for the different scenarios

Scenario	Yearly cost electricity	Yearly cost H_2	Sum yearly operation cost	Cost index (Scen.1=100)	P_{pv} [kW]	$P_{hp,max}$ [kW]	$P_{fc,max}$ [kW]	E_{bess} [kWh]	Additional investment [15]	Payback time [years]
1	€ 2,937.00	€ -	€ 2,937.00	100	0.00	11.20	0.00	0.00		
2	€ 1,202.00	€ -	€ 1,202.00	41	0.00	4.22	0.00	0.00	€ 5,013.50	2.9

4. CONCLUSIONS

The fuel cell dynamics mitigate the heat pump shortcomings during periods of high heat demand and/or price peaks, making it an interesting solution for certain applications. However, the economic viability of a heat pump-fuel cell system for domestic applications is largely dependent on the development of the prices on hydrogen and fuel cell systems. In the current market, utilizing electricity from the grid and producing heat with just a heat pump, even in conditions with reduced COP, is more cost effectively to fulfill household's energy demand.

Future investigations will evaluate scenarios involving CO_2 emissions pricing, rush hour-based grid fees and electric car charging. These evaluations could provoke a favor for utilizing hydrogen in an integrated fuel cell - heat pump system. This is because green hydrogen has a significant lower CO_2 emission, the grid fees increase price of utilizing the electricity grid, making local production favorable and electric car charging has a large impact on the electricity grid demand as well.

An interesting application arises in the context of a centralized heat pump-fuel cell system. If small scale decentralized fuel cells are not economically viable, a centralized fuel cell could supply heat to a district heating network during winter. Centralized heating network benefit from their economy of scale. Therefore, there is a potential business case for the co-generation of power and heat with centralized heat pump-fuel cell systems.

ABSTRACT

This study investigates the synthesis and electrochemical performance of CoAl layered double hydroxide (LDH) catalysts prepared via two distinct methods: a conventional approach and a novel ultrasonic spray synthesis. The ultrasonic spray synthesis, employing a vapor-liquid interface reaction, is introduced for the first time as a scalable and innovative method for CoAl LDH preparation. Comparative analyses were conducted using scanning electron microscopy (SEM), energy-dispersive X-ray analysis (EDAX), Fourier Transform Infrared Spectroscopy (FT-IR), and cyclic voltammetry (CV). Morphological characterization revealed significant differences in particle size and surface texture between the two synthesis methods, with the ultrasonic spray approach producing more uniform and porous structures. Elemental composition analysis confirmed the successful incorporation of Co and Al in both catalysts. Electrochemical performance demonstrated improved catalytic stability and enhanced charge transfer properties for the catalyst synthesized via ultrasonic spray. These findings highlight the potential of ultrasonic spray synthesis as a cost-effective and efficient method for developing advanced LDH-based catalysts for electrochemical applications.

Keywords: Ultrasonic spray synthesis, CoAl LDH, electrochemical performance

1. INTRODUCTION

Hydrogen energy is increasingly recognized as a critical component of sustainable energy strategies [1]. In the pursuit of efficient ways to store and convert hydrogen energy, materials like Layered Double Hydroxides (LDHs) come to the forefront due to their versatility in catalytic, electrochemical, and environmental applications [2]. LDHs, consisting of positively charged brucite-like layers and charge-balancing interlayer anions, offer unique properties such as high surface area, tunable composition, and excellent stability, making them promising candidates for energy conversion and storage technologies, including oxygen reduction reactions (ORR) [3, 4]. In this study, we present a novel synthesis route for LDH materials using an ultrasonic spray method. Ultrasonic spray offers advantages such as rapid production, uniform particle size distribution, the creation of crystalline structures, and scalability [5, 6]. To the best of our knowledge, this is the first report on LDH synthesis using ultrasonic spray technology. The synthesized materials were characterized using FT-IR, SEM, and EDAX to investigate structural and morphological differences. Furthermore, electrochemical performance was evaluated through CV to assess their potential in ORR applications. A detailed comparison of the properties and performance between the ultrasonic spray-synthesized LDH and conventionally prepared LDH materials highlights the novelty and efficacy of the new synthesis approach.

2. EXPERIMENTAL

2.1. CoAl LDH Synthesis via Co-precipitation Method

Using a conventional co-precipitation technique, referenced from established literature [7] , we synthesized CoAl-LDH nanosheets, hereafter referred to as “CON-CoAl”. Initially, solutions were prepared by dissolving 2 mmol of cobalt nitrate hexahydrate and 1 mmol of aluminum nitrate nonahydrate into 20 mL of deionized water (Solution A), stirred for 15 minutes. Concurrently, 6 mmol of sodium hydroxide and 5 mmol of anhydrous sodium carbonate were dissolved in an equal volume of deionized water to form Solution B. Solution A was then incrementally introduced into Solution B with continuous stirring. After mixing, the blend was enclosed in a 50 mL Teflon-lined autoclave and subjected to a temperature of 110 °C for a duration of nine hours. Once the process was complete, the resultant solid was isolated through filtration, extensively rinsed with deionized water, and subsequently dried under vacuum conditions at 60 °C.

2.2. CoAl LDH Synthesis via Ultrasonic Spray Method

The ultrasonic spray synthesis method is similar to the conventional co-precipitation method but includes a key variation: Solution A, containing cobalt nitrate hexahydrate and aluminum nitrate nonahydrate in 20 mL deionized water, was atomized into fine droplets using nitrogen gas in an ultrasonic spray atomizer. These droplets were continuously introduced into Solution B, which held dissolved sodium hydroxide and anhydrous sodium carbonate in an equivalent volume of water, under constant stirring. The subsequent steps of autoclave heating, filtration, washing, and drying mirrored the conventional method. The material produced is termed 'US-CoAl', with the setup detailed in Fig. 1.

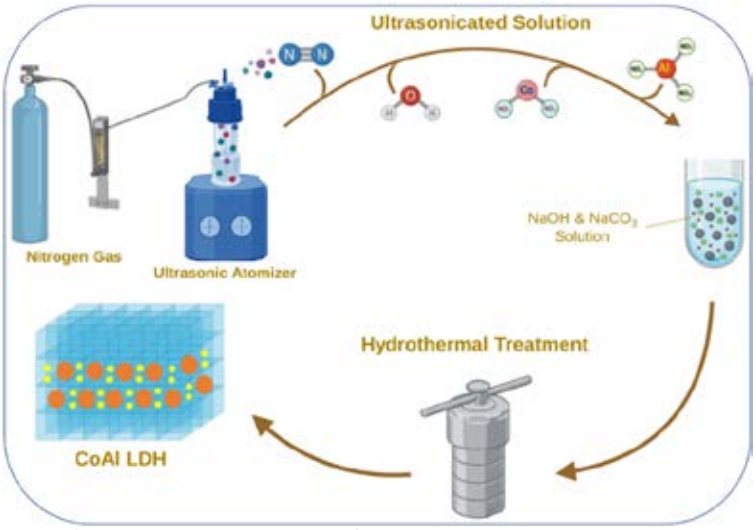

Fig. 1. Schematic representation of the ultrasonic spray synthesis method.

2.3. Material Characterization and Electrochemical Measurements

Analyses involving SEM and EDAX were carried out using a Zeiss EVO LS 10 microscope. FT-IR was employed to characterize the samples in transmission mode under normal conditions, spanning a spectral range from 4000 to 400 cm^{-1}. These measurements were conducted at room temperature using a Thermo Scientific Nicolet 380 spectrometer. Electrochemical characterization, including cyclic voltammetry, was performed with an Ivium Vertex.One potentiostat. A three-electrode system was used, consisting of a platinum wire as the counter electrode, an Ag/AgCl reference electrode, and a glassy carbon electrode (GCE) with a diameter of 3 mm serving as the working electrode. A volume of 5 µL from a 10 mg/mL catalyst suspension was applied onto the surface of the GCE. All electrochemical tests were carried out in 0.1 M KOH solution saturated with oxygen gas (O_2), with the CV scans conducted at a rate of 10 and 100 mV/s.

3. RESULTS AND DISCUSSION

The FT-IR spectra of both US-CoAl and CON-CoAl LDH samples demonstrated in Fig. 2 align with literature values for layered double hydroxides (LDHs) [8]. A broad band near 3434 cm^{-1} corresponds to O–H stretching of water molecules or hydroxyl groups in the brucite-like layers [9]. The absence of peaks in the 2931–2864 cm^{-1} range indicates a lack of organic C–H groups. A strong band around 1176 cm^{-1}, present in both samples, corresponds to carbonate ion (CO_3^{2-}) asymmetric stretching, as commonly observed near 1360 cm^{-1} [10]. In the 400–800 cm^{-1} range, peaks at 497 cm^{-1} and 576 cm^{-1} for US-CoAl, and at 418 cm^{-1} for CON-CoAl, align with M–O and M–OH vibrations characteristic of LDHs [11]. These findings confirm the structural integrity and functional features of CoAl-LDHs.

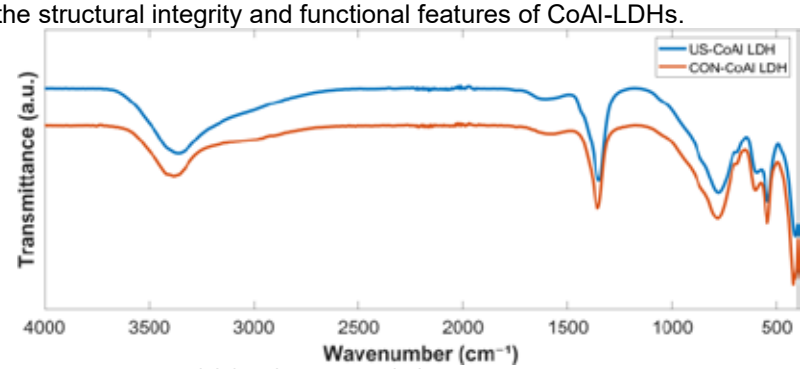

Fig. 2. Analysis of CON-CoAl and US-CoAl LDHs using FT-IR spectroscopy.

SEM analysis revealed distinct morphological differences between the CoAl LDH catalysts synthesized using the conventional method (Fig. 3a, b) and the ultrasonic spray synthesis approach (Fig. 3c, d). Hydrothermal treatment has been reported to improve CoAl LDH materials by forming compact nanosheets [12], which is evident in the conventional synthesis. However, the material produced through this method exhibited larger, aggregated particles with irregular shapes and dense packing, indicating a lower surface area and limited accessibility of active sites, potentially restricting catalytic efficiency. In contrast, the ultrasonic spray-synthesized CoAl LDH displayed a uniform and porous structure, characterized by well-dispersed nanosheets or smaller particles. This morphology results in a higher surface area and improved accessibility of active sites, enhancing catalytic activity. Additionally, the increased porosity observed with the ultrasonic spray method facilitates better mass transport, a critical factor for electrochemical reactions.

EDAX confirmed the successful incorporation of cobalt and aluminum in both catalysts. Figs. 3e and 3f demonstrate the elemental mapping of the conventional method and ultrasonic spray-synthesized CoAl LDH material, respectively. It is evident that both methods achieved the intended stoichiometry, as shown in Figs. 3g and 3h. Additionally, the uniform distribution of elements in both catalysts is clearly visible. This homogeneity ensures the effective utilization of active sites during electrocatalytic reactions.

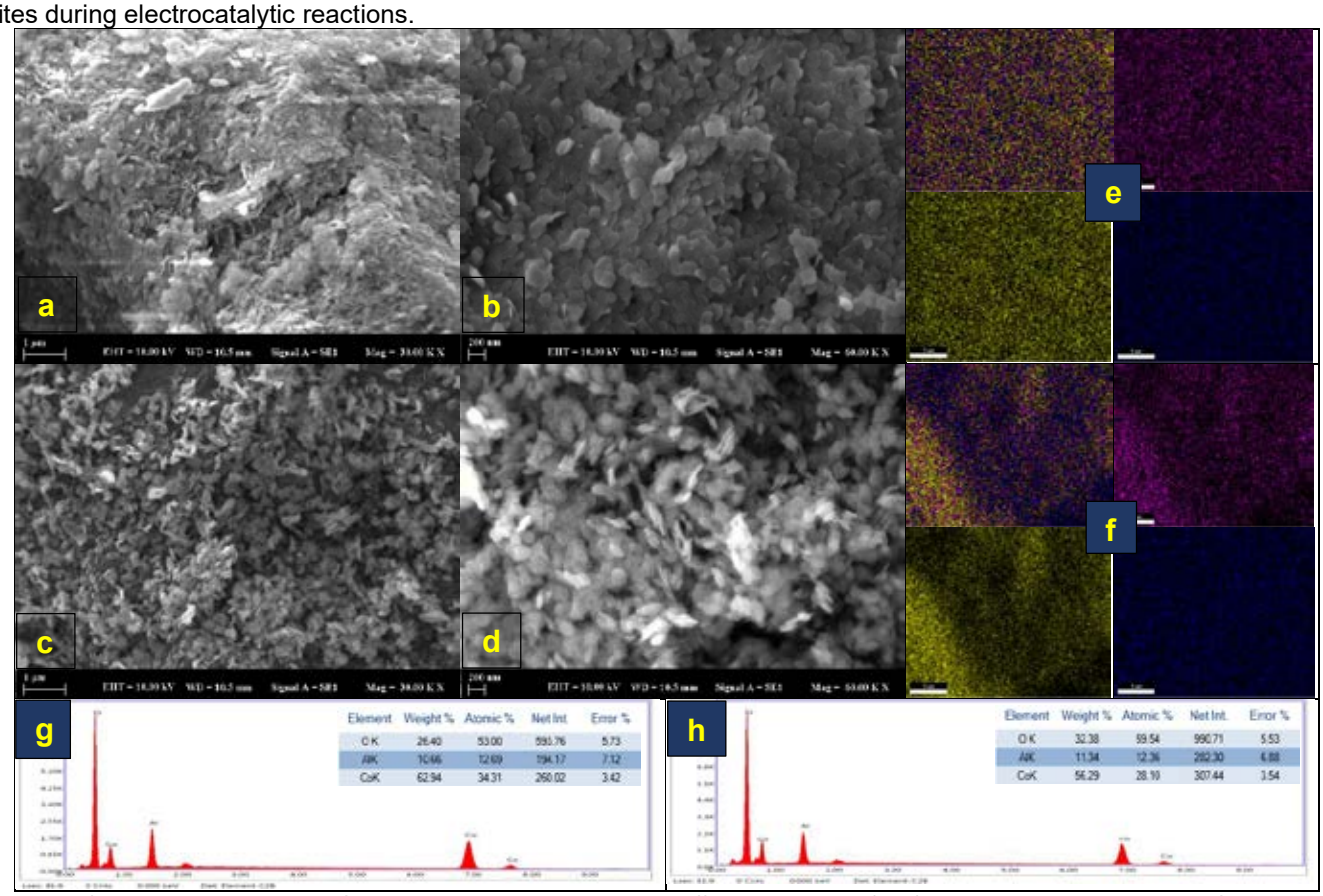

Fig. 3. SEM images comparing CoAl LDH catalysts prepared by different methods: (a, b) conventionally synthesized CoAl LDH, showing larger, aggregated particles with irregular morphology; (c, d) ultrasonic spray-synthesized CoAl LDH, exhibiting a uniform, porous structure with well-dispersed nanosheets. EDAX elemental mapping of (e) conventionally synthesized and (f) ultrasonic spray-synthesized catalysts. Stoichiometry validation for (g) conventional and (h) ultrasonic spray methods.

Both LDH materials exhibit the same peak current at a scan rate of 10 mV/s, which aligns with the literature [13], as shown in Fig. 4a, indicating similar levels of maximum ORR activity. However, the peak potential differs slightly, with US-CoAl LDH displaying a more negative peak potential. A more negative peak potential can indicate slightly better catalytic activity, as it suggests that the catalyst can reduce oxygen at a lower overpotential. These results suggest that the LDH produced via ultrasonic synthesis might be slightly more effective or efficient at catalyzing the ORR under the given experimental conditions.

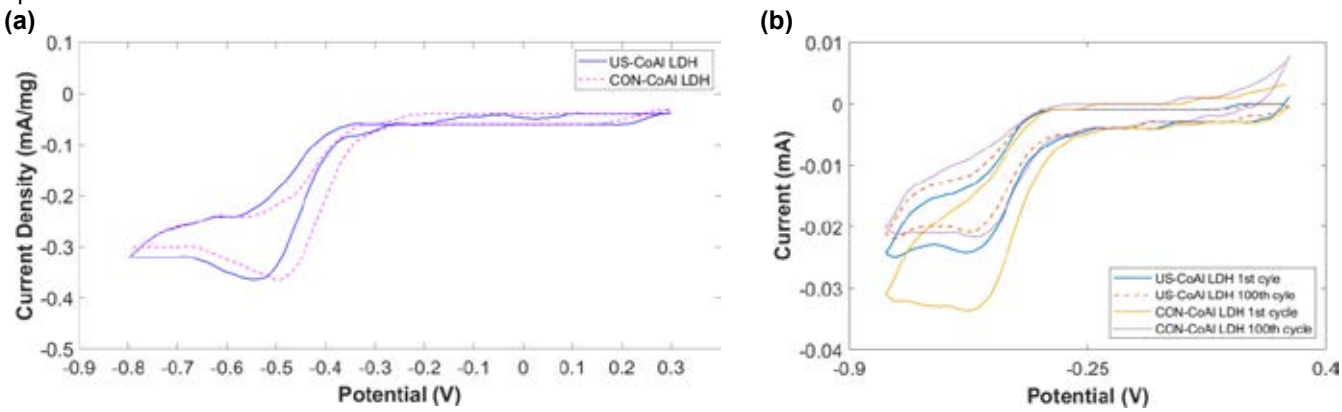

Fig. 4. Cyclic voltammetry analysis of CON-CoAl and US-CoAl LDHs: (a) at a scan rate of 10 mV/s and (b) at 100 mV/s over 100 cycles.

The electrochemical stability of CON-CoAl LDH and US-CoAl LDH catalysts was evaluated over 100 cycles using CV at 100 mV/s scan rate. The stability assessment focused on the changes in peak current between the first and last cycles. For CON-CoAl LDH, the peak current decreased from 0.034 mA in the first cycle to 0.022 mA in the 100th cycle, as shown in Fig. 4b. This corresponds to a 35.3% degradation in activity, indicating a significant decline in performance. In contrast, for the US-CoAl LDH catalyst, the peak current decreased from 0.025 mA in the first cycle to 0.022 mA in the 100th cycle, as shown in Fig. 4b. This corresponds to a 12.0% degradation, suggesting a relatively better retention of activity compared to CON-CoAl LDH. The data indicate that US-CoAl LDH exhibits superior electrochemical stability under identical conditions, with a significantly lower percentage degradation of peak current. In contrast, CON-CoAl LDH shows a higher degradation rate, suggesting a more pronounced loss of catalytic activity over time.

4. CONCLUSIONS

This study highlights the synthesis and electrochemical performance of CoAl LDH catalysts prepared via conventional and ultrasonic spray methods. Both catalysts demonstrated similar maximum oxygen reduction reaction (ORR) activity at a scan rate of 10 mV/s, with comparable peak currents. However, US-CoAl LDH exhibited a more negative peak potential, indicating slightly better catalytic activity due to its ability to reduce oxygen at a lower overpotential. Stability testing over 100 cycles at 100 mV/s revealed that US-CoAl LDH retained 88% of its initial activity, compared to 64.7% for CON-CoAl LDH, confirming the superior durability of the ultrasonic spray-synthesized material.
The improved electrochemical durability and heightened catalytic performance of US-CoAl LDH indicate its viability for use in systems that convert energy, such as in fuel cells and metal-air batteries, where robust stability and effective oxygen reduction reaction (ORR) catalysis are essential. To further improve its performance, integrating other materials, such as conductive carbon supports, graphene derivatives, or doping with noble metals, could boost charge transfer properties and overall activity. These findings underscore the viability of ultrasonic spray synthesis for producing advanced, scalable, and cost-effective catalysts tailored for next-generation energy systems.

ABSTRACT

The several fuel mixtures, including gasoline-bioethanol combinations (E10 and E70), this work explores the effects of hydrogen and oxygen (HHO) gas on the ecological and energy efficiency characteristics of a spark ignition (SI) engine, were used. Under several air excess ratios (λ), experimental investigation was carried out to assess the effects of HHO gas on brake thermal efficiency (BTE), fuel economy, and emissions. Especially in lean mixtures, results demonstrate that adding HHO gas greatly increases BTE and lowers hazardous emissions including nitrogen oxides (NOx), hydrocarbons (HC), and carbon monoxide (CO). E70 gasoline combined with HHO gas showed the best BTE and lowest emissions, so verifying its possible use as a sustainable solution for maximising engine performance and reducing environmental effect. Programmable control systems and real-time emission analysis were part of advanced experimental settings that guaranteed exact and consistent results, thereby helping to clarify HHO gas as a useful and environmentally benign additive for internal combustion engines.

Keywords: HHO gas, brake thermal efficiency, emissions reduction, bioethanol-gasoline blends.

1. INTRODUCTION

As the use of HHO gas as a fuel additive in internal combustion engines reduces emissions and fuel consumption, it is becoming increasingly important as a sustainable way to improve the environmental friendliness and energy efficiency of gasoline engines. Studies show that HHO gas burns more efficiently overall, reduces fuel consumption in a certain range, and increases the brake thermal efficiency. Including HHO gas increases the indicated mean effective pressure (IMEP) and reduces the burning time. The lean of the combination will determine the outcomes, though [1,2].
Furthermore highly significant are HHO gas cuts in NOx, HC, and CO. Adding relatively little amounts of HHO gas when the engine was idle reduced CO emissions by up to 98% according one study [3]. Burning a mixture of gasoline and bioethanol (E70) with HHO gas reduced CO and HC emissions per another study. When the fuel was not burning completely, the best effects were observed. Further lowering emissions, HO gas accelerates and increases the temperature of burning, hence lowering emissions [4].
One more great advantage is the several applications for HHO gas. Studies have indicated that HHO technologies are more energy efficient since they can be readily included to already in use engine systems. Using HHO gas in power generators and dual-fuel vehicles, for example, improved the thermal efficiency from 28% to 35% and, depending on the load, lowered CO and HC emissions by 7–11% [5]. New technologies such as thermoelectric generators and fast DC power systems are increasingly being used to produce HHO gas [6].
To fully understand the long-term effects of HHO technology on humans, additional research is needed to fully assess engine performance factors such as torque, power, and economy, as well as to determine the technological limits of engine operation [7].
The scientific novelty of this work is confirming under lean mixture conditions the synergistic effects of HHO gas and bioethanol-blended fuels (E70) on lowering emissions (CO, HC, and NOx) and enhancing combustion efficiency. This work also presents cutting-edge experimental methods to assess the practical relevance of HHO gas as a sustainable addition improving gasoline engine ecological and energy efficiency.

2. MATERIALS AND METHODS

The impact of HHO gas on the environmental and energy efficiency of a spark ignition (SI) engine was studied using different fuel mixtures in this study. In the study, E70 fuel (30% gasoline and 70% ethanol) was switched out for E10 fuel (90% gasoline and 10% ethanol) with an extra supply of HHO gas addative. The experiment was carried out using a Nissan Qashqai HR 16DE engine (four cylinders in one cylinder with a four-valve mechanism). It was controlled by a programmable MoTeC M800 electronic control unit (ECU); an AMX 200/100 load bench generated the engine load to

ensure accurate measurement conditions for the study.
Fuel consumption was calculated using an AMX 212F electronic fuel meter; air intake was measured using a BOSCH HFM 5 mass flow meter. The AVL DiCom 4000 analyzer was used to analyze the exhaust gas composition and obtain accurate, consistent emission data. The fuel mixtures were prepared by blending pure gasoline and bioethanol, and their properties were assessed in terms of density, carbon-to-hydrogen (C/H) ratio, and lower heating value. Additionally, a constant flow of 3.8 l/min HHO gas was introduced into the engine's intake manifold to evaluate its effects on combustion processes. Driven by an external energy source, an electrolysis machine created hho gas. With a 700 W power consumption during gas generation, the system's efficiency was at 0.65%. A flashback arrestor was included to the system to protect the HHO generator from any backfire, therefore guaranteeing safety. The throttle was set at 15% and the experimental trials ran at a 2000 rpm constant engine speed. Considering changes in fuel mixture composition and air excess ratio (λ= 1.0, 1.1, 1.2, 1.3, 1.4) the ignition duration was varied over a broad range. This experimental system replicated real-world engine operating circumstances, allowing for a thorough examination of the impacts of fuel mixes and HHO gas delivery under various operating regimes. The study collected data on engine torque, fuel consumption, and BTE. In addition, ecological indicators such as CO, HC, NOx, and CO_2 emissions were measured to thoroughly assess the impact of fuel composition and HHO gas on the engine's performance and emissions.
The findings of this study provide insights into the influence of fuel composition and HHO gas on engine performance and emissions. They also highlight the potential of such fuels and technologies for practical applications in real-world operating conditions.

2.1. Mathematical aparatus

Let $\{(x_i, y_i)\}_{1\le i\le n}$ the set of realisations of features X and Y. Below we analyse the dependence betwen these features as follows (1):

$$y = Ce^{\beta_1 x + \cdots + \beta_k x^k} \tag{1}$$

To estimate the unknown parameters we transform the model (2) to auxiliary form

$$\tilde{y} = \beta_0 + \beta_1 x + \cdots + \beta_k x^k + \varepsilon e^{\beta_1 x + \cdots + \beta_k x^k}, \tag{2}$$

where $\tilde{y} = \log(y)$, $\beta_0 = \log(C)$ and ε is a random variable with $N(0, \sigma^2)$ normal distribution.

The coefficient of determination presents (3) proportion of the variation in the dependent variable that explained by the model and is calculated as follows

$$R^2 = 1 - \frac{\sum_{j=1}^{n} \varepsilon_j^2}{\sum_{j=1}^{n} (\bar{y}_i - \bar{y})^2}, \tag{3}$$

where $\bar{y} = \frac{1}{n}\sum_{j=1}^{n} \tilde{y}_i$.

To assess the quality of the model (1) in explaining the dependent variable (the statistical significance of the model as a whole) at significant level $0 < \alpha < 0$ we define the null hypothesis:
H_0: $R = 0$ (the coefficient of multiple correlation is equal zero or insignificantly differ from zero)
and alternative hypothesis
H_1: $R \neq 0$ (the coefficient of multiple correlation significantly differ from zero).
The test statistic

$$f = \frac{R^2}{1-R^2}\frac{n-k}{k-1}, \tag{4}$$

has Fisher–Snedecor distribution with $(k-1, n-k)$ degrees of freedom.

3. RESULTS AND DISCUSSION

For each fuel type and λ we analyse the influence IT into BTE as follows (5):

$$\log\big(BTE(IT)\big) \overset{def}{=} \log(BTE) = \beta_0^{BTE} + \beta_1^{BTE} IT + \beta_2^{BTE} IT^2 + \varepsilon_{BTE} \tag{5}$$

and the impact of IT on the pollution rate to BTE (6-9):

$$\log\left(\frac{CO}{BTE}(IT)\right) \overset{def}{=} \log\left(\frac{CO}{BTE}\right) = \beta_0^{CO} + \beta_1^{CO} IT + \beta_2^{CO} IT^2 + \varepsilon_{CO,} \quad (6)$$

$$\log\left(\frac{CO_2}{BTE}(IT)\right) \overset{def}{=} \log\left(\frac{CO_2}{BTE}\right) = \beta_0^{CO_2} + \beta_1^{CO_2} IT + \beta_2^{CO_2} IT^2 + \varepsilon_{CO_2,} \quad (7)$$

$$\log\left(\frac{HC}{BTE}(IT)\right) \overset{def}{=} \log\left(\frac{HC}{BTE}\right) = \beta_0^{HC} + \beta_1^{HC} IT + \beta_2^{HC} IT^2 + \varepsilon_{HC}, \quad (8)$$

$$\mathrm{llog}\left(\frac{NOx}{BTE}(IT)\right) \overset{def}{=} \log\left(\frac{NOx}{BTE}\right) = \beta_0^{NOx} + \beta_1^{NOx} IT + \beta_2^{NOx} IT^2 + \varepsilon_{NOx.} \quad (9)$$

For each model the parameters, standard deviation of residuals, determination coefficient and test probability have been estimated.
Additionally the optimal IT has been determined (10-14):

$$IT_{BTE} = \arg_{\max_{IT_{min} \le IT \le IT_{max}}} BTE(IT), \quad (10)$$

$$IT_{CO} = \arg_{\min_{IT_{min} \le IT \le IT_{max}}} \frac{CO}{BTE}(IT), \quad (11)$$

$$IT_{CO_2} = \arg_{\min_{IT_{min} \le IT \le IT_{max}}} \frac{CO_2}{BTE}(IT), \quad (12)$$

$$IT_{HC} = \arg_{\min_{IT_{min} \le IT \le IT_{max}}} \frac{NC}{BTE}(IT), \quad (13)$$

$$IT_{NOx} = \arg_{\min_{IT_{min} \le IT \le IT_{max}}} \frac{NOx}{BTE}(IT). \quad (14)$$

The findings (Table 1) indicate that the incorporation of HHO gas consistently enhances BTE across all evaluated fuel combinations, especially under lean air-fuel situations (elevated λ values). Furthermore, the amalgamation of E70 fuel with HHO gas attains elevated determination coefficients (R^2), signifying a more significant effect on enhancing engine performance and diminishing residual standard deviation in comparison to E10 fuel mixtures.

Table 1. Summary Parameters of model (5), optimal IT, standard deviation of residuals and determination coefficient

Fuel	λ	β_0^{BTE}	β_1^{BTE}	β_2^{BTE}	IT_{BTE}	σ	R^2	p.val

The determination coefficient is high. At significant level 0.05 for each fuels and λ for model null hypothesis H_0 should be rejected in favour of the alternative hypothesis, thus the coefficient of multiple correlation significantly differ from zero. From Table 1 we can conclude, that as parameter λ the optimal IT also increases.

The BTE of all fuel blends is considerably enhanced by the addition of HHO gas, with the E70+HHO combination obtaining the highest BTE values. Additionally, the combination of bioethanol-rich fuels with HHO gas significantly reduces CO, HC, except NOx emissions, thereby demonstrating its efficacy in improving combustion efficiency and minimizing environmental impact.

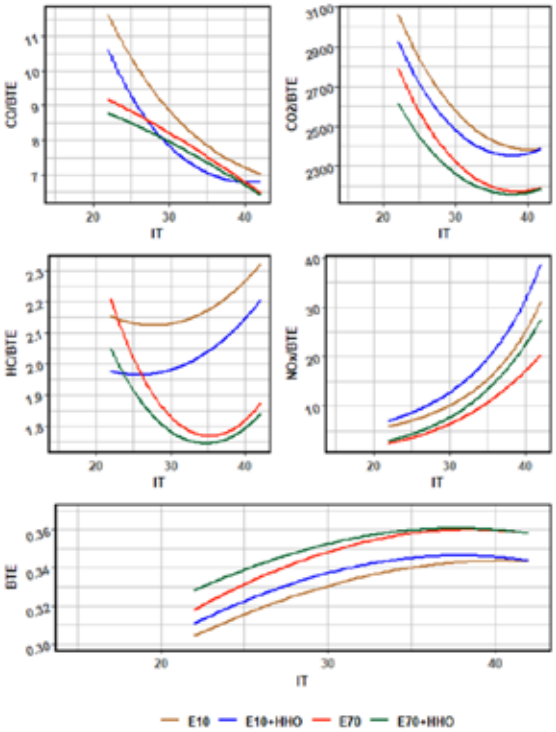

Fig. 1. BTE and pollutant ratios to BTE due to fuel type for λ =1.4

4. CONCLUSIONS

1. The introduction of HHO gas, particularly under lean mixture conditions, significantly improves the combustion efficiency of gasoline-bioethanol combinations in spark ignition engines.
2. With the best environmental benefits seen in E70 fuel blends, HHO gas fundamentally reduces harmful emissions such as CO, HC, and NOx.
3. The best BTE comes from combining HHO gas with bioethanol-rich fuel mixes like E70, therefore proving their ability to raise engine performance.
4. The findings validate the feasibility of including HHO gas as a sustainable additive in current internal combustion engines, so offering a route towards more environmentally friendly and effectively run vehicles.

ABSTRACT

In this study $MgCr_{2-x}Mn_xO_4$ (x=0.1/0.5/1) spinel and LSM composite layers were deposited on 430 stainless steel. The coated steels were exposed to 500 hour oxidation at 800 °C. The growing Cr_2O_3 layer has been investigated, which is cause of chromium poisoning and a critical parameter for the electrical conductivity of SOFC interconnects. Interface analysis was carried out using scanning electron microscopy. Results demonstrated that for the spinel protection increasing chromium content in the B-site decreased forming oxide layers. After oxidation, $MgCr_{1.9}Mn_{0.1}O_4$ and LSM composite coating offered high stability and the growing Cr_2O_3 layer stopped at 2 microns.

Keywords: SOFC, Interconnect, Chromium Poisoning, Spinel Coating

1. INTRODUCTION

Solid oxide fuel cells are energy-converting devices that convert chemical energy to electrical energy. SOFC has a large fuel selection from hydrogen to hydrocarbons [1]. After the chemical energy conversion, SOFC usually produces only water as a waste product. For this reason, these devices are classified as environmentally friendly energy. However, they operate at high temperatures and this negatively affects cell components. One of the most affected components is the interconnect due to its metallic structure, which has low oxidation resistance. Stainless steel contains 10-25% chromium in its composition and can form easily Cr_2O_3 layer in high temperatures 600-800 oC. Forming a Cr_2O_3 layer increases area specific resistance, and can cause delamination problems and chromium poisoning throughout the cathode layer with the diffusion of chromium volatiles[2]. To address this issue, there are two methods which are new alloy design via doping elements and coating with protective layers[3]. The coating approach is a more common method because of cost-effective manufacturing [4].

2. EXPERIMENTAL

In this study, as an interconnect substrate AISI 430 stainless steel was selected. They were cut into 2x10x10mm dimensions. Square steel pieces were sanded with silicon carbide P240 and P600. In the next step the stells were kept in ultrasonic acetone bath to clean the remaining particles after polishing. For the spinel protective layer, three different spinel powders $MgCr_{2-x}Mn_xO_4$ (x=0.1/0.5/1) were prepared with sol-gel combustion method. For the second layer coating commercial LSM ($(La_{0.65}Sr_{0.35})_{0.95}MnO_3$, Praxair, 99.9%) powder was used. In the ink preparation period, appropriate amounts of terpineol, DBP (dibutyl phthalate), PEG 300 (polyethylene glycol), PVB (polyvinyl butyral) was mixed with spinel and LSM powders. It is obtained high adhesion inks for screen printing and then deposited on the steel surface. After coating the substrates were exposed drying and sintering process in order room temperature, 80 ^{0}C in air, 800 ^{0}C in 5%H2/Ar, and 800 ^{0}C in air furnaces. After obtaining coated steels, they were oxidized at 800 ^{0}C 500 hour in air. Firstly, X-ray diffraction patterns were collected on a PANalytical X-ray diffractometer operating with CuKα radiation (λ = 1.5406 Å). The range of 2θ is 5-90˚ for the spinel powders. Secondly, the Scanning Electron Microscope (SEM) was used to observe cross-section interfaces of coated steels. Finally, area specific resistance (ASR) test was carried out by using two probes four-point DC method.

3. RESULTS AND DISCUSSION

X-ray diffraction (XRD) patterns of spinel powders are illustrated in Fig.1 with different amounts of manganese doping. All spinels have a single-phase cubic structure without any secondary phase formations. Diffracted peak positions were matched with collected magnesium chromite spinel data. Obtained spinels were deposited on the steel surface as first layer and secondary layer LSM were applied. Spinel and perovskite bilayer coating was studied by Ludwig et. al [5], they used $NiFe_2O_4$ and $La_{0.6}Sr_{0.4}CoO_3$ for coating on the steel surface and observed dual layer coating increase oxidation resistance. In Fig.2, bilayer coated steel SEM cross-section analysis is demonstrated together EDS (Energy-dispersive X-ray spectroscopy) elemental line analysis after 500-hour oxidation. According to the results, all samples showed stability against chromium poisoning. The growing Cr_2O_3 oxide layer is a critical parameter in decreasing electrical conductivity. Here, it is detected that chromium content in the spinel composition effects chromium outward diffusion from steel. After heat treatment $MgCr_{1.9}Mn_{0.1}O_4$ and LSM coated steel showed best performance with the growing Cr_2O_3 oxide layer stayed at 2 microns thickness.

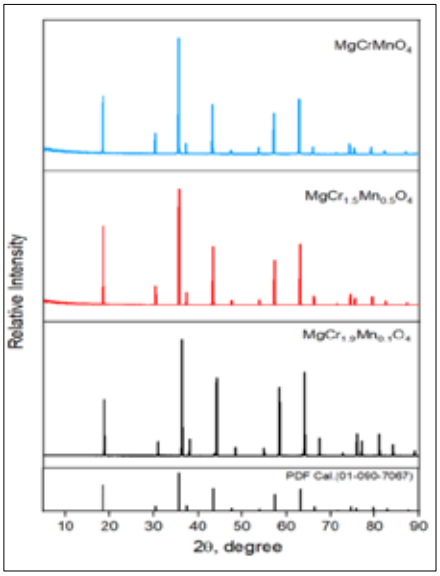

Fig.1. XRD patterns of spinel powders

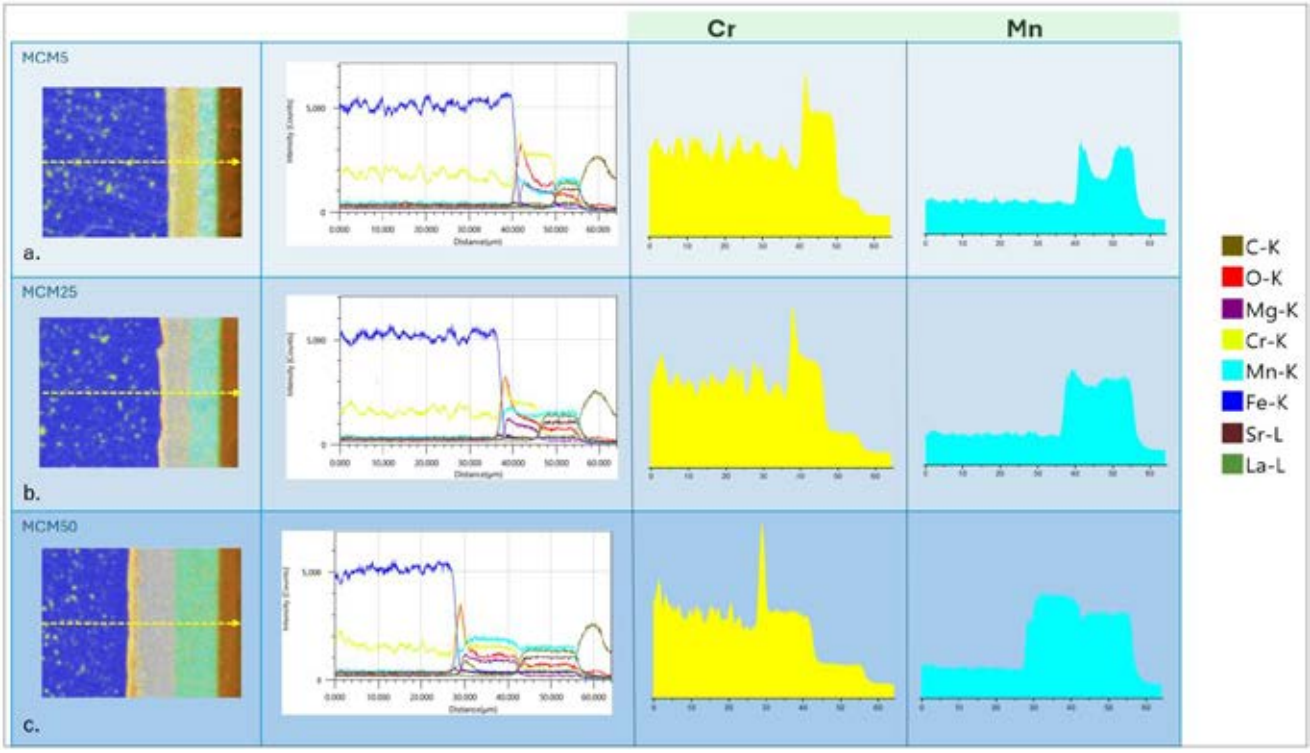

Fig. 2. SEM Cross-Section analysis of coated 430 stainless steel after 500-hour oxidation at 800 ºC a.MCM5: $MgCr_{1.9}Mn_{0.1}O_4$ and LSM b.MCM25: $MgCr_{1.5}Mn_{0.5}O_4$ and LSM c.MCM50: $MgCrMnO_4$ and LSM

Electrical tests were measured before and after 500-hour oxidation at 800 °C of coated steels (Fig. 3). Significant increase in ASR values was noticed for $MgCrMnO_4$ and LSM coated steel with a rise from 50 to 94 mΩ.cm^2. However, $MgCr_{1.9}Mn_{0.1}O_4$ and $MgCr_{1.5}Mn_{0.5}O_4$ dual-coated steel samples showed stability before-after oxidation tests.

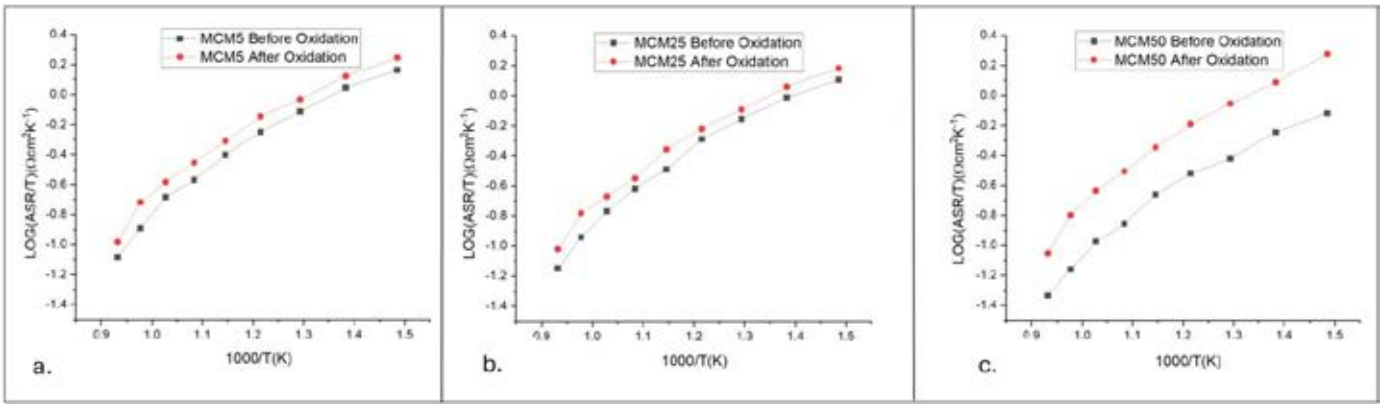

Fig. 3. ASR results with temperature plots before and after 500-hour oxidation at 800 °C. a.MCM5: $MgCr_{1.9}Mn_{0.1}O_4$ and LSM b.MCM25: $MgCr_{1.5}Mn_{0.5}O_4$ and LSM c.MCM50: $MgCrMnO_4$ and LSM

4. CONCLUSIONS

After the oxidation test, it is observed that spinel composition has critical importance against oxidation. The results showed that manganese-doped Mg chromite spinel coating on steel surfaces has high oxidation resistance. However, increasing manganese in spinel content enables to grove Cr_2O_3 layer, which can cause spallation and delamination problems in long-term operating conditions. Composite $MgCr_{1.9}Mn_{0.1}O_4$ spinel coating with LSM dramatically reduced the growing Cr_2O_3 oxide layer and showed stable ASR results after-before oxidation. Dual-layer coating with magnesium-based chromium-rich spinel and LSM coating is promising for SOFC interconnect materials.

ABSTRACT

This study aims to analyse the integration of a hybrid system, including a Molten Carbonate Fuel Cell (MCFC), battery and an organic Rankine cycle-based waste heat recovery system (WHRS) into marine power distribution through numerical simulations and environmental assessments using sensory data. It contributes to the literature by evaluating the environmental viability of a liquefied natural gas-powered MCFC system as an investment for maritime decarbonisation goals. The data collection was undertaken on a Kamsarmax bulk carrier. The environmental assessment examines the plant's upstream (well-to-tank) and operational (tank-to-wake) emissions. Results indicate that implementing LNG tanks and MCFC has required design modifications to accommodate additional volume and weight. The hybrid MCFC/Battery/WHRS configuration has significantly reduced the marine power distribution plant's equivalent carbon dioxide (CO_2-Eq). Although methane (CH_4) emissions have increased due to LNG usage, non-greenhouse gas emissions have decreased considerably. A rise in combined CH_4 emissions from propulsion and electrification plants has been found. However, the hybrid system has achieved a considerable reduction in CO_2-Eq.

Keywords: Hybrid power system, fuel cell, maritime decarbonization, emissions, ship electrification

1. INTRODUCTION

Maritime transportation has been responsible for a great deal of air pollution due to the increasing usage of fossil fuels and its utilisation share in transportation [1, 2]. Marine diesel engines (MDE) in shipping have produced 3 % of global greenhouses (GHGs) that increase the risk of global warming while also yielding other health hazards [3-5]. To decrease the environmental damage due to shipping activities, the International Maritime Organization (IMO) has entered emission reduction objectives into force and revised them in July 2023 [6]. The updated decarbonisation targets aim to reduce emissions by 20% before 2030 and 70% by 2040 relative to 2008. Finally, there is an intention to achieve net-zero emissions by 2050 [7]. Energy efficiency improvements can be achieved through conventional measures such as engine power limitation, alternative energy sources or speed optimization [8, 9].

Molten Carbonate Fuel Cells (MCFC) have been investigated as an option in hybrid or stand-alone applications for marine propulsion and power distribution units focusing on large commercial vessels. Dimopoulos et al. [10] conducted an exergy analysis on MCFC and WHRS while optimising the configurations. Optimising the simple MCFC system has improved exergy efficiency. In the combined cycle MCFC, heat recovery boosted power by 40%and achieved a 45% relative increase in efficiency. İnal and Deniz [11]presented a case study reducing emissions based on MCFC usage on a chemical tanker's propulsion unit., Baccioli et al. [12] created an MCFC-MDE hybrid model to gauge the efficiency. Compared to the sole MDE-utilised conventional scenario, efficiency improvement was obtained. Korkmaz et al. [13] performed a benchmarking of different FC types and found that a MCFC/battery combination led to a 49.75% operational CO_2 reduction. Yuksel and Bayraktar [14] built an analysis considering MCFC plants in propulsion and auxiliary systems and obtained a 51.7% CO_2 decrease.

This study's motive is to provide an analysis of hybrid MCFC/Battery/WHRS integration to the marine power distribution plant through numerical simulation, and environmental performance assessments using sensory data for more precise data analysis.

2. MATERIALS AND METHODS

This section explains the framework and mathematical background of the methodology used while highlighting the specifications of the case study elements. Data collection included power output, engine speed, fuel consumption of main and auxiliary engines and vessel-specific parameters such as speed, draft, and deadweight over 1.96 years. The study's industry partner provided the ADLM-sourced data and noon reports from the Kamsarmax bulk carrier, Laskaridis Shipping Co. Ltd. The data was analysed and an MCFC/Battery/WHRS hybrid system was designed to meet the vessel's power demand. A numerical model was developed to estimate the LNG consumption of the MCFC and benchmark its

emission reduction against conventional diesel engines. The algorithm calculates exhaust flow and temperature based on engine power, followed by power generation from the WHRS. It then evaluates the main and auxiliary engines' utilization times, fuel consumption, and emissions. Subsequently, LNG consumption and emissions from the MCFC system are computed. Results are logged, converted into data frames, and exported to spreadsheets for analysis.

2.1. Case Study

The vessel selected for the case study is a Kamsarmax bulk carrier, the M/V KASTOR. Constructed in 2020, the ship has a deadweight (DWT) of 80,996 tons and a length overall (LOA) of 229 meters. Its propulsion system comprises of a HYUNDAI 6S60ME-C8.5 engine, capable of delivering a maximum power output of 9,930 kW. Additionally, the vessel is equipped with an electrification plant consisting of three YANMAR 6EY22LW diesel generators (DGs), each providing a terminal power capacity of 720 kW. Figure 1 indicates a simplified schematic of the proposed hybrid marine power distribution system, which integrates an MCFC, battery, and WHRS. The diagram also includes the LNG cracking process based on water-gas shift reactions.

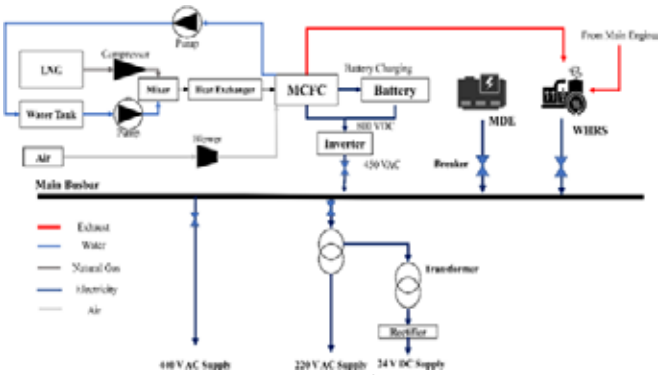

Fig. 1. The schematic of the hybrid plant

The conventional power plant consists of three equivalent DGs with a total output of 2,160 kW. In contrast, the hybrid plant features a single MCFC unit with a power output of 1,400 kW and a battery with a capacity of 40 kWh to accommodate instantaneous increases in power demand. The WHRS can generate up to 200 kW of electrical power, primarily utilising waste heat from the main engine's exhaust, with supplemental heat from the MCFC when necessary. The MCFC unit has an LNG reforming system for hydrogen production. One DG is maintained to ensure emergency reserve. The battery cell for assembling the stack utilized in the hybrid configuration to support the SureSource 1500 MCFC system is the Panasonic NCR18650GA, featuring a capacity of 3.45 Ah and a nominal voltage of 3.6V. The specifications of the MCFC unit employed in the system are presented in Table 1. LNG consumption and emissions of MCFC system have been computed from the coefficients given in Table 1 depending on the energy generated.

Table 1. MCFC specifications[15].

Parameter	Value	Unit
Electric Power Output	1400	kW
Electrical Efficiency	47%±2%	-
LNG Consumption	615.12	m³/h
NO_x	0.0045	kg/MWh
CO_2	444.5	kg/MWh
PM	9.07*106	kg/MWh
SOx	0.000045	kg/MWh
Weight	48.53	t
Length/Width/Diameter	16.98/3.88/6.09	m

2.2. Modelling Background

The WHRS utilises an Organic Rankine Cycle (ORC) to generate electricity from the exhaust waste heat. The exhaust flow rates and temperatures of the main engine after the turbine exit data have been gathered from the main engine (ME) manufacturer's datasheet [16]. The ORC model is based on the models developed by Konur et al. [17]. Equation 1 indicates the calculation of WHRS power generation $\dot{W}_{WHRS}$) in kW [18].

$$\dot{W}_{WHRS}\ (kW) = \dot{m}_{ex} \times \left(T_{in,\,ex} - T_{out,\,ex}\right) \times C_{p,\,ex} \times \eta_{ORC}. \quad (1)$$

where $\dot{m}_{ex}$ represents the exhaust mass flow rate in kg/s, $T_{in,\,ex}$ denotes the inlet temperature of the exhaust (after the

exhaust boiler), and $T_{out,\,ex}$ is the outlet temperature from the ORC, which is set at 100°C. The specific heat capacity at constant pressure, $C_{p,\,ex}$, is the amount of thermal energy the exhaust gas emits or absorbs when its temperature changes, assuming constant pressure, and is taken to be 1.089 kJ/kg [19]. The efficiency of ORC (η_{ORC}) is 13.2% [17].

The algorithm calculates the required engine power and the number of active generators for each time interval (t = 1 minute). In the simulation, the load and power of each generator were determined, and their specific fuel consumption was obtained by interpolating the curve provided by the manufacturer. The load distribution has been established using the model presented by Yuksel and Koseoglu [4]. The operational emissions (OE) in g of the MCFC and MDEs have been calculated employing the operational emission factors (OEF) given in Table 1 (for MCFC) and Table 2 (for heavy fuel oil (HFO)) [14]. The OEF and upstream emission factors (UEF)for HFO and the UEF for LNG are presented in Table 2.

Table 2. Emissions of the main propulsion plant [20-22].

Emission Factor	CO_2	N_2O (g/kWh)	CH_4 (g/kWh)	NO_x	SO_x	PM	VOC
LNG - UEF	0.131	0.004	1.718	0.007	0.158	0	0
HFO - UEF	0.147	0.004	0.879	0.010	0.102	0.022	0
HFO – OEF	3.114	0.00015	0.00006	0.903	0.025	0.00278	0.004

The LNG – UEF SOx coefficients, nitrous oxide (N_2O), and methane (CH_4) units are in g/kWh, while others are in g-UE/g-OE. Equation 2 indicates the calculation of upstream emissions (UE) depending on the unit of the UEF [1].

$$UE(g)= \sum P\ (kW) \times\ t(h) \times UEF\ (\frac{g}{kWh})\ \text{or}\ UE(g)= UEF\ \left(\frac{g\text{-}UE}{g\text{-}OE}\right) \times OE\ (g) \quad (2)$$

The power output of the electrification plant, in general, is depicted as P in Equation 2. The equivalent CO_2 (CO_2-Eq) considering the global warming potential for 100 years has been calculated using the IMO Life Cycle Assessment Guideline for alternative fuels [23]. The CH_4 slip in MCFCs has been insignificant, unlike dual-fuel engines, and can be prevented by smart engineering applications [24].

3. FINDINGS

The analysis spans 17,167 operating hours (1.96 years), covering the entire operation period. Fuel consumption was measured at 8,851.62 t for the ME and 1,823.15 t for the DGs, while the MCFC LC required 3,491.13 t to meet the same power demand. Accordingly, the LNG capacity of the hybrid plant was set at 655.95 m³, with a reduced HFO capacity for the MDEs calculated at 2,425.52 m3. The marine power distribution plant delivered 6,749.27 MWh over 1.96 years, averaging 3,443.93 MWh annually. Table 3 summarises emissions from the main propulsion plant during this period.

Table 3. Emissions of the main propulsion plant

Pollutant	OE	UE	Total
CO_2	27,563.96	4,051.90	31,615.86
N_2O	1.33	0.19	1.52
CH_4	0.53	41.97	42.50
CO_2-Eq	27,930.68	5,277.62	33,208.30
NO_x	7,993.02	79.93	8,072.95
SO_x	221.29	22.57	243.86
PM	24.61	0.54	25.15
VOC	27.26	0.00	27.26

The propulsion plant has emitted 33,208.3 tons of CO_2-eq over 1.96 years, resulting in an average annual emission of 16,943 tons of CO_2-eq. NOx emissions have been the second highest, averaging 4,118.85 tons (t) annually. Fig. 2 illustrates the operational and upstream emissions for conventional and hybrid marine power distribution plants. Fig. 2 shows that the conventional plant emitted much more CO_2 overall than the hybrid plant. Notably, the hybrid plant eliminated operational N_2O emissions, but the upstream component remains the same. Likewise, the hybrid plant eliminated operational CH_4 emissions.

Figure 3 indicates the non-GHG emissions from the hybrid and conventional plants. The hybrid plant is shown to eradicate overall NOx emissions. Operational SOx emissions were effectively eliminated. LNG usage has been proven to reduce SOx upstream emissions substantially.

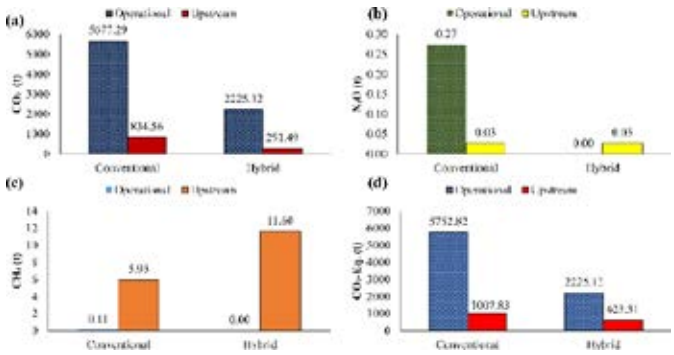

Fig. 2. GHG emissions of the ship electrification plants: (a) CO_2, (b) N_2O, (c) CH_4, and (d) CO_2-Eq.

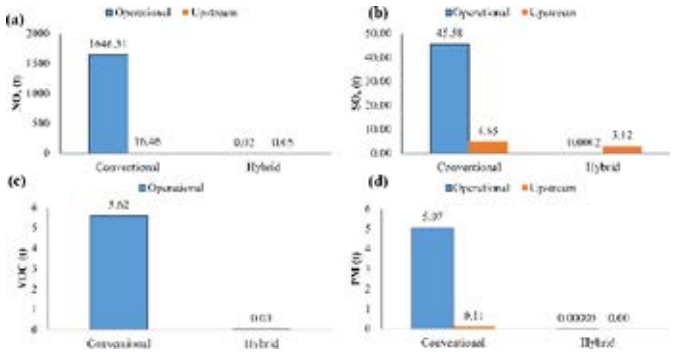

Fig. 3. Other emissions of the ship electrification plants: (a) NOx, (b) SOx, (c) VOC, and (d) PM.

LNG avoids upstream PM emissions from HFO. Additionally, the hybrid unit heavily reduces operational PM and operational VOC emissions.

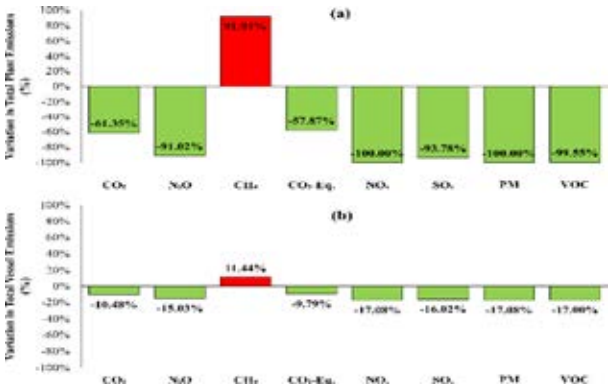

Fig. 4. Emission variations of the hybrid system in (a) sole electrification plant and (b) overall vessel emissions including propulsion unit in comparison with that using the conventional system.

Figure 4 summarizes total emissions from the electrification plant and combined emissions from the power and propulsion units, highlighting significant reductions in NOx, SOx, PM, and VOC emissions achieved through the hybrid configuration. The total emissions of the ship's electricity generation plant have been reduced, except for CH_4, which increased significantly, as shown in Figure 4 (a). The overall CO_2 reduction of the plant is considerable, yielding a slight decrease in the overall emissions of the propulsion and electrification plants. Despite the small CH_4 increment in combined emissions, the hybrid plant achieved a CO_2-Eq decrease while other emissions have been reduced drastically.

4. CONCLUSIONS

This study evaluated the integration of an MCFC/Battery/WHRS hybrid system into a marine electrification plant using a mathematical model supported by sensor-based data from a Kamsarmax bulk carrier recorded over a period of nearly two years. Environmental performance was assessed, including a future cost projection scenario, to examine the viability of an LNG-powered MCFC system as an alternative solution to decarbonize the maritime sector. The analysis incorporated upstream and operational emissions. Key findings include:

- The MCFC/Battery/WHRS hybrid system reduced CO_2-Eq emissions from the marine power distribution plant by 57.87%.
- CH_4 emissions increased due to LNG usage, but non-GHG emissions were significantly reduced.
- Despite an 11.44% rise in combined CH_4 emissions from propulsion and electrification plants, the hybrid system achieved a 9.79% reduction in overall CO_2-Eq emissions.

ABSTRACT
This study analyzed a database of 37 articles (1300 instances) published between 2000 and 2023 on hydrogen storage in boron materials using machine learning techniques. The database was created with 35 descriptors, including preparation methods, post-preparation processes, and physical properties of boron materials. A descriptive analysis was first conducted using basic statistical tools to identify trends in variables and hydrogen adsorption. Association rule mining was then applied to identify the most impactful variables on hydrogen adsorption. The random forest (RF) technique was used to test the predictability of key output variables. RF and decision tree algorithms also helped develop simple heuristics for identifying optimal conditions or avoiding conditions that lead to low hydrogen adsorption. The best decision tree model achieved 56% accuracy, with temperature, pressure, and preparation method identified as critical variables. These variables also had a significant impact in the RF analysis. While temperature and pressure are clearly important, the preparation method is emphasized because many studies fail to measure or report factors like pore characteristics which are the actual key variables. Therefore, the preparation method, indirectly influencing these factors, is found to be effective. This study underscores the need for a standardized measurement and reporting approach in hydrogen adsorption research to ensure accurate comparisons.
Keywords: Hydrogen Storage, Machine Learning, Association Rule Mining, Random Forest, Decision Tree

1. INTRODUCTION

The high hydrogen content, attractive thermodynamic properties, and low atomic weight of boron-containing materials make them highly appealing as solid-state hydrogen storage media [1]. Material properties play a crucial role in determining hydrogen storage capacity and kinetics. Among these materials, boron-based compounds, particularly borohydrides, have been recognized as suitable candidates for high-density hydrogen storage at low pressures [2]. To optimize their performance as hydrogen storage media, guidelines are needed for the rational design of these materials. Machine learning techniques, applied to large and diverse experimental datasets, can reveal powerful trends and interrelationships [3]. This study focuses on developing a database containing experimental data on hydrogen storage in boron-containing materials. Machine learning is used to establish correlations between material characteristics and hydrogen storage capacity. The database, created specifically for this research, stores experimental data on hydrogen storage in boron-based materials. We apply machine learning techniques to develop strategies for predicting hydrogen storage capacity based on material properties. This work generates a machine learning model trained on experimental data to identify correlations between various material properties and hydrogen storage capacity [4]. Multiple machine learning algorithms, including decision trees, random forests, and neural networks, are used to predict the optimal conditions for hydrogen storage, providing guidelines for the design of next-generation materials. Insights into how machine learning can be applied to material configuration will guide efforts to advance hydrogen storage systems along the technology roadmap

2. MATERIALS AND METHODS

A comprehensive database was constructed by scanning hundreds of scientific papers on hydrogen storage in boron materials published between 2000 and 2023 at 13 different online sources. After a detailed review (top hits in relevance sorting), 1300 experiments from 37 experimental articles were included in the database. The materials used for the storage and their preparation processes, as well as the factors related to hydrogen storage (such as temperature and pressure) were chosen as input variables (descriptors), while hydrogen adsorption (%wt) of the working hydrogen storage volume (%wt) and hydrogen desorption (%wt) were defined as the output variables. An important aspect discussed here is converting continuous hydrogen adsorption data into categorical form. In many studies, adsorption results are given as a function of pressure, which increases with adsorption. To avoid bias, a new term was introduced for each experiment. The logarithm of pressure values was taken, linearizing the adsorption graph, and its slope was used as a single evaluation criterion. Finally, hydrogen storage volume data were categorized into three classes: high (Class A), medium (Class B), and low (Class C).
The "arules" package in R was utilized to apply association rule mining to the dataset. The results from ARM are also visualized using the " arulesviz" package. The random forest algorithm was applied for the prediction of hydrogen storage performance parameters based on the identified effective input variables. The “randomForest” package of R was used for the RF application. During the prediction process, 5-fold cross-validation (5-fold CV) was used, and instances with unknown hydrogen storage values were excluded. The optimal model, identified through the 5-fold CV results, was then

tested using unseen data, comprising 25% of the total dataset. The evaluation criteria for RF algorithm were selected as the mean absolute error, root mean squared error (RMSE), and R^2. A wide range of the parameters of ntree (number of trees in the forest) and node size (number of instances in a terminal node of a tree) were scanned and the results were evaluated to find the model with minimum complexity and highest prediction accuracy. In the last step, decision tree (DT) analysis extracts heuristic rules that can help identify which input variables are crucial for classifying hydrogen storage and pinpointing high-performance materials and methods. This analysis was performed using rpart and rattle packages for modeling and visualization, respectively. The complexity parameter was chosen as the optimization criterion in the DT algorithm, and again 5-fold CV was applied to obtain the optimum tree model. All models created using R were developed in RStudio.

3. RESULTS AND DISCUSSION

3.1 Effective Variables

In this study, an extensive literature review was conducted, and useful information and generalizations were presented using simple descriptive analyses. This approach was applied to each variable in the dataset. For example, the relationship between surface area and hydrogen storage is thoroughly explained in Fig. 1. The y-axis represents the SSA in m²/g, while the x-axis shows the different types of materials. The size of the spheres indicates the hydrogen storage capacity (wt% H_2) for each sample; larger spheres represent higher storage capacity. The spheres represent BC (boron-carbon compounds), blue spheres represent BN (boron nitride-based compounds), red spheres represent lithium borohydrides, and yellow spheres represent MgNi/BG-based compounds. Our preliminary statistical analysis of experimental articles in the literature revealed that while specific surface area positively influences hydrogen storage, it is not a dominant or sufficient variable on its own. Fig. 1 shows examples from our database where materials with high surface area have low storage capacities, while high-capacity materials tend to have lower surface areas. Additionally, consistent with the literature, lithium borohydride compounds are more likely to exhibit higher adsorption capacities

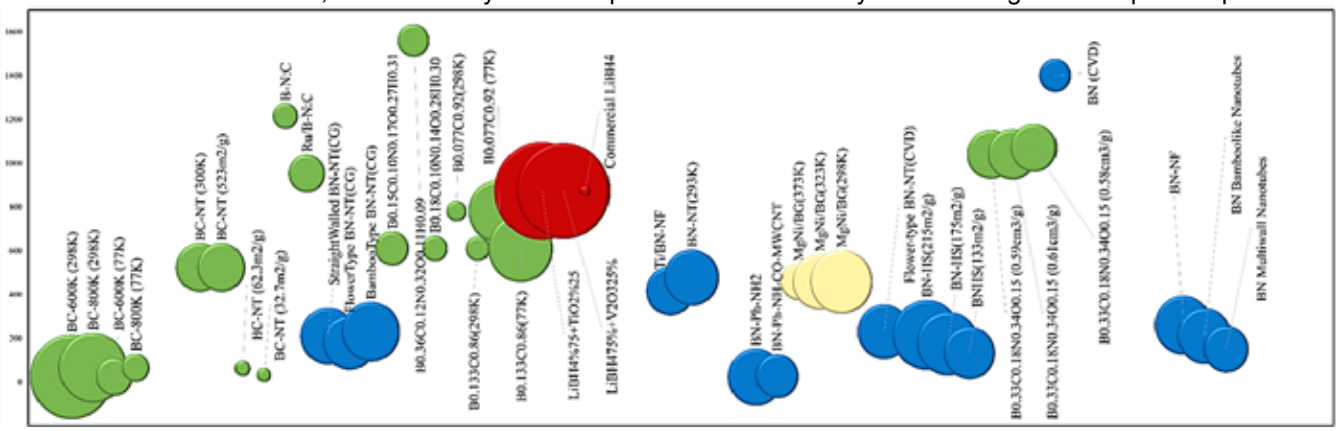

Fig. 1. The relation graph between surface area and hydrogen adsorption obtained from the dataset developed

3.2 Association Rule Mining

Association Rule Mining (ARM) was used to identify relationships among variables that provide the highest efficiency for hydrogen storage. This technique analyzes relationships between different variables to determine the most effective combinations. In Table 1, data with "slope=low" indicates low hydrogen storage capacity and inefficient adsorption. The "SurfaceArea=3" term represents materials with a surface area between 500 and 1600, showing that while hydrogen storage reaches a certain level, it is not sufficient for high-efficiency adsorption. Only relationships with a lift value greater than 1.0 were considered, indicating that these relationships are stronger than expected, suggesting they are significant and warrant further investigation. A lift value of 1.76 demonstrates a strong positive relationship between these factors, revealing that materials with a surface area in this range tend to have lower hydrogen adsorption capacity. This relationship, observed in 12 instances, highlights the need to avoid materials in this surface area range for improving hydrogen adsorption efficiency. The other rules in the table can be interpreted using a similar approach.

Table 1. Association rules affecting hydrogen storage capacity

Lhs	Rhs	Support	Confidence	Coverage	Lift	Count
{slope=high}	{Env=N2}	0.159	0.466	0.340	2.281	14
{slope=medium}	{SurfaceArea=0}	0.102	0.321	0.318	2.571	9
{slope=low}	{PrepMeth=CVD}	0.102	0.3	0.340	2.030	9
{slope=low}	{Env=Ar}	0.204	0.6	0.340	2.030	18
{slope=medium}	{PrepMeth=Others}	0.102	0.321	0.318	2.020	9
{slope=low}	{SurfaceArea=3}	0.136	0.4	0.340	1.76	12

3.3 Decision tree

In this study, hydrogen adsorption data were evaluated using the "slope," representing the rate of change in adsorption for each experiment. Factors like temperature, pressure, surface area, pore volume, preparation method, and conditions were defined as input variables. The decision tree model below (Fig. 2) was developed to classify and identify conditions for high-performance hydrogen adsorption.

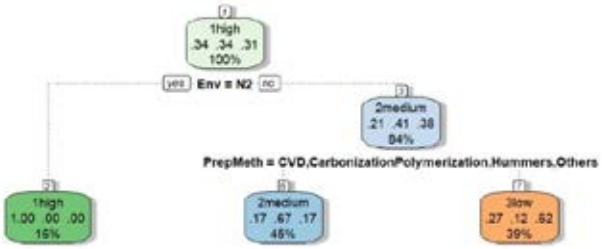

Fig. 2. Decision tree mode for hydrogen adsorption

Fig. 2 shows the results of the decision tree for hydrogen storage classification, where the optimal cp value is set to 0.04. The decision tree (DT) should be read through the branches to the leaf node; data meeting the condition specified in the node are directed to the left branch, while the remaining data go to the right branch. In the decision tree shown in Fig. 2, the first node (1high) was selected as the hydrogen storage class since it contains 34% of 1high class examples. The class distribution at this node is 34% (1high), 34% (2medium), and 31% (3low), covering 100% of the total samples. The first rule is based on the "Env = reactions under N_2 gas" environmental condition. If this condition is met, the tree moves left; otherwise, it moves right. The decision tree should be interpreted like this through the last node (leaf node).

The model's normal test accuracy is calculated as 54.54%, and the balanced test accuracy is 55.62%. While the normal test accuracy does not take into account the number of samples in each group, the balanced test accuracy adjusts the accuracy values based on the number of elements in the predicted dataset. The small difference between these values indicates that the distribution of samples across the classes is well balanced. The model predicted the examples in the 1high, 2medium, and 3low classes with accuracies of 50%, 45.5%, and 71.4%, respectively. More detailed information about the accuracies is provided in Table 2.

Table 2. Confusion matrix created with decision tree algorithm results

		Predicted Class				
		1high	2medium	3low	#Total number	Class Accuracy (Recall) %
Real Class	1high	2	0	2	4	50
	2medium	1	5	5	11	45.5
	3low	2	0	5	7	71.4
	Accuracy	0.40	1	0.417		

The confusion matrix given in Table 2 shows the performance of the classification model for hydrogen data. Accuracy rates were calculated by comparing the actual results (rows) with the predicted results (columns). For the "1high" class, the model correctly predicted 2 out of 4 data points, resulting in an accuracy of 50%. For the "2medium" class, the model correctly predicted 5 out of 11 data points, achieving 45.5% accuracy. In the "3low" class, 5 out of 7 data points were correctly predicted, resulting in 71.4% accuracy. Precision values were calculated as 0.40, 1, and 0.417 for the respective classes. These results indicate that the model performs better in the "3low" class but shows lower performance in the other classes.

3.4 Random Forest

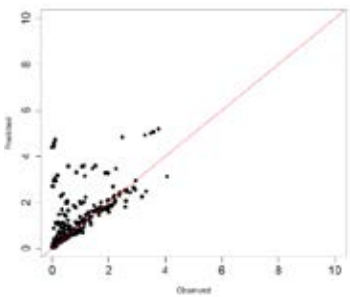

Fig. 3. Actual vs predicted values by random forest algorithm

As mentioned earlier, the modeling process using the Random Forest (RF) algorithm was validated and tested using the five-fold cross-validation method. In this process, each round labeled 648 samples for training, 162 samples for validation, and 270 samples for testing. The parameters for the best model were determined as ntree=22 and nodesize=10. This model was then applied to the test set. Fig. 3 shows the hydrogen adsorption data predicted by the model on the test data. The x-axis represents the actual values, while the y-axis represents the predicted values. Therefore, the more data points are located along the diagonal line (y=x) drawn in red, the higher the prediction accuracy. The test error for the model, reflecting its performance, was measured as 0.5831 RMSE, 1.16 MAE, and -0.79 R^2.

The random forest algorithm generates importance analysis by including and excluding each variable in the dataset, measuring its contribution to improving the model's performance. According to the analysis results, pressure, preparation method, temperature, and material used are the most influential variables in predicting hydrogen storage in boron-based compounds. However, the lack of expected importance of factors such as pore volume, pore size, and surface area may be due to the incomplete reporting of these data in the literature.

4. CONCLUSIONS

This study analyzed hydrogen storage in boron-based materials using machine learning techniques, focusing on a database of 37 articles (1300 instances) from 2000 to 2023. The database incorporated 35 descriptors, such as preparation methods, physical properties, and post-preparation processes of boron materials. Descriptive analysis and association rule mining (ARM) were employed to identify key variables affecting hydrogen adsorption. A random forest (RF) algorithm was used for prediction, revealing the critical influence of temperature, pressure, and preparation methods on hydrogen storage performance. The best decision tree model achieved 56% accuracy, highlighting that preparation methods, indirectly influencing factors like pore characteristics, are vital. The study also stressed the importance of consistent reporting of pore characteristics, as many studies overlook these details. ARM identified the most efficient combinations of variables for hydrogen storage, finding that surface area between 500 and 1600 tends to lower hydrogen adsorption capacity. The decision tree model, optimized with a complexity parameter of 0.04, classified conditions for high-performance adsorption. The model's test accuracy was 54.54%, with a balanced accuracy of 55.62%, indicating well-distributed sample classes. A confusion matrix showed that the model predicted the "high," "medium," and "low" classes with accuracies of 50%, 45.5%, and 71.4%, respectively. The RF model achieved significant predictive performance with a test error of 0.5831 RMSE, 1.16 MAE, and -0.79 R^2. Random forest also evaluated variable importance by assessing their impact on model performance. The findings revealed that pressure, temperature, preparation methods, and material used were the most significant factors, while factors like pore volume and surface area were less influential, potentially due to inconsistent reporting in the literature. This study underscores the need for standardized measurement and reporting practices in hydrogen adsorption research.

ABSTRACT

The use of renewable fuels in energy and transport is a priority to effectively reduce the use of depleting fossil resources and greenhouse gas emissions. This paper presents a study of the performance of a compression ignition engine over a wide range of engine loads, by replacing fossil diesel with dual biofuels. Diesel has been replaced by hydrotreated vegetable oil and biogas, with gas energy shares of 40%, 60% and 80%. Biogas is one of the cheapest renewable energy sources suitable for the internal combustion engine. In order to improve the combustion and energy efficiency of biogas, different concentrations of hydrogen additives were used in the experimental study. The paper presents the engine performance with different fuel cases: fossil diesel; hydrotreated vegetable oil and natural gas; hydrotreated vegetable oil and biogas; hydrotreated vegetable oil and biogas-hydrogen gas mixtures. It has been shown that under certain conditions, an engine running on dual hydrogen-added biofuels can maintain high energy performance and reduce environmental pollution such as NO_x and CO_2 emissions and smokiness.

Keywords: Dual biofuel, Hydrotreated vegetable oil, Biogas; Engine thermal efficiency, Environmental pollution

1. INTRODUCTION

Greenhouse gas (GHG) emissions are one of the most pressing issues of our time, affecting many aspects of our environmental sustainability [1]. Gases such as methane (CH_4), carbon dioxide (CO_2), nitrous oxide (N_2O) and ammonia (NH_3) are the main factors in the greenhouse effect [2]. One of the main ways of reducing the greenhouse effect is through the use of renewable energy sources and increasing energy efficiency [3]. The extensive use of internal combustion engines in transport, power generation, which emit greenhouse gases, necessitates the increased use of renewable fuels [4]. Compression ignition (CI) engines have higher energy efficiency due to higher compression ratio [5], and it is rational to use this advantage. Various renewable fuels can be used in CI engine, among which hydrotreated vegetable oil (HVO) is one of the most promising, which has higher energy density, lower NO_x emissions and better storage properties compared to biodiesel [6]. One of the cheapest biofuels is biogas (BG), which has a high raw material potential and less complex production technology [7]. In dual-fuel (D-F) engines, gas and diesel can be used in different proportions, with diesel used for the pilot ignition of the gas [8]. However, in D-F engines, the CO_2 suppression effect of biogas slows down the combustion process, reduces the thermal efficiency of the engine, and increases CO, HC and smoke emissions [9]. Studies show that the addition of hydrogen to biogas increases the intensity and quality of combustion of the gas mixture [8]. However, there are limited studies and no reliable information on the excess air ratio (λ) at which different concentrations of biogas in the engine cylinder reach the flammability limit and achieve high energy efficiency, and how the addition of hydrogen affects combustion at different levels of λ. The aim of this study is to determine the influence of a hydrogen additive on the combustion process, energy and environmental performance of a CI engine fuelled with dual biofuels at different excess air ratios.

2. MATERIALS AND METHODS

The four-cylinder turbocharged CI engine Audi-Wolkswagen 1.9 TDI (1z) was used for the experimental tests. Engine displacement 1869 cm^3, compression ratio 19.5, direct fuel injection, maximum torque 180 Nm (2000–2500 rpm), maximum power 66 kW (4000 rpm). A schematic of the experimental equipment is shown in Fig. 1, and the main details of the equipment are given in Table 1. For more information on the equipment, see the article [10].
During testing, the CI engine was run on a wide variety of fuels and fuel blends. The first case used pure diesel (D100) and the second case used pure hydrotreated vegetable oil (HVO100). In swcond cases, different dual fuels are used: gas was supplied to the intake manifold and the gas energy fractions (GES) are 40%, 60% and 80%. The third case used D-F, hydrotreated vegetable oil – natural gas (HVO_NG). The fourth case uses dual biofuel: hydrotreated vegetable oil – biogas (HVO_BG). Biogas was simulated using a mixture of NG (96.8% CH_4) and CO_2 with a 60/40 volume ratio of NG to CO_2. For the fifth, sixth and seventh cases, HVO_BG fuels were used, with hydrogen added to the gas, with H_2 at 10%, 20% and 30% of NG volume (HVO_BG+H10, HVO_BG+H20 and HVO_BG+H30). The main characteristics of the fuel are described in article [10]. The tests were carried out with the engine running at n = 2000 rpm (maximum torque mode), using brake torques of 30 Nm, 60 Nm, 90 Nm, 120 Nm (corresponding to brake mean effective pressures (BMEP) of 0.2 MPa, 0.4 MPa, 0.6 MPa and 0.8 MPa). In order to better evaluate the changes in combustion, the fixed start of

injection time was set to -4 CAD, -5 CAD, -6 CAD and -7 CAD respectively for each load.

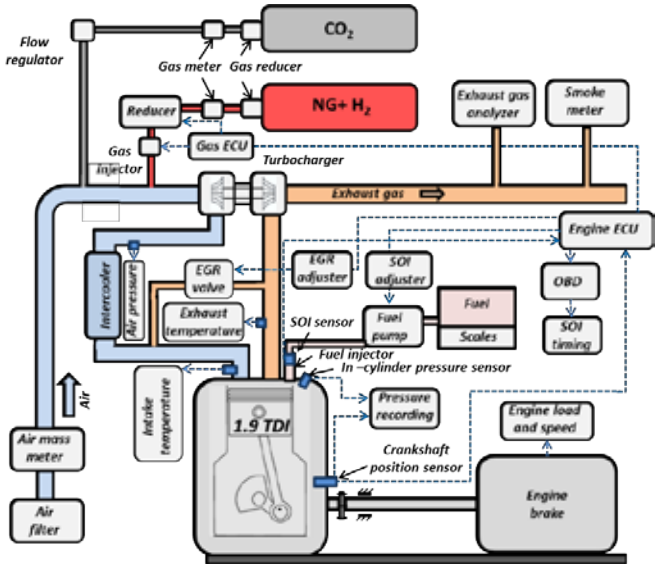

Fig. 1. Schematic of the experimental test equipment

Table 1. Basic data on the experimental test equipment

Equipment		Measurement ranges, accuracy
КИ-5543, engine load bench		0–440 Nm, ±1.2 Nm
RHM 015, gas mass flow meter		0.09–36 kg/h, ±0.1%
BOSCH HFM 5, air mass flow meter		8–370 kg/h, ±2%
SK-5000, fuel scales		0–5.0 kg, ±1.0 g
AVL GH13P, in cylinder pressure sensor		0–250 bar, ±0.3 %
A58M-F, crankshaft position sensor		0–360 CAD, 0.176 CAD
Delta OHM HD, pressure meter		0–10 bar, ±0.25%
K-type thermocouple, temperature sensor		0–1200, ±1.5° C
AVL DiCom 4000, exhaust emissions tester	CO_2 CO HC NO_x Smoke (K-Val.)	0–20% vol., 0.1% v. 0–10% vol., 0.01% v. 0–20000 ppm v., 1 ppm 0–5000 ppm vol., 1 ppm 0–99.99 m^{-1}, 0.01 m^{-1}

The rate of heat release (ROHR), temperature rise, cylinder pressure rise and other combustion parameters in the cylinder were determined using the BURN subprogram of the AVL BOOST programme. Cylinder pressure, fuel and air flow rates, and other experimental data were used. The energy efficiency of the engine was evaluated by calculating the brake thermal efficiency (BTE) using Eq. (1), where the fuel properties of the individual fuels were considered:

$$BTE = (P_B \cdot 3.6)/\sum_i (B_{f_i} \cdot LHV_i) \quad (1)$$

where P_B – brake pover (kW); B_{f_i} – hourly fuel consumption (kg/h); LHV_i – lower heating value (MJ/kg).
The environmental performance is evaluated by calculating the specific emissions, in the case of CO_2 using Eq. (2):

$$SCO_2 = (CO_2 \cdot M_{CO2} \cdot m_{ex} \cdot 10)/(M_{ex} \cdot P_B) \quad (2)$$

where CO_2 – CO_2 concentration in exhaust gases (% vol.); M_{CO2} – molecular mass of the components (g/mol); m_{ex} – exhaust mass flow (kg/h); M_{CO2} – molecular mass of the exhaust gases (g/mol).

3. RESULTS AND DISCUSSION

3.1. Combustion characteristics

The combustion process in a CI engine is strongly affected by the excess air ratio. With a D-F fuel system and an increase in GES, λ decreases (Fig. 2) as the gas occupies the volume in the cylinder and less volume is left for fresh air. λ also decreases with the increase in engine load due to the increase in fuel supply. The composition of the gas also has an impact, with the largest reduction in λ occurring with BG due to its low calorific value. Increasing the H_2 concentration in the biogas increased λ by increasing the LHV of the fuel mixture, and in the case of HVO_BG+H30, λ increased by 6–10% compared to HVO_BG. However, at high excess air ratios, the gas does not reach the flammability limit. For NG and BG to burn, λ must not exceed 1.8 and 1.9, respectively, and hydrogen extends these limits. This limit is only achievable when the engine is running at an medium load of 90 Nm (BMEP = 0.6 MPa) and above and GES reaches 80%. Rate of heat realase diagrams at medium load (BMEP = 0.6 MPa) show that HVO100 has a lower ROHR in the pre-combustion phase due to higher cetane number and shorter ignition delay phase (Figure 3), but the maximum ROHR is similar. Increasing the GES to 80% resulted in a significant slowing of the combustion process, and in the case of HVO_BG, the maximum ROHR decreased by 22% with a delay of 3 CAD compared to HVO100. In the case of HVO_BG+H30, the ROHR drops by 17%, indicating that H_2 partially compensates for the slower initial combustion of biogas and reduces the ROHR in the later combustion phase. The ROHR graph confirms that in all D-F cases, if the gas does not reach the flammability limit, combustion is delayed, which increases the exhaust temperature and reduces the thermal efficiency of the engine.

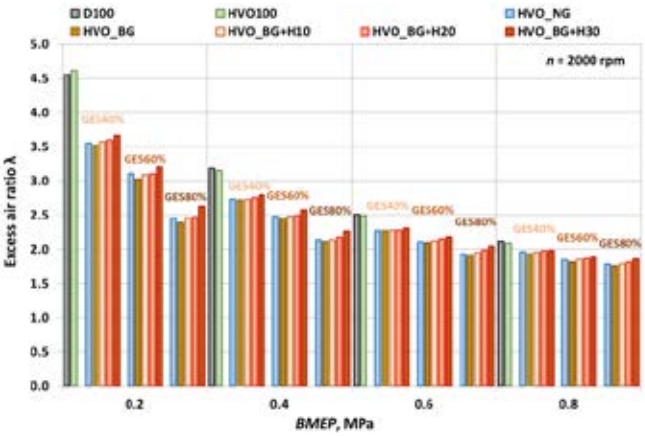

Fig. 2. λ at different fuel compositions and engine loads

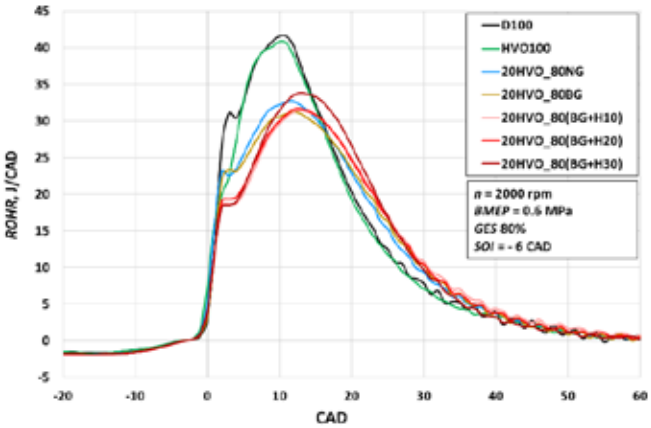

Fig. 3. ROHR at different fuel compositions

3.2. Energy characteristics

Over the entire engine load range, HVO biofuel achieved the highest thermal efficiency as it was easier to ignite due to its higher cetane number and had better combustion quality due to the higher H2 concentration in the fuel compared to D100 (Fig. 4). For HVO100, the lowest BTE (0.255) was achieved at low load (BMEP = 0.2 MPa). In the case of D-F engine BTE was significantly dependent on load, GES and gas composition. The largest reduction in BTE (46%) was observed at low load using BD, at GES 80%, as the excess air ratio exceeded 2.4 and the gas combusted late, inefficiently and incompletely. For HVO_BG+H30, the reduction in BTE was slightly lower (41%), as too high a λ could not ensure high-quality combustion. This is confirmed by the significant increase in specific emissions of incomplete combustion products (CO, HC). The highest BTE = 0.375 was achieved for HVO100 at BMEP = 0.8 MPa. At this load, the flammability limit of the gas is reached throughout the GES range, and the BTE reaches 0.36 for HVO_NG and slightly lower at 0.355 for HVO_BG due to the effect of CO2 combustion suppression. When HVO_BG+H30 was used, the BTE increased to 0.374 for 80% GES and equalled HVO100.

3.3. Environmental pollution

Specific CO_2 emissions were significantly influenced by fuel composition, engine load and BTE. At BMEP = 0.2 MPa, SCO_2 was the highest, reaching 895 g/kWh for HVO100. Using D-F at 80% GES, SCO_2 increased by 20% when switching from HVO100 to HVO_BG (Fig. 5), but SCO_2 decreased by 6% for HVO_BG+H30 and by 24% for HVO_NG due to the lower carbon content of the fuel. At the highest BTE, at BMEP = 0.8, SCO2 decreased to 667 g/kWh for both fuels (HVO100 and D100), but it is more sustainable to use HVO as it is a renewable fuel. With HVO_BG_H30, SCO_2 was reduced by an additional 10%, as combustion was efficient, with the lowest fuel consumption, and hydrogen reduced the carbon content of the fuel. In this case, renewable fuel was also used, which means an additional 70% reduction in CO_2 emissions over the life cycle. At low BTE, specific emissions of products of incomplete combustion (CO and CH) increased significantly with D-F, but at higher BTE, emissions decreased several times, especially with hydrogen addition. For HVO_BG+H30, NO_x emissions were reduced by about 30% and smoke abaut 5 time compared to HVO due to less intensive combustion in the initial combustion phases and lower carbon content in the fuel.

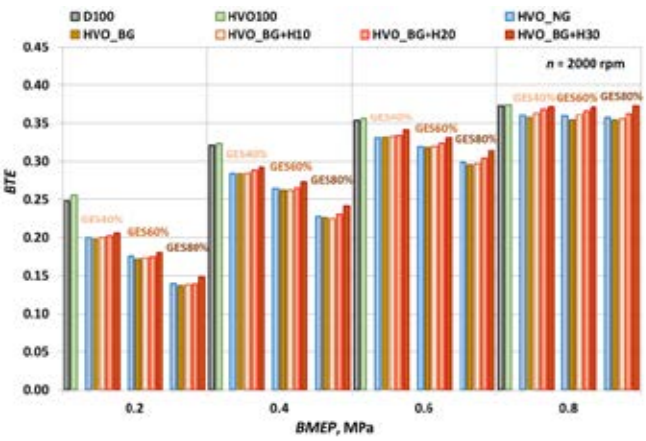

Fig. 4. BTE at different fuel compositions and engine loads

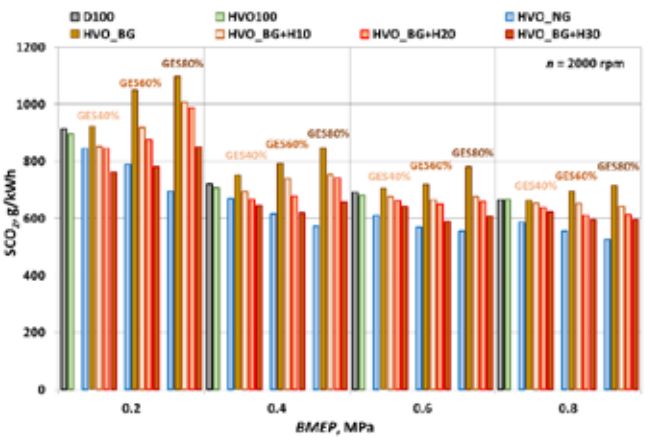

Fig. 5. CO_2 emissions at different fuel compositions

4. CONCLUSIONS

The change from D100 to HVO100 due to higher cetane number resulted in shorter ignition delay phase and lower ROHR during the pre-combustion phase, resulting in lower NO_x emissions. Due to the lower carbon and higher hydrogen content and the intensive combustion in the diffusion combustion phase, HVO reduced CO, HC specific emissions and smoke emissions compared to D100. When HVO100 was used for pilot ignition of gas in D-F engines, these fuel characteristics had a positive effect on the energy and environmental performance of the engine. Using dual biofuels consisting of HVO and simulated biogas (consisting of 60% vol. NG and 40% vol. CO_2), the engine performance was significantly dependent on the GES and the exces air ratio. At low engine loads, when λ was well above the flammability limit, the energy and environmental performance of the D-F engine deteriorated compared to pure HVO, and the addition of H2 did not significantly improve these parameters. By increasing the engine load to BMEP = 0.8 MPa and the GES to 60–80%, when λ was reduced to the biogas flammability limit (1.8), the addition of hydrogen (20–30% of vol. NG) had a significant effect in reducing CO, HC and smoke emissions. For HVO_BG+H30, the smoke emission reduction is about 5 times, NO_x emission reduction is about 30% and CO_2 emission reduction is about 10% compared to HVO100, which in most cases is better than for HVO_NG fuel. When analysing GHG emissions, it should be taken into account that HVO, BG and H2 are renewable fuels and can further reduce CO2 emissions by about 70% over their life cycle, while biogas combustion avoids methane emissions to the atmosphere.

NOMENCLATURE

BG	Biogas
BMEP	Brake mean effective pressures
BTE	Brake thermal efficiency
CI	Compression ignition
D100	Pure diesel fuel
D-F	Dual-fuel
GHG	Greenhouse gas
H_2	Hydrogen
HVO100	Pure hydrotreated vegetable oil
LHV	Lower heating value
NG	Natural gas
ROHR	Rate of heat release
SCO_2	Specific CO_2 emissions
λ	Excess air ratio

ABSTRACT

In this study, a dataset that contains 498 data points gathered from 67 published articles on photocatalytic H2 evolution over halide perovskites was constructed and analyzed by machine learning techniques. Random forest (RF) algorithms were employed to predict bandgap of halide perovskite photocatalysts and H_2 production rates. The predictive model for bandgap was quite successful with RMSE of 0.12 (R2=0.95) and 0.19 (R2=0.86) for training and testing, utilized to estimate missing bandgap values within the dataset. The other RF model was developed to predict H_2 production rates by means of 19 descriptors such as perovskite properties, synthesis methods, cocatalysts, and reaction conditions; RMSE of training and testing were 0.35 (R2=0.91) and 0.62 (R2=0.71) respectively.

Keywords: Photocatalysis, hydrogen evolution reaction, halide perovskites, machine learning

1. INTRODUCTION

Hydrogen is a promising and environmentally friendly energy carrier, which can be used as a fuel or reactant in various chemical processes[1,2]. Despite of its abundance, hydrogen is not present as molecules in nature and mostly produced from fossil fuels causing greenhouse gas emissions[3]. Hence, novel clean hydrogen generation strategies have been extensively studied nowadays.

One alternative approach is the conversion of solar energy into hydrogen by means of photocatalytic processes [4,5]. So, there was a need for an efficient photocatalyst, hence, numerous semiconductors have been used to facilitate H_2 production reactions[6]. Among them, halide perovskites appeared to be a favorable photocatalyst owing to their adjustable bandgap, excellent light absorption, and convenient charge mobility[6,7].

Halide perovskites are compounds that exhibit ABX_3 chemical structure, where A-site and B-site is a cation and X-site is a halide anion[8]. Since the properties of halide perovskites can be easily tuned by change in composition or synthesis method, various experimental studies have been conducted to explore the most efficient photocatalyst under optimal reaction conditions[9–11]. The recent popularity of halide perovskite photocatalysts resulted in accumulation of experimental data in literature, which can be extracted and investigated further applying machine learning techniques to discover the way leads to excellent photocatalysis.

The aim of this work is to get valuable information on photocatalytic H_2 production rate over halide perovskites from literature, to create a dataset using experimental data, and to examine by machine learning. Key trends on the data distribution were analyzed and influential factors were determined to build predictive models for bandgap of halide perovskites and H_2 production rates.

2. COMPUTATIONAL DETAILS

Literature on photocatalytic H_2 evolution over halide perovskites was investigated for years between 2016 and 2024. A search was conducted on Web of Science using keywords *"photocatalytic H_2 evolution" "or" "photocatalytic H_2 production" "and" "halide perovskite"* to get a list of relevant articles. Then, experimental data was extracted manually by reading the selected 67 articles in detail. A dataset with 498 data points was formed by recording 21 descriptors which cover the halide perovskite properties including dimension, bandgap, elemental compositions, and synthesis methods, cocatalysts, cocatalyst deposition techniques, reaction conditions, photocatalyst stability, and H_2 production rate.

Some publications did not provide bandgap values for halide perovskites; hence, there were 246 data points without bandgap information. Due to the fact that bandgap is a key property for photocatalysts, deficiency of this data was undesirable. Therefore, a random forest model was developed to calculate unknown bandgap values with the help of known properties such as perovskite synthesis method and temperature, A-site, B-site and X-sites of perovskites, their dimensions and cocatalysts. Then, the dataset was completed with predicted bandgap values.

The target variable was determined to be H_2 evolution rate, which exhibited a skewed data distribution since the data was gathered at the lower values as seen in Fig. 1a. In order for a better understanding of data, logarithmic transformation

was applied on H_2 evolution rate providing normal data distribution as in Fig. 1b.

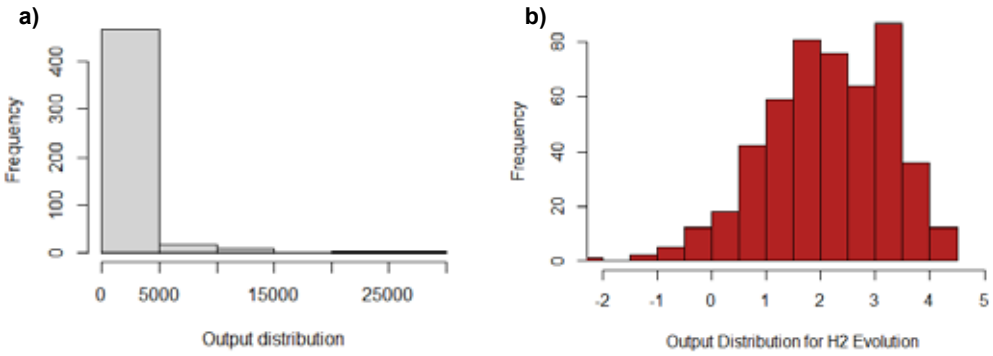

Fig. 1. Distribution of H_2 evolution rate data points before (a) and after (b) application of logarithmic transform.

A predictive RF model for H_2 production rate was developed as a function of 19 descriptors from the dataset. First, the dataset was divided into training (75%) and testing (25%) subsets. Training data was processed further applying 5-fold cross validation procedure to optimize hyperparameters of the model. Iterations were performed for nodesize (from 5 to 50), ntree (from 5 to 300) and mtry (from 3 to 9) for each fold to determine the hyperparameter values with minimum root mean square error (RMSE). Once the optimum hyperparameters were decided to be nodesize of 6, ntree of 43, and mtry of 3, test set was used to assess the predictive accuracy of the model.

3. RESULTS AND DISCUSSION

The performance of a photocatalyst largely depends on its optoelectric properties, mainly the bandgap. On the other hand, there were 246 data points without bandgap information. RF regression was employed to calculate the unknown bandgap values in order not to lose valuable data in further analysis. Original versus predicted bandgap values for train and test sets were shown in Fig. 2a and Fig. 2b and their RMSE values were 0.12 (R2=0.95) and 0.19 (R2=0.86), respectively. The significance of descriptors was represented via MSE and Node Purity methods in Fig. 2c. The most influential parameters were related to perovskite structure: the materials that were used to form perovskite, namely A, B, X-site elements, followed by perovskite synthesis methods and dimensions. The importance analysis showed that bandgap was essentially dependent on the perovskites' constitutional properties.

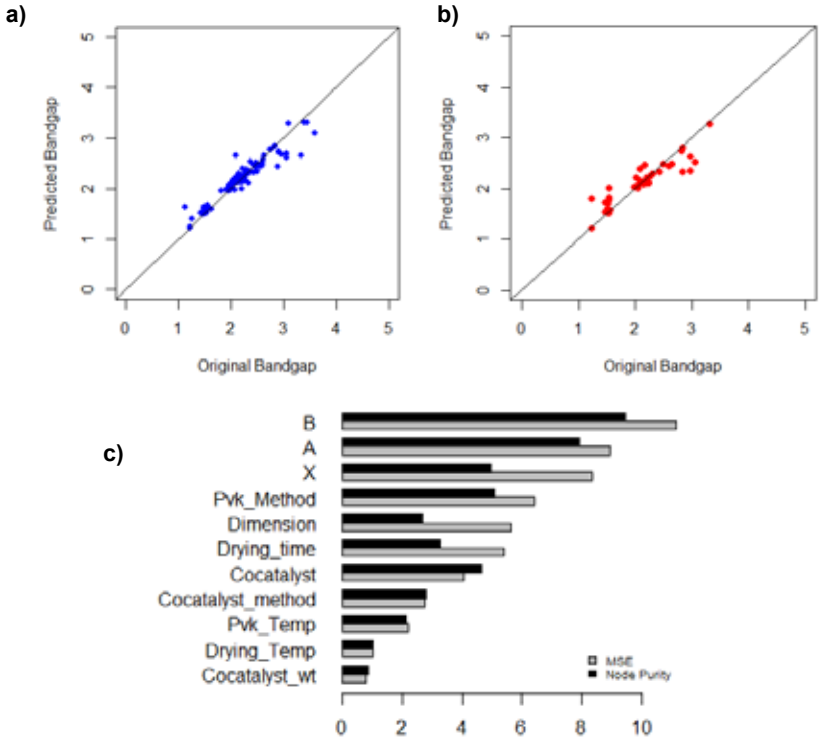

Fig. 2. Bandgap prediction results for (a) training, (b) testing and (c) descriptor importance

RF algorithm was applied on the dataset where the output variable H2 production rate was transformed into logarithmic scale to normalize the data distribution (the missing bandgap values were filled with the predictions by the model mentioned above). The original versus predicted H2 production rate for training and testing are shown in Fig. 3a and Fig. 3b with RMSE values of 0.35 (R2=0.91) and 0.62 (R2=0.71), respectively. As seen in Fig. 3a, RF model showed an excellent performance on training set, with predictions almost matching the original data points; the predictions for the test set, which is not seen by the model before, were also quite accurate. The model had a slight inclination to underestimate lower values and overestimate higher values of hydrogen production; this is more apperent in testing dataset, and it is probably stemmed from a missing information that I not represented by the current descriptors. However, the RF model can be still considered as successful for predicting the hydrogen producyion rate.

In contrast to bandgap prediction, the significant variables were not only related to perovskite structure but also reaction environments and cocatalysts (Fig. 3c). The liquids used as reaction medium also exhibited a strong effect on H2 evolution, since the medium is the source of hydrogen itself. The cocatalyst deposited on perovskite was found to be significant because it provided improved stability against reaction conditions, enhanced charge mobility, and tuned bandgap.

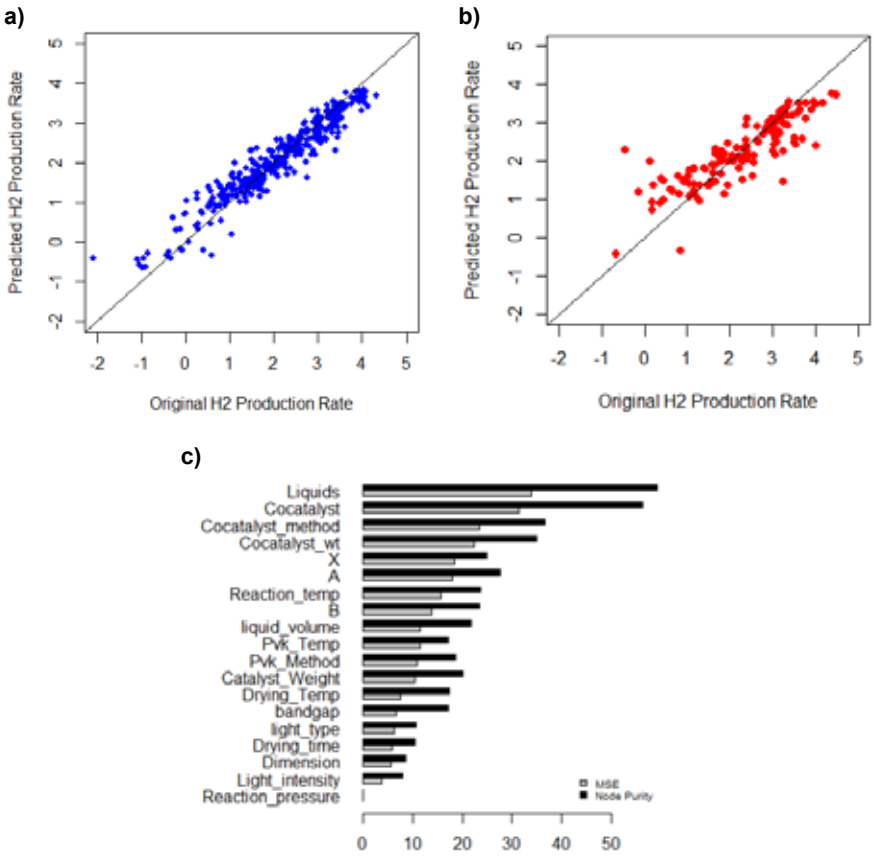

Fig. 3. H_2 production rate prediction results for (a) training, (b) testing and (c) descriptor importance

4. CONCLUSIONS

In summary, a detailed dataset was established using the data collected from articles on photocatalytic H2 evolution over halide perovskites and analyzed using machine learning tools. The variable importance analysis revealed that bandgap was primarily influenced by the structural components of perovskites which were mainly B-site cations, A-site cations, halogens as well as the synthesis methods and dimensions. The random forest model for bandgap prediction exhibited a good performance with RMSE of 0.12 (R2=0.95) and 0.19 (R2=0.86) for train and test set, respectively. Additionally, RF regression successfully predicted H2 production rate in training with RMSE values of 0.35 (R2=0.91). On the test set, predictions were reliable with RMSE of 0.62 (R2=0.71) despite minor overestimations for lower end of the data. Besides perovskite structure, reaction environment and cocatalysts were identified as critical descriptors influencing photocatalytic activity.

ABSTRACT

Hydrogen is one of the cleaner alternative energy sources for hydrogen fuel cell electric vehicles (HFCVs) in the transportation sector. The infrastructure for the production, storage, distribution and use of hydrogen needs to be well planned. Various traditional and renewable energy sources are used in hydrogen production. This study aims to find grid-based risks for the designed Hydrogen Supply Chain (HSC) when hydrogen is obtained from traditional and renewable energy sources. In grid-based risk calculation, the model is associated with capacities, unlike existing studies in literature. Risks arising from production, transportation and storage are redefined. In addition, the Fermatean Fuzzy Weighted Product Method (FF-WPM) method, one of the Multi-Criteria Decision Making (MCDM) techniques, is used to determine optimal renewable alternative energy source for grids. The results show that as the penetration rate increases, the risks of grids can be distributed more equally and the risks can be reduced thanks to the established renewable energy facilities. This study presents a methodology that aims to integrate optimal renewable energy sources determined for grids into hydrogen supply chains connected to traditional energy sources. It also aims to contribute to the assessment of risks in the design of a sustainable HSC for Türkiye.

Keywords: Hydrogen supply chain, Risk analysis, Renewable Energy, Mixed integer programming, Multi-Criteria Decision Making

1. INTRODUCTION

With population growth, increased consumption of fossil fuels leads to environmental problems. Environmental pollution, especially in the transportation sector, has reached a remarkable point. At this point, HFCVs seem to be a good alternative. While designing HSC for widespread adoption of HFCVs, production facilities, raw material supply and delivery of hydrogen to the consumer are points to be considered. Conventional and renewable alternative energy sources can be used in hydrogen production. Güler et al. [1] designed a multi-period HSC for Turkey and then transformed it into a single-period, multi-purpose HSC [2]. Although one of the main objectives in the HSC designed by Erdogan et al. [2] is to minimize the risk, renewable alternative energy sources are not considered within the scope of the study. Azadnia et al. used an integrated approach of the Delphi method and Best-worst method (BWM) to determine and analyze the risk factors of the green hydrogen supply chain in Europe [3]. They aimed to develop a framework for sustainable supply chain risk management (SSCRM) assessment [4]. For this purpose, an integrated fuzzy MCDM approach based on the technique of preference order according to similarity to the ideal solution (TOPSIS) and correlation between criteria (CRITIC) methods was proposed [4]. The best renewable energy options in the sustainable development of the country in Turkey were analyzed using the IF-TOPSIS method [5]. Gatzert and Kosub [6] presented the current risks and risk management solutions of renewable energy projects in a comprehensive manner. In this study, a single-objective model is first proposed to find grid-based risks when an HSC is designed considering traditional energy sources for Turkey. Green hydrogen production potential, which has recently been one of the most important factors in HSC design, will also be addressed in this study. The optimal renewable alternative energy sources for grids will be determined with the MCDM method.

2. MATERIALS AND METHODS

Erdogan et al. [2] propose HSC design in Turkey until 2050. Their model is a multi-purpose model that minimizes cost, CO2 emissions and risk by considering traditional energy sources. The aim of this study is to first present a grid-based model to minimize the risk in HSC based on traditional energy sources and then to determine optimal alternative renewable energy sources for grids in Turkey with the MCDM method and add them to the model to address the risk factors that will occur in the sustainable HSC network. First, it is seen that the studies in the literature have disproportionate risk levels according to the capacities of the components of the supply chain. A model is proposed that normalizes according to their capacities while calculating the risk. With this model, the risks of grids based on traditional production HSC are calculated. Then, renewable energy sources will be integrated into the model for a sustainable HSC. For this purpose, the most suitable alternative energy sources for grids will be determined with the FF-WPM, one of the MCDM methods. In this context, a determination is made among six renewable energy sources such as Wind (WI), Solar

(SO), Geothermal (GE), Biomass (BI), Wave (WA) and Hydraulic (HC) according to the expert evaluations of three academicians. There are 21 sub-criteria, including five main criteria in the selection of renewable energy types. In addition, the FF-WPM method is used to rank one or more alternatives among possible alternatives according to more than one criteria. There are two important points that distinguish this study from other models. The first of these is to calculate the grid-based risk in Turkey by normalizing it with capacities. The second is to include optimal alternative renewable energy sources for inputs in the model.

2.1. Redefining the risk measures

Risk in the supply chain process occurs in production, storage, and transportation processes. The total risk of production facilities *(TPR)* is related to the number of facilities opened, the hazard level of the facility opened and the population weight factor of the facility opened. The total risk of storage facilities *(TSR)* is calculated by multiplying the number of storage facilities, the risk level of the storage facility and the population weight factor of the facility. The risks arising from transportation *(TTR)* are related to the number of vehicles, the road used and the type of transportation. In this study, some changes are made to the risk definition used in [2,7]. *TPRs* are remodeled to be associated with production capacities. For this purpose, *TPR* is normalized with production capacities by dividing $(pCap_{plarge}^{max})$ by the largest capacity and multiplying $(pCap_{pj}^{max})$ by the associated capacity. According to the new normalized risk calculation, the risk of a small electrolysis production facility established in Istanbul is now 0.21 units, and the risk of a large electrolysis production facility established in Istanbul is 21 units. Similarly, *TSR* and *TTR* are normalized with storage and transportation capacities.

$$TPR = \left(\sum_{p,i,g} (((NP_{pjg} * PR_p * PW_g) * pCap_{pj}^{max}) \,/\, pCap_{plarge}^{max}) \right) \tag{1}$$

$$TSR = \sum_{s,g} (((NS_{sg} * SR_s * PW_g) * sCap_s^{max}) \,/\, pCap_{plarge}^{max}) \tag{2}$$

$$TTR = \sum_{g,g'} (((NTU_{gg'} * DR_{gg'l} * TR_l) * tCap_l) \,/\, pCap_{plarge}^{max}) \tag{3}$$

$$TDR = TPR + TSR + TTR \tag{4}$$

TPR is obtained by multiplying the number of hydrogen production facilities installed in the grid *(NPpig),* the hazard level of the production facility *(PRp)* and the risk level of these production facilities by the population weighting factor *(PWg)*. *TSR* is obtained by multiplying the number of hydrogen storage facilities (NS_{sg}), SR_s by the risk level of storage facilities and *(PWg). TTR* is $(NTU_{gg'})$ where *g* is the number of transportations between grids *g and g'*, TR_l, is the risk level of transportation model *t*, $DR_{gg'l}$, represents the risk level of the path between grids for transportation mode t for hydrogen distribution. *TDR* is equal to the sum of all risk levels associated with production, transportation and storage.

2.2. FF-WPM

For an MCDM problem specified in the Fermatean fuzzy environment, suppose that there are m alternatives, S_i $(i = 1,2,\dots,m)$ and *n* criteria C_j $(j = 1,2,\dots,n)$ and the criterion weight vector is $w = (w_1, w_2, \dots, w_n)^T$ and $0 \le W_j \le 1$, $j = 1,2,\dots,n$ and $\sum_{j=1}^{n} W_j = 1$.

Step 1: Fermatean fuzzy decision matrix is created.

$$R = (X_{ij})_{mxn} = \begin{pmatrix} u_{11}, v_{11} & u_{12}, v_{12} & \dots & u_{1n}, v_{1n} \\ u_{21}, v_{21} & u_{22}, v_{22} & \dots & u_{2n}, v_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ u_{m1}, v_{m1} & u_{m2}, v_{m2} & \dots & u_{mn}, v_{mn} \end{pmatrix} \tag{5}$$

Here each of the elements $X_{ij} = u_{ij}, v_{ij}$ is an FFN, which means that if the alternative S_i satisfies the attributes C_j the degree will be the value u_{ij} and if the alternative S_i does not satisfy the attributes C_j the degree will be the value v_{ij}.

Step 2: It is to normalize the matrix $\mathrm{R} = (X_{ij})_{mxn}$ by a linear method. The decision matrix R, normalize matris is

transformed into the normalized matrix $\bar{R}$. The criteria are classified into a subset of benefit criteria, B and a subset of cost criteria, C. The linear normalization for any $j \in \boldsymbol{B}$ and the linear normalization for any $j \in \boldsymbol{C}$ are defined as follows, respectively:

$$\bar{X}_{ij} = \frac{X_{ij}}{max_i X_{ij}}, \tag{6}$$

$$\bar{X}_{ij} = \frac{min_i X_{ij}}{X_{ij}}, \tag{7}$$

Step 3: The total relative importance of alternative *i* according to WPM is denoted as Q_i and is defined as:

$$\bar{Q}_i = \prod_{J=1}^{n} X_{ij}{}^{w_j} \tag{8}$$

Step 4: In the last step, the score functions (SF) for $\bar{Q}_i$ $(i = 1,2, \dots, m)$ are calculated and the final rankings of the alternatives are determined according to the decreasing order of $\bar{Q}_i$ $(i = 1,2, \dots, m)$.

$$SF = \left(\mu_T^3 - \mathrm{v}_T^3\right) \tag{9}$$

3. RESULTS AND DISCUSSION

The calculation results of grid-based risks normalized by capacities produce optimal solution as shown in Table 1. With the proposed solution method, the risks of the three grids are reduced by 13.8% in G1 (Istanbul), 17.2% in G2 (Ankara) and 37.6% in G3 (Izmir), respectively. Despite the decrease in risk values in densely populated areas, the overall risk is increased by only 4.1%.

Table 1. Total risk values for G1 and G2 and G3

G1(İstanbul) Risk (unit)	G2(Ankara) Risk (unit)	G3(İzmir) Risk (unit)	Total Risk (unit)
103	26	9	286,67

Finally, FF-WPM calculations are made for all alternatives to determine optimal renewable energy source for their grids. The results are shown in Table 2. The rankings of the alternatives in Table 2 were obtained by calculating the score function of FF-WPM.

Table 2. Numerical results obtained by FF-WPM

Alternatives/Grids	**FF-WPM**						**Score**			**Rank**		
	G1		**G2**		**G3**		**G1**	**G2**	**G3**	**G1**	**G2**	**G3**
S_1	0.734	0.761	0.744	0.725	0.753	0.729	-0.045	0.031	0.039	3	3	2
S_2	0.742	0.760	0.760	0.722	0.763	0.728	-0.031	0.062	0.060	2	**1**	**1**
S_3	0.707	0.767	0.752	0.724	0.743	0.733	-0.098	0.046	0.017	6	2	4
S_4	0.729	0.762	0.703	0.743	0.685	0.753	-0.055	-0.063	-0.104	4	5	6
S_5	0.732	0.772	0.542	0.890	0.751	0.729	-0.068	-0.546	0.037	5	6	3
S_6	0.745	0.758	0.710	0.730	0.740	0.733	-0.023	-0.032	0.011	**1**	4	5

According to the results, it is seen that the alternative renewable energy source type is suitable for the renewable energy potential in the grids. When the alternatives are ranked with FF-WPM, optimal alternative energy source for G1 is S6 (Hydropower), and optimal alternative energy source for G2 and G3 is S2 (Solar). In the ranking obtained with the FF-WPM method, it is seen that the values for G1 are very close to each other. This situation can be considered as Istanbul is suitable for various alternative energy sources.

4. CONCLUSIONS

This study aims to find optimal alternative renewable energy sources for grids designed to minimize the HSC network risk for the transportation sector in Turkey in 2050. The FF-WPM methodology, one of the MCDM techniques, is fused in the selection of renewable energy resources because it can take into account many criteria that change over time, such as renewable energy types and priorities, and six renewable energy sources were evaluated for grids with five main criteria and 21 sub-criteria. According to the results, the alternative energy source in the grids is compatible with the renewable energy sources of that grid.

ABSTRACT

Evidence synthesis is a method that systematically collate and synthesize existing research evidence to provide a comprehensice summary of available knowledge on a particular topic. Based on the evidence synthesis approach, this study presents a comprehensive analysis of the research conducted on biohydrogen production in Turkey. In this context, the methods of photofermentation, dark fermentation, and biophotolysis have been evaluated using systematic literature review and meta-analysis methods. The research aimed to compare the hydrogen efficiency performance of these methods, bringing together the evidence from the existing literature and providing a holistic perspective. Based on evidence synthesis, the strengths and limitations of biological methods have been identified, and it has been discussed how these limitations can be overcome with innovative approaches. The results of the study provide a detailed perspective on the research in Turkey, while also highlighting areas that are lacking and need improvement. This study aims to make a significant contribution to the knowledge base on sustainable hydrogen production and offers recommendations that will guide future research in this field.

Keywords: Evidence Synthesis, Biohydrogen Production, Dark Fermentation, Photofermentation, Biophotolysis

1. INTRODUCTION

The evidence synthesis method is an effective approach for methodically presenting critical and summarized information to decision-makers. The evidence synthesis approach offers a framework for the methodical integration, combination, and interpretation of research findings, thereby providing an in-depth overview of the current information relevant to a certain issue. The evidence synthesis technique enables the clear identification of system gaps, strengths, and weaknesses, offering a robust reference for decision-makers and policymakers. Evidence Synthesis (ES) are currently being utilized in fields such as international development and environmental decision-making [1-2].ES offers numerous advantages in academia, similar to its role in decision-making and policy development. It fosters transparency and impartiality, reduces bias, and improves the dependability of results. This fosters stakeholder confidence in the conclusions derived from the evidence, resulting in more efficient and dependable decision-making processes. Furthermore, it assists in recognizing deficiencies in knowledge and research. Through the systematic examination of existing literature, researchers may identify regions with limited or conflicting evidence. This promotes the development of new evidence and can inform future research objectives.

Due to the increasing global demand for energy and the growing problems caused by the environmental impacts of fossil fuels on human life, the need for sustainable energy sources is increasing. Hydrogen is a promising resource that stands out among sustainable energy sources. Biohydrogen is one of the most sustainable hydrogen production methods due to the advantages of organic waste conversion potential and low energy need of operation[3]. Moreover compared to fossil fuels, biohydrogen is the type of fuel with the highest energy potential per unit mass. One kilogram of hydrogen is equivalent to the energy contained in 2.8 kilograms of petroleum or 2.1 kilograms of natural gas [4]. Biohydrogen can be produced by recycling organic materials such as sugarcane bagasse, corn cobs, fruit pulps, wheat bran, and grass residues [5]. This method offers significant contributions to both environmental and economic sustainability. In this study, academic studies on biohydrogen production in Turkey over the past 10 years will be systematically examined, and the biological methods used in biohydrogen production will be comprehensively analyzed in accordance with efficiency criteria. In addition to the advantages of biological methods, their current limitations will also be evaluated, and suggestions on how to overcome these limitations will be discussed. In this context, it is aimed to provide a holistic perspective on the potential and limitations of biological methods in energy production processes by examining the existing literature through the evidence synthesis method.

Biohydrogen production can be carried out using different methods. The common feature of these methods is that they do not require high pressure and high temperature conditions. These projects, which have low energy requirements, can be carried out in accordance with the principles of zero waste and zero emissions. The biohydrogen production methods are [6];

-Dark fermentation: Dark fermentation occurs using carbohydrates by spore-forming anaerobic and anoxic bacteria. Regardless of day or night, the process can be carried out without the need for any light source. In the dark fermentation process, different organic materials can be used as sources for hydrogen production. In hydrogen production through Dark Fermentation, agricultural wastes containing starch and cellulose, wastewater rich in carbohydrates from the food industry, and sewage sludge can be considered as raw materials [7].

-Photofermentation: The photofermentation method is an innovative biotechnological approach that stands out in biohydrogen production. This method is a biotechnological process that enables the production of hydrogen gas from organic waste using light energy. During this process, organic materials are used as an energy source by bacteria. The efficiency of this process can vary depending on the organic matter used, light intensity, and other environmental factors.

-Biophotolysis: In direct biophotolysis, solar energy directly separates water molecules into hydrogen ions and oxygen through photosynthetic reactions. The hydrogen ions released from this reaction are converted into hydrogen gas using the hydrogenase enzyme. This hydrogenase enzyme is provided by green algae and blue-green algae. Indirect biophotolysis is used to avoid the problems caused by O_2 accumulation in the direct biophotolysis method. Indirect biophotolysis is a method that involves the biomass production capability of photosynthetic microorganisms and the use of this biomass for hydrogen production [6].

-Hybrid processes are the combination of at least two biohydrogen method to improve the hydrogen production yields and process efficiencies[6].

2. METHODOLOGY

Meta-analysis is a method in which various analyses are conducted to summarize the results of quantitative research on a topic. To facilitate comparison between studies, quantitative meta-analysis uses a statistic called effect size, which defines the strength and magnitude of an effect [4]. The purpose of this method is to evaluate the results of quantitative studies conducted on the same topic in a brief and detailed manner. Meta-analysis studies are generally grouped into six stages.

i. Determining the Objectives and Goals of the Research
ii. Literature Review
iii. Coding of Studies
iv. Effect Size Index
v. Statistical Analysis
vi. Results and Comments

As in all research, it is important in meta-analysis to fully understand the quality of the data, the rigor applied during the coding and analysis phases, and the statistical assumptions made [8].
Research Approach
This study aims to conduct a comparative analysis of the biological methods used in biohydrogen production in terms of efficiency criteria. For this purpose, the existing literature has been systematically examined using the "evidence synthesis" method. This method allows for a comprehensive evaluation by bringing together information obtained from different studies.

Data collection
In the study conducted by Melitos et al [9], it is observed that there has been an increasing trend in biohydrogen production over the past 10 years. As in the rest of the world, it is observed that the number of academic studies on hydrogen production has increased in our country as well, and with the guidance of government incentives and national policies, there have been advancements in academic studies in this field. Within the scope of this study, academic works in Turkey have been examined. Therefore, academic studies in Turkey have been examined both in terms of articles and completed theses. With the results of this study, the current state of the biohydrogen topic is presented, aiming to prepare a resource for decision-makers to create a roadmap.

Literature Review Method
The literature review was conducted using the following databases and keywords:
• Databases: YÖK-Tez, GoogleScholar (for Turkish journals), DergiPark

Keywords are “Biyohidrojen Üretimi”, “Biyofotoliz”, “Direkt Biyofotoliz”, “İndirekt Biyofotoliz”, “Karanlık Fermentasyon”, “Fotofermentasyon”, “Biohydrogen Production”, “Biophotolysis”, “Direct Biophotolysis”, “Indirect Biophotolysis”, “Dark Fermentation”, “Photofermentation”.

Initial screening
In the initial screening, articles were evaluated based on their titles and abstracts. Duplicate articles in different databases and articles not directly related to the research question were removed from the list, and the remaining articles were included for the next step.

Inclusion and Exclusion Criteria

The inclusion and exclusion criteria for the study have been established in accordance with specific standards. Among the inclusion criteria are that the studies were published between 2014-2024, written in Turkish, addressed the production of biohydrogen using biological methods, and reported hydrogen efficiency metrics. On the other hand, the exclusion criteria include publications that are not directly related to biological methods, studies that do not contain sufficient technical details, and sources whose full text is not accessible. Search results will primarily be evaluated through title and abstract screening; studies that pass this stage will then be included in the detailed full-text analysis process.

Full Text Review
At this stage, the articles that pass the initial screening and criteria review are examined in detail. At this stage, the scientific approach, quality, and accuracy of the article, as well as the relevance and comparability of the results, are examined.

Data Source and Selection
Initially, YOKTEZ system, DergiPark and google scholar was screened. This selection process was carried out according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines.

3. RESULTS AND DISCUSSION

In the initial screening conducted within the scope of this study, 62 studies were found in the YÖKTEZ system, 14 studies in Turkish sources on Google Scholar, and a total of 54 studies in the DergiPark database. When systematic elimination is performed according to the specified criteria, a total of 26 studies are found. When these studies are examined, it is observed that biohydrogen research has gained importance in our country academically. Using the evidence synthesis method, the stages to be detailed in these studies will include the type of process used, the amounts of organic waste, hydrogen production yields, and efficiency values. With the results obtained, the current status of biohydrogen studies in our country will be presented to decision-makers. Studies on biohydrogen are of significant strategic importance in achieving zero waste and zero emissions within the framework of a circular economy. Therefore, the results of this study will serve as a guide for increasing the number of studies on biohydrogen, diversifying the incentives provided, and advancing academically in this field [Fig.1]. In the analysis based on the evidence synthesis method, it is observed that various academic studies have been conducted on all processes of biohydrogen production in Turkey. Based on the diversity of organic waste in our country, dark fermentation studies have been conducted using different types of waste as substrates [10]. As a country that receives sunlight for a long period of the year, both photofermentation and biophotolysis studies have been carried out. In photofermentation studies, pilot-scale outdoor systems are noteworthy[11]. The ability to produce biohydrogen at an industrial level is crucial for achieving higher yields from academic studies and for collaboration with industry. Collaboration with industry and the determination of production capacities at an industrial scale should be established, and roadmaps to achieve these capacities should be drawn. With this study, it is aimed to create one of the starting points of this roadmap.

4. CONCLUSION

In conclusion, our synthesis of biohydrogen studies in Türkiye reveals a dynamic and rapidly evolving field with significant potential for sustainable energy solutions. The evidence highlights the importance of continued research and development to overcome current limitations and harness biohydrogen's full potential. Future studies should focus on optimizing production methods, exploring new biomass sources, and enhancing the scalability of biohydrogen technologies. This evidence synthesis reveals that biohydrogen research in Turkey has shown promising advancements. Fostering collaboration among academic, industrial, and governmental stakeholders could accelerate innovation and commercialization. Future studies should prioritize biohydrogen production to align with global trends and Turkey’s strategic energy objectives. Biohydrogen holds the potential to significantly contribute to a sustainable and circular economy, positioning Turkey as a leader in renewable energy technologies. By addressing these challenges, this study aims to be a brief report for researchers and for policy makers.

ABSTRACT

Biohydrogen production is a promising sustainable energy source, requiring accurate yield predictions to optimize processes and scale industrial applications. This study evaluates advanced boosting regression algorithms—Gradient Boosting Regressor (GBR), Extreme Gradient Boosting (XGBoost), Adaptive Boosting (AdaBoost),—for modeling biohydrogen production. Experimental data, including inoculum, glucose and oxygen concentrations were used to train and test the models. Key evaluation metrics—mean absolute error (MAE), root mean square error (RMSE), and coefficient of determination (R^2)—highlight the effectiveness of boosting algorithms in capturing complex, nonlinear relationships in biohydrogen production. Among the models, XGBoost demonstrated superior accuracy. This study emphasizes the potential of boosting regressors as robust tools for biohydrogen process optimization. It also offers guidance on algorithm selection and parameter tuning, contributing to predictive framework development for biohydrogen research and industrial applications.

Keywords: Biohydrogen Production, Boosting Regressors, Gradient Boosting Regressor (GBR), Extreme Gradient Boosting (XGBoost) and Adaptive Boosting (AdaBoost) Algorithms

1. INTRODUCTION

Sustainability, one of the most important concepts of recent years, has environmental, social and economic dimensions. For a sustainable world, these three concepts should proceed in harmony with each other like the gears of a machine. However, the emphasis on economic growth to meet the demands of the growing world population has left environmental and social growth behind. At this point, it is necessary to turn to clean technologies and clean energy sources to achieve a rebalance. Biotechnological approaches play a major role in clean technologies. Renewable energy sources and especially the use of biofuels meet many of the United Nations Sustainable Development Goals[1]. Hydrogen is one of the most important resources because it can be used both as a fuel, in electricity generation and in the production of valuable chemicals. Hydrogen energy has the potential to meet 80% of the world's energy needs[2]. Among renewable energy sources, biohydrogen is one of the best alternative fuels because, among hydrogen production technologies, biohydrogen production is the most sustainable as it occurs at ambient temperature and therefore requires only a low energy input [3-6]. In addition, since different organic wastes can be used, an important evaluation is made on waste recycling. The biggest indicator that biohydrogen production is a clean technology is that only water is produced as a by-product of combustion or conversion to electricity [7]. Among different hydrogen production methods, biohydrogen production is the most environmentally friendly method because of the advantages of operating at mild conditions, possibility of organic waste transformation and less energy input [8]. The main disadvantages of biohydrogen production are low production yields and high process costs. Therefore, many studies are focused on cost reduction and process optimization. The optimization of the parameters such as carbon/nitrogen ratios, pH levels, temperature, and light wavelength and intensity, among other characteristics could be done by using experimental design methodologies. In recent years, machine learning algorithms have been increasingly applied to model and optimize biohydrogen production. These methods have shown promising results in capturing complex and nonlinear relationships between process parameters. However, studies utilizing machine learning techniques for biohydrogen production remain limited in the literature. In this study, we focus specifically on boosting methods and evaluate the performance of Gradient Boosting Regressor (GBR) [9], Extreme Gradient Boosting (XGBoost) [10] and Adaptive Boosting (AdaBoost) algorithms[11]. The potential of these algorithms to model and predict biohydrogen yields under varying experimental conditions was investigated. The results demonstrate that boosting-based models offer high accuracy and low error rates, making them powerful tools for process optimization. This study highlights the applicability of machine learning methods to improve the efficiency and scalability of biohydrogen production systems.

2. MATERIALS AND METHODS

Experimental data were collected from a study on optimization of sequential microaerobic dark-and photo-fermentation biohydrogen production by photo fermentative biohydrogen production [12]. The key optimization parameters - inoculum amount, glucose and oxygen concentrations, were systematically varied to capture a wide range of production scenarios using Box-Behnken experimental design and the regression analysis performed to predict biohydrogen production.

Boosting algorithms are ensemble techniques designed to transform weak base learners into strong predictive models. These algorithms improve performance by iteratively focusing on samples that are difficult to predict, reducing bias and variance in the process. At each iteration, a weak learning model is applied to the data, giving more emphasis to samples that were misclassified in previous steps. This iterative approach ensures that the model continuously refines its predictions, becoming increasingly accurate over time. The boosting process typically follows a series of steps. First, the model is initialized by assigning equal weights to all data samples. Next, a weak learner is trained, and prediction errors are calculated. Weights of misclassified samples are then increased to emphasize harder-to-predict instances. This process is repeated until a predefined accuracy level or maximum number of iterations is reached. Finally, the predictions from all weak learners are combined to form a strong final output. The general block diagram of boosting algorithms is illustrated in Figure 1, highlighting the sequential training and integration process that defines these methods.

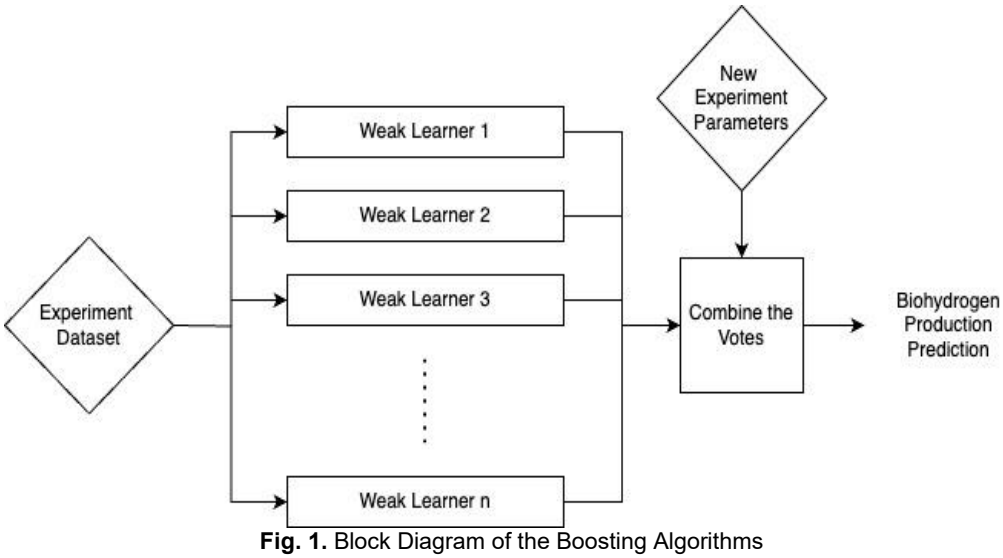

Fig. 1. Block Diagram of the Boosting Algorithms

In the literature, three boosting algorithms are commonly discussed: AdaBoost [11], Gradient Boosting [9], and Extreme Gradient Boosting (XGBoost) [10]. AdaBoost applies weak learners sequentially, updating weights to emphasize misclassified samples. Each iteration seeks to improve upon errors made by previous iterations. It is simple and effective for smaller datasets, with tunable hyperparameters like learning rate and number of estimators. GBR minimizes prediction errors by fitting new models to the residuals of prior models. Each step improves upon previous errors by calculating gradients and minimizing loss using gradient descent. It is highly customizable, offering hyperparameters such as learning rate, number of estimators, and maximum tree depth. XGBoost builds on gradient boosting by introducing regularization terms to prevent overfitting. It uses advanced techniques such as column subsampling and parallel computing for faster training. It also handles missing values and prunes trees effectively, making it one of the most efficient boosting algorithms. Since the objective was to predict H_2 production values, model performance was evaluated using root mean square error (RMSE) and coefficient of determination (R^2). These metrics were selected to assess the precision, reliability, and generalization ability of the models. RMSE emphasizes larger errors, and R^2 indicates the proportion of variance explained by the model, providing a comprehensive evaluation of predictive performance.

3. RESULTS

The dataset consists of the following columns based on the raw file inspection: Inoculum concentration, which represents the concentration of the inoculum used in the experiment and is likely measured in units such as g/L or mg/L; oxygen concentration, which denotes the concentration of oxygen in the experimental setup and potentially influences anaerobic conditions necessary for biohydrogen production; and glucose concentration, which refers to the glucose concentration in the medium, acting as a carbon source for microbial activity and measured in specific units (e.g., g/L). These variables

serve as key predictors in determining hydrogen yield. Data preprocessing and analysis were conducted in Python 3.8. Libraries such as Pandas and NumPy facilitated data handling, while Matplotlib and Seaborn supported data visualization. Model development leveraged Scikit-learn and XGBoost frameworks for training and evaluation.

Table 1.Experiment Values and Hydrogen Production Predictions

	İnoculum Concentration	Oxygen Concentration	Glucose Concentration	H2 Yield (Y),mol/mol	Hydrogen Production, mmol	Predictions_AdaBoost	Predictions_GradientBoosting	Predictions_XGBoost	Is_Test

4. CONCLUSION

The results of this study demonstrate that boosting regression algorithms are effective in predicting biohydrogen production under varying experimental conditions. These methods can reduce experimental costs by enabling accurate predictions of hydrogen yield, thereby minimizing the need for extensive physical experiments. Furthermore, in experiments involving multiple variables, each material or parameter can be treated as a feature. Feature importance can be calculated to determine the most influential factors affecting biohydrogen production. This insight can guide future experiments and process optimizations. Future work will extend this study by applying these regression techniques to different biohydrogen production processes and exploring their performance with more complex datasets. This expanded approach aims to further enhance the predictive modeling of biohydrogen yields, contributing to improved efficiency and scalability in biohydrogen production systems.

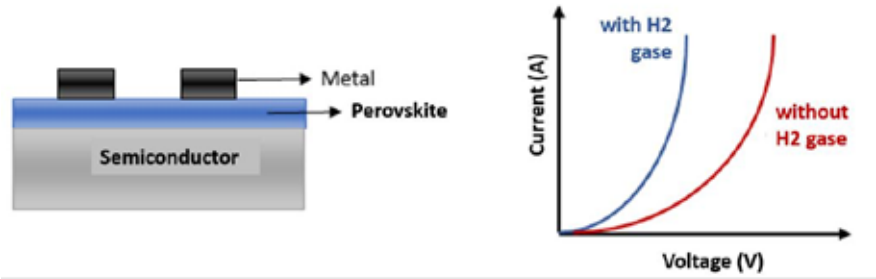
ABSTRACT
Hydrogen (H_2), a clean, efficient and renewable energy source, is considered as an ideal energy source in the near future. Today, H_2 is used in many industrial areas such as chemistry, food, semiconductor, transport. There is a need for sensors that can measure hydrogen quickly and accurately in a wide concentration range. These sensors are used in security, determination of H_2 purity in hydrogen production plants and leakage control in H_2 storage areas. In this research, perovskite $BaTiO_3$ based H_2 sensors will be investigated. H_2 sensor applications of perovskites, which are a very large family, easily available and low cost, are very limited.

Keywords: $BaTiO_3$, perovskite, hydrogen sensors, electrical characterization

1.INTRODUCTION
As a sustainable, renewable and clean fuel, hydrogen (H_2) can be used as a kind of green fuel due to its advantages (Hübert et al., 2011; Zhang et al., 2013), such as low density, significant combustion heat and no pollution emission (Mirzaei et al., 2019). In recent years, there has been a lot of research and investment in the world to obtain clean energy. These studies are especially focused on hydrogen. In addition, the importance of hydrogen sensors is increasing due to the development of hydrogen gas as an energy carrier and chemical reactant and the expansion of its usage area. As a colourless, odourless and tasteless flammable gas, hydrogen cannot be detected by human senses and therefore other methods are required to detect its presence and measure the concentration (Esfandiar et al., 2014; Seekaew et al., 2019). Fast and accurate hydrogen gas concentration measurement is crucial to herald the formation of potentially explosive mixtures with air and help prevent the risk of explosion. As the diffusion coefficient in air is large (0.6 cm^2/s), they are highly likely to cause a sudden explosion (Hübert et al., 2011). However, hydrogen has many disadvantages in terms of safety. The very low minimum energy required for ignition in air at atmospheric pressure causes it to ignite easily olur (Kabcum et al., 2016; Korotcenkov et al., 2009). When mixed with air, the explosive concentration range is quite wide between 4-75 % by volume (Korotcenkov et al., 2009; Y. Liu et al., 2014). Due to its ultra-small molecular size, it can easily leak out of containers (Nakate et al., 2018). Therefore, it is very important to develop H_2 sensors to precisely monitor H_2 concentration. H_2 sensors have different uses such as safety, leakage, quality and biomarker.
The perovskite oxide structure, formula ABO_3, consists of a wide variety of oxides with transport properties ranging from predominantly ionic conduction to electronic conduction. Perovskite oxides are particularly attractive for high-temperature applications because they often have high melting and/or decomposition temperatures, as well as providing microstructural and morphological stability to improve reliability and long-term sensor performance. In addition, the perovskite structure has two different sized cations, making it amenable to a variety of dopants. This doping flexibility allows control of transport and catalytic properties to optimize sensor performance in specific applications (Fergus, 2007). Perovskite oxides have been used in many gas sensor applications such as oxygen (Shimizu et al., 1985), CO (Malavasi et al., 2005), CO_2 (Wang et al., 2013), NO_2 (Ueda et al., 2009), acetone (X. Liu et al., 2008), ethanol/methanol (Doroftei et al., 2013), hydrocarbon (Sahner et al., 2005) and H_2 (Huang et al., 2019).
The detection of H_2 gas, which is difficult to be detected by human senses because it is colorless and odorless, requires the development of highly sensitive, selective and low-cost portable sensors (Sisman et al., 2024). One of the most promising sensors developed for this purpose is semiconductor metal oxide (SMO)-based chemoresistive gas sensors with high sensitivity, low fabrication cost and compatibility with standard semiconductor technologies (Dey, 2018). In the semiconductor-based Schottky diode H_2 sensors shown in Figure 1, gas molecules are decomposed on the metal surface through a catalytic reaction (Kilinc et al., 2024). The reaction products and intermediates can be polarized and absorbed on the metal surface or spilled onto the exposed parts of the oxide surface. Hydrogen atoms formed by the decomposition reactions of hydrogen or hydrogen-containing species diffuse through the catalytic metal and form dipoles at the metal-insulator interface (Tobias et al., 1997). The resulting dipole layer alters the electric field distribution within the sensors, causing a shift in current-voltage (I-V), capacitance-voltage (C-V) or conductance-voltage (G-V) characteristics.



(a) **(b)**

Figure 1. (a) Cross-sectional representation of semiconductor-based gas sensors and **(b)** I-V variations under the influence of H_2 gas (Trinchi et al., 2008).

SMO-based gas sensors, especially small-sized SMO-based gas sensors, have become increasingly important as they enable the development of portable sensors (Gu et al., 2012; Sahoo & Kale, 2021). However, there are some problems with SMO-based gas sensors such as high operating temperature, poor stability, sensitivity and selectivity (Korotcenkov & Cho, 2017). To solve these problems, research has been conducted on various perovskite oxides (Fergus, 2007). Because perovskite oxides generally have a stable structure, they have attracted particular attention to improve long-term sensor performance. Perovskite-based sensors have proven to provide high sensitivity and good selectivity in addition to their stable structure (Toàn et al., 2003).
In the research conducted on $BaTiO_3$ based CO sensors, an increase in gas detection sensitivity was observed due to the increase in porous structure at high temperature (400 ^{0}C) (Park & Seo, 2004). $BaTiO_3$ thin films have been used in many gas sensors such as CO_2 (Mandayo et al., 2006), NO_2 and NH_3 (Patil et al., 2019). Metal oxide doped $BaTiO_3$ has been proposed as a thin film for the detection of LPG gas and has shown high sensitivity and selectivity for gases such as H_2, H_2S, CO (Chaudhari et al., 2006). In addition, $BaTiO_3$ nanotubes have shown efficient results as humidity sensors (Soderznik et al., 2019). The advantages that make $BaTiO_3$ material attractive for industrial applications include high response, low operating temperature and fast response-recovery times. Therefore, investigating the H_2 sensor parameters of $BaTiO_3$ material will make an important contribution to the literature.

2. MATERIALS AND METHODS

2.1. Experimental Set-up and Procedure

For the fabrication of n-Si/$BaTiO_3$/Pt devices, commercially available n-Si wafer RCA1 cleaning procedure was applied (Taşyürek 2022). The matte surface of the cleaned n-Si wafer was coated with 100 nm aluminum (Al) metal by DC sputter method as a back contact. $BaTiO_3$ was coated on the glossy surface of the n-Si wafer by drip-coating method as an interface. Finally, platinum (Pt) point contacts for electrical measurements were coated by DC sputtering. I-V and AC measurements of the fabricated n-Si/$BaTiO_3$/Pt devices were performed at room temperature and temperature dependent. Keysight B2901BL Precission Source/Measure Unit was used for I-V measurements and Hioki IM3536 LCR Meter was used for AC measurements.

2.2. Analysis

The I-V characteristic of the Schottky type contact and the corresponding voltage at forward bias can be explained by the Thermionic Emission (TE) theory (Tung, 2001);

$$I = I_0 \left[exp\left(\frac{(qV)}{nkT}\right) - 1 \right] \quad (1)$$

$$I_0 = AA^*T^2\, exp\left(\frac{q\Phi_B}{kT} - 1\right) \quad (2)$$

where A* is the Richardson constant, A is the current diode area, Φ_B is the barrier height, T is the temperature, k is the constant of Boltzmann, V is the voltage, q is the electric charge, I_0 is the saturation current, and n is the ideality factor. The following formulae are used to calculate n and Φ_B using the TE method;

$$n = \frac{q}{kT}\frac{dV}{d(ln\, I)} \quad (3)$$

$$q\Phi_B = kT\, ln\left(\frac{AA^*T^2}{I_0}\right) \quad (4)$$

3. RESULTS AND DISCUSSION

Figure 2 shows the I-V characteristics of the n-Si/$BaTiO_3$/Pt device measured in the range 293-433 K in 20 K steps. As can be seen from the graphs, the n-Si/$BaTiO_3$/Pt device exhibited Schottky behavior at low temperatures near room temperature. However, it exhibited ohmic behavior as the temperature increased. This can be attributed to the inhomogeneities in the contact area and the series resistance effect. Figure 3 shows the H_2 sensor tests of the n-Si/$BaTiO_3$/Pt device. The normal and semi-logaritmic I-V variations of the device at room temperature in dry air and 1% H_2 flow are given. As can be seen from the figure, the n-Si/$BaTiO_3$/Pt device showed sensitivity to H_2 gas. Sensor response $(I_{H2}-I_{air})/I_{air}$ value was calculated 6.99.

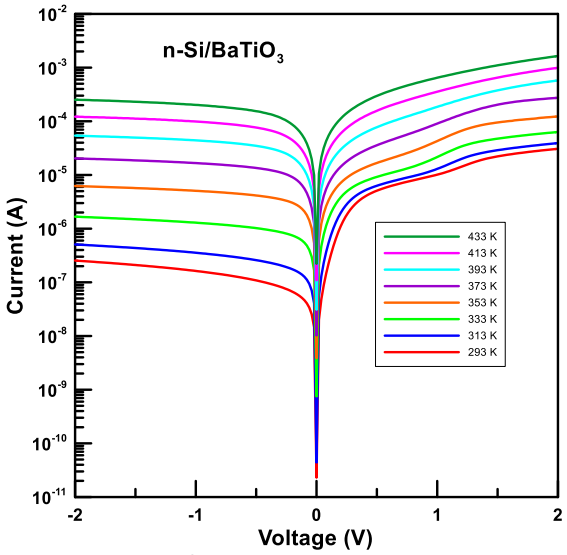


Figure 2. Temperature dependent changes of semi-logaritmic I-V graphs with 20 K steps between 293-433 K

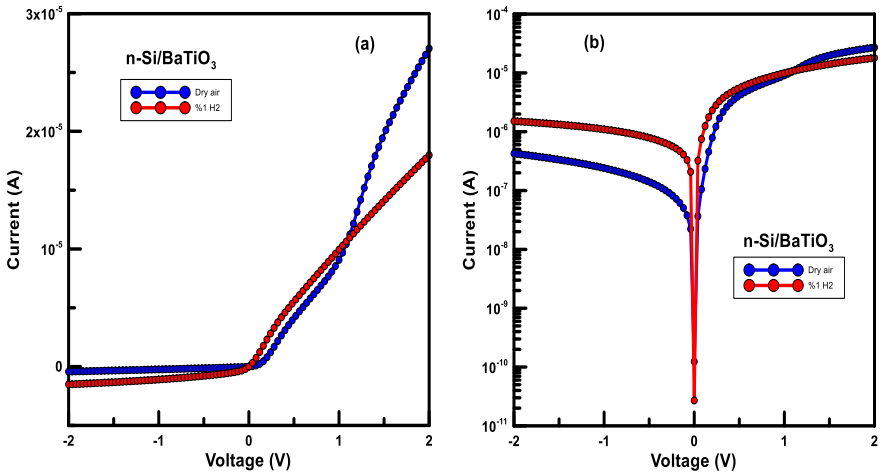

Figure 3. Variation of **(a)** I-V and **(b)** semi-logaritmic I-V graphs at room temperature, dry air and 1% H_2 flow

4. CONCLUSIONS

DC magnetron sputtering and drip-coating methods were used to fabricate n-Si/$BaTiO_3$/Pt devices. I-V measurements showed Schottky behavior at low temperatures and ohmic behavior as the temperature increased. In gas measurements at room temperature, measurements were made in dry air and 1% H_2 flow. According to the gas tests, the device showed sensitivity to H_2 gas.

ABSTRACT

In this study, articles on hydrogen energy were examined with the bibliometric analysis technique and the first 100 most cited articles were analyzed. Bibliometric analysis allows planning research, determining trends in the field and focusing on important studies in the field. In this context, it is aimed to contribute to the literature by analyzing hydrogen energy studies with the bibliometric approach. Bibliometric analysis is an important tool for measuring the scientific impact and popularity of authors, keywords, journals, institutions and countries in the field of research, as well as being used to determine potential directions for future studies in the field of research. The most fundamental determinant of bibliometric research is the quality of the data representing the relevant literature. It is important to choose the relevant database correctly and determine the search criteria. There are many databases that provide data sets for bibliometric research. Web of Science (WoS) is the oldest and most widely used database in the world. For this purpose, 83500 articles were found in the search made on hydrogen energy in the Web of Science database. The first 100 most cited articles were selected and this data set was analyzed with the VOSviewer Program for bibliometric analysis, and comments were presented along with suggestions.

Keywords: Citation analysis, Bibliometric analysis, hydrogen, hydrogen energy

1. INTRODUCTION

Hydrogen is not a natural fuel, but there are various ways to produce hydrogen by utilizing primary energy sources, extracting it from fossil fuels, or by greener and more sustainable methods such as electrochemical methods, thermochemical cycles, photonic methods, biological methods, etc. In addition, biomass utilization using thermochemical processes is a promising way to produce hydrogen while treating waste. Pyrolysis is a thermal process that breaks down biomass into liquid biofuel, solid coal, and synthesis gas, which can be further processed to obtain hydrogen [1]. The most important feature that distinguishes hydrogen from other alternative energy sources is that it can be transported and stored. With the development of hydrogen production over approximately thirty years, there is a hydrogen economy that is dependent on the chemical and petroleum industry worldwide and is growing. For this reason, hydrogen is pointed out as the only alternative to petroleum, coal and natural gas that can become widespread in the future [2]. Bibliometric analysis serves as a tool used to map the latest status in a field related to given scientific knowledge. For this reason, the bibliometric method is used to analyze the scientific performance of authors, articles, journals, institutions, countries, keywords, and citation counts [3]. Although the number of bibliometric analyses in our country has increased, it is seen that the studies conducted in the field of bibliometrics in our country have not reached a sufficient level when compared to the international literature. Scientific knowledge is increasing exponentially today. Researchers need to look at more research and studies than in the past. It is not easy for researchers to follow developments with traditional literature reviews. In this sense, bibliometric analysis is of critical importance for researchers to follow all developments in the field of research. Bibliometric analysis allows the researcher to reach the data required at the beginning of the research in a short time with minimal effort [4]. Bibliometric analysis is an analysis method that is used to obtain qualitative and quantitative data on current developments in the field of hydrogen energy and provides information by visualizing what has been done before us. Citation analysis is a method that examines how often an academic study is cited by other studies. With citation analysis, the most influential studies, authors, journals, institutions and countries in the field of hydrogen energy can be quickly determined before reading and researching. If more than one author is listed as a co-author for the same publication, it is clear that these authors collaborated [5]. In these studies, a network is created based on author and citation relationships. When these networks are examined, clusters are seen with different densities and high interactions between clusters are seen with the same colors. The size of the clusters is directly proportional to the number of cited articles. As the size of the clusters increases, the number of citations and interactions increases. In bibliometric research, network analysis and network maps are made available [6]. VOSviewer is a software tool used to create and visualize bibliometric networks. Visualization is done through VOSviewer. The first visualization shows the clusters in a clustering solution and the citation relationships between these clusters. Bibliometric studies are valuable tools that allow us to understand the performance, change, interaction of literature in a scientific field to a certain extent, with its structure affected by different disciplines, and are increasingly used every day. The first 100 most cited articles in the field of hydrogen

energy were selected and this data set was analyzed with the VOSviewer Program for bibliometric analysis, and comments were presented with suggestions.

2.1. Results Regarding Co-Author Analysis

In the co-author analysis, authors who collaborated in the dataset and the collaboration networks between authors were presented. In our study, authors with at least 4 articles were included.

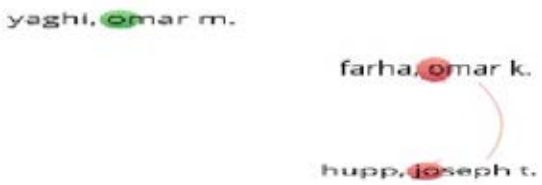

Fig.1. Co-author analysis relationship network map and country relationship network map

2.2. Results Related to Common Keyword Analysis

Common keyword analysis shows the frequency of words in the titles, keywords, and abstracts of studies on hydrogen energy and the relationship network between them. Common keyword analysis is done based on bibliographic data, on the keywords of the studies. It is very important to choose the keywords in the article well and use them in their proper place [7]. Keywords used at least 2, 3 and 6 times were included and determined.

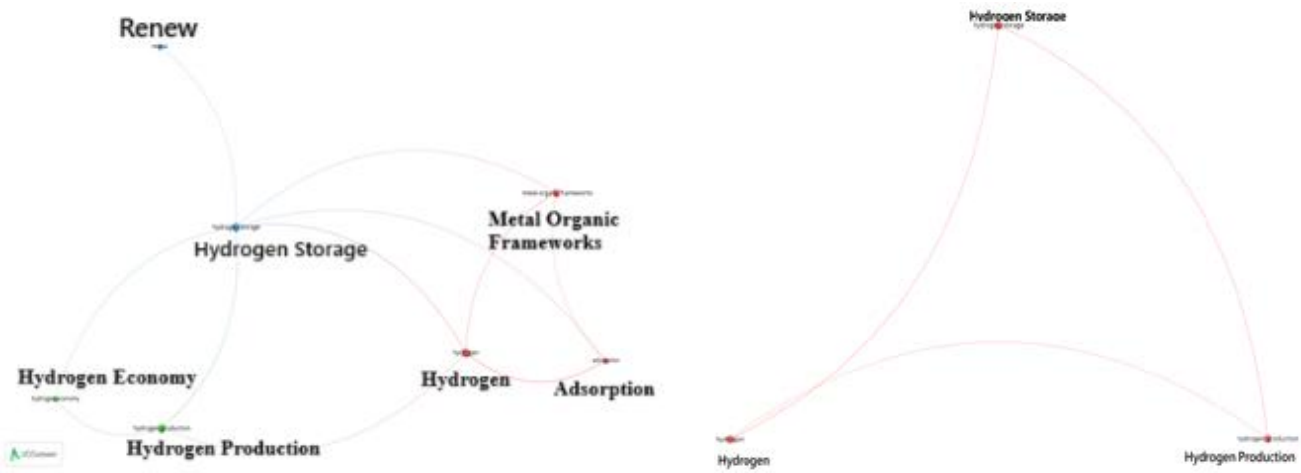

Fig. 2. Common three-times-repeated keywords network map and six-times-repeated keywords network maps

2.3. Results Regarding Citation Analysis

Citation analysis is related to the impact of studies and how often other researchers are cited as sources. It is known that citation analysis is used in the literature for two purposes:

- Citation analysis of studies downloaded as data
- Citation analysis of bibliographies of studies downloaded as data

VOSviewer performs citation analysis on studies in the dataset. It offers an approach where the performance of each element is measured based on the number of studies and citations. However, citation information only shows the number of citations made to the articles in the downloaded dataset by articles published in the Web of Science. The citation counts of articles are an important indicator in measuring their impact. In order to reach the citation count, the publication of the article and its scientific recognition and citations require a long-term process. As a scientific article attracts attention, the number of citations increases. The number of citations is one of the most important measurements used to measure the impact of the article [6]. Fig.4 shows that out of a total of 14649 studies, only 111 studies were cited 6 or more times by the studies in the dataset.

3. RESULTS AND EVALUATION

In this study, articles on hydrogen energy were examined with the bibliometric analysis technique and the first 100 most cited articles were analyzed. Bibliometric analysis is a modern type of analysis and detailed information is obtained by analyzing the co-author, common keyword, citation counts, and reference match of important studies

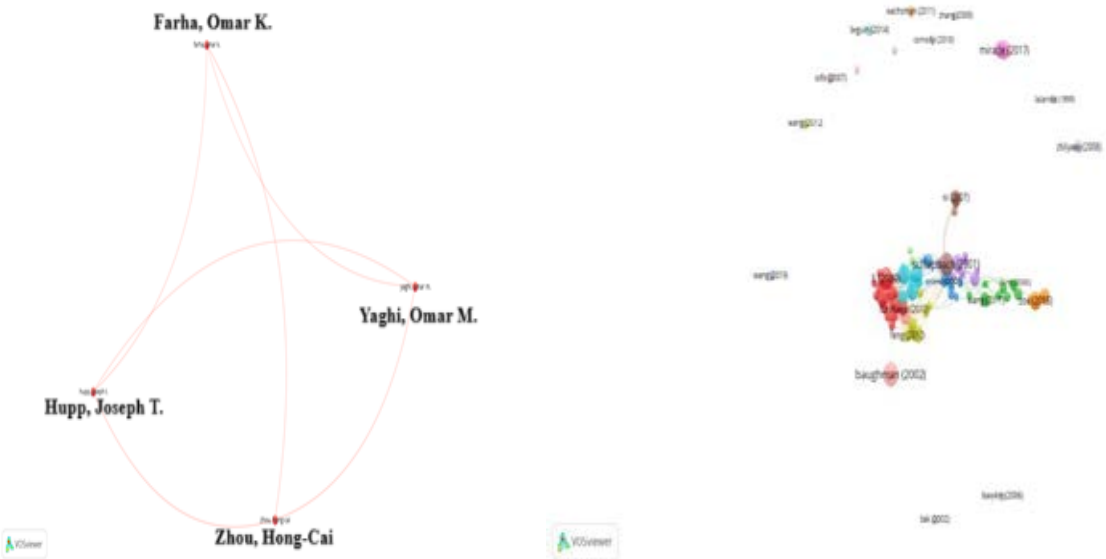

Fig. 3. Network map of the most influential authors analysis and authors with at least 100 citations

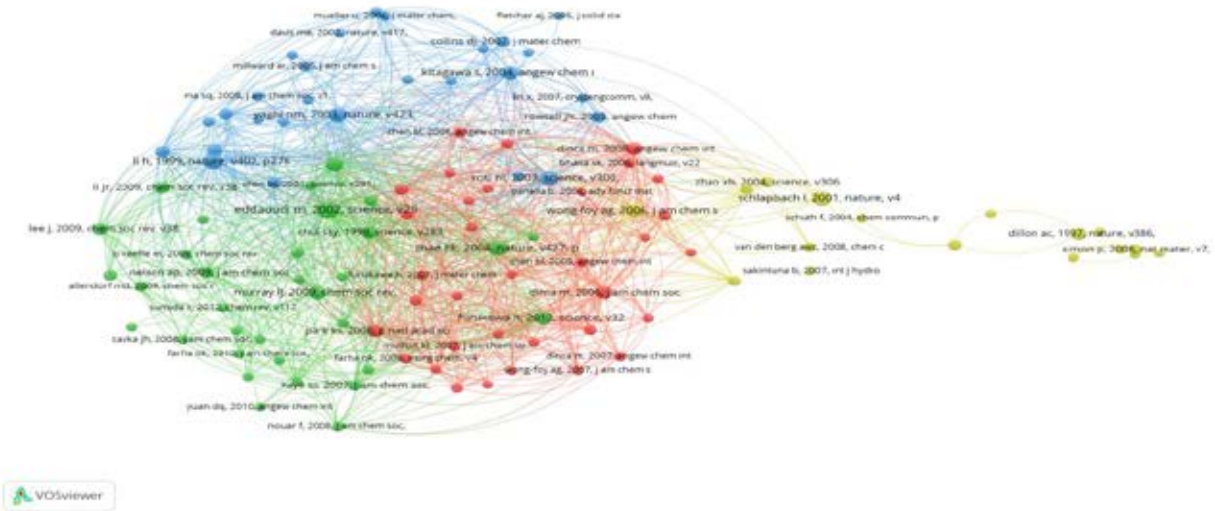

Fig. 4. Co-citation analysis network map in the context of cited studies

on hydrogen energy. In this context, bibliometric analysis allows researchers to quickly and easily access qualified studies on hydrogen energy. Bibliometric analysis used in the study is a modern type of analysis and has contributed to the development of researchers' perspective as a method that can quickly and easily access qualified studies on hydrogen energy. The main purpose is to examine the trend in the field of hydrogen energy and to provide researchers with quick and easy access. In this context, a comprehensive bibliometric analysis guiding the literature on hydrogen energy and visualizing the most cited scientific studies in the Web of Science (WOS) database was applied. The most cited 100 studies were analyzed under co-author analysis, keyword analysis, co-citation analysis and reference matching in terms of the most influential study, author, country, institution and journals, etc. and their relationship with various aspects. When the common keyword was repeated at least 2 times, it was seen that hydrogen storage, hydrogen, hydrogen production, metal organic frameworks, adsorption, carbon dioxide, zeolites, catalysis, porous

materials, water electrolysis, hydrogen economy, microporous materials, high-entropy alloys, hydrogen evolution, renewable energy, energy storage, review. The author who has done the most studies was determined as Yaghi, Omar M. with 5 articles and 14181 citations. When the 100 most cited articles on hydrogen energy were examined, it was seen that the classification of the citations to the articles according to their subjects was Chemical Society Reviews. Although the bibliometric analysis method has gained great popularity recently, it is one of the first bibliometric analysis studies conducted directly in the field of hydrogen energy. Bibliometric analyzes on hydrogen energy can determine serious contributions to research conducted over the years and highlight scientific developments in many studies. It is thought that it will provide convenience to researchers who want to research the literature on hydrogen energy.

ABSTRACT

Hydrogen (H_2) is a clean and sustainable energy source, and it has an important role for the future and environment. Catalysts are essential for H_2 production by catalytic hydrolysis of sodium borohydride ($NaBH_4$). Here, effective cobalt-copper-boron doped graphitic carbon nitride (g-C_3N_4@Co-Cu-B) catalyst was fabricated by reduction method. Then, this new synthesized catalyst showed a high catalytic activity on the hydrolysis of $NaBH_4$. The structural characteristics of this catalyst were verified by X-ray diffraction (XRD), Scanning Electron Microscopy (SEM), and Energy Dispersive X-ray (EDX) methods. The performance of the catalyst was investigated via carried experiments based on metal Co-Cu-B/(g-C_3N_4+Co-Cu-B) ratio, wt%NaOH concentration, temperature, and reusability parameters. As a result, the best metal ratio and wt% NaOH were found as 40% and 7% respectively. Besides, g-C_3N_4@Co-Cu-B catalyst was viewed as reusable, and about 100% reaction conversion was observed at each cycle in reusability tests. In the studies, H_2 generation rate (HGR) was calculated as 6598 $mlH_2\ min^{-1}\ g_{cat}^{-1}$ at 30 °C. According to all obtained results, it was deduced that using of g-C_3N_4@Co-Cu-B is suitable for $NaBH_4$ hydrolysis.

Keywords: Borohydride, Catalyst, Hydrogen, Hydrolysis

1. INTRODUCTION

In recent years, hydrogen is a prominent alternative energy source against common unrenewable fossil fuels leading to environmental pollution. Hydrogen can be stored in the form of solid metal hydrides, liquid form, and as compressed gas. Borohydrides, outstanding lately are a part of metal hydrides. Borohydrides such as sodium borohydride ($NaBH_4$), potassium borohydride (KBH_4), lithium borohydride ($LiBH_4$) and ammonium borohydride (NH_4BH_4) are effective hydrogen storage sources. Besides, when the borohydrides were used, half of the hydrogen obtained in the production of hydrogen by hydrolysis of borohydrides in aqueous environment came from water. Thus, they can be used for hydrogen production. The most preferred borohydride used in the studies is sodium borohydride ($NaBH_4$) due to its good stability, practicality, and easy workability. $NaBH_4$ has 10.8% hydrogen storage capacity. $NaBH_4$ solutions are very stable, non-flammable, and non-toxic. Various substances such as metal catalysts (Ru, Co, Cu, Ni), complex hydrides and supported catalysts are used to facilitate the degradation of $NaBH_4$ and accelerate the release of H_2 by reducing the required activation energy [1-8].

Hydrogen production reaction via catalytic hydrolysis of $NaBH_4$ is shown in Eq.(1) [2]:

$$\mathrm{NaBH_4 + 4H_2O \xrightarrow{catalyst} NaBO_2 + 4H_2} \quad (1)$$

Supporting materials provide a structural framework, providing a stable environment for catalyst activities. The metal catalysts can be loaded to the supporting materials such as alumina (Al_2O_3), active carbon (C), multiwalled carbon nano tubes (MWCNT), carbon nitride nanotubes (CNNT), zeolite, graphitic carbon nitride (g-C_3N_4), titanium dioxide (TiO_2), cobalt oxide (CoO and Co_3O_4), which are common-used for $NaBH_4$ based catalysts. The choice of supporting material is important to optimize catalyst performance since it can affect the chemical stability, dispersion, and overall effectiveness of the catalyst by providing high surface area. [2, 9-13].

g-C_3N_4 is an interesting supporting material used primarily with $NaBH_4$-based catalyst. Its chemical stability, photocatalyst activity, electronic structure, high surface area, interaction with catalyst, synergistic effects and environmental friendliness effect the overall strength of the combined catalyst system performance positively [14].

In general perspective, it is well-known that cobalt and copper catalysts are highly efficient in sodium borohydride hydrolysis [5, 15-17]. Thus, in this study, boron bounded cobalt-copper bimetallic catalyst was prepared with g-C_3N_4 supporting material. As a result, g-C_3N_4@Co-Cu-B catalyst was synthesized first time at the end of adsobtion of g-C_3N_4 and reduction with $NaBH_4$ processes, then the suitability and performance of this new catalyst on sodium borohydride hydrolysis were investigated.

2. MATERIALS AND METHODS

2.1. Problem Description and Materials

In this study, as a solution to the hydrogen storage and safety problems, sodium borohydride which has high hydrogen storage capacity was preferred. However, the hydrolysis reaction of sodium borohydride is a slow process. As a solution to this, g-C3N4@Co-Cu-B catalyst was developed to accelerate the reaction.

Throughout the study, cobalt (II) chloride hexahydrate ($CoCl_2.6H_2O$, ≥99% purity, SRL), copper (II) nitrate trihydrate ($Cu(NO_3)_2.3H_2O$, 99.5% purity, SRL), sodium borohydride ($NaBH_4$, ≥98% purity, Sigma-Aldrich), sodium hydroxide (NaOH, ≥97% purity, Merck), ethanol (C_2H_5OH, 96% purity, Merck), nitrogen gas, distilled water, and dicyandiamide ($C_2H_4N_4$, 99% purity, Sigma-Aldrich) were used as materials.

2.2. Methods and System Description

Firstly, during the g-C_3N_4 supporting material synthesis step, 6 g dicyandiamide ($C_2H_4N_4$) was placed in a closed-crucible to a muffle furnace with a 3 ˚C/min heating rate. When the temperature was 550 ˚C, it was kept for 4 hours under this temperature. After the sample was cooled and crushed, it was then placed in the open-crucible to the muffle furnace with a 5 ˚C/min heating rate -starting from room temperature- as the second step. After the furnace temperature reached 500 ˚C, the sample was kept for 2 hours there. Finally, it was waited for cooling.

In the experiments carried out in order to find the best metal ratio, five aqueous solutions containing $CoCl_2.6H_2O$ - $Cu(NO_3)_2.3H_2O$ salts and g-C_3N_4 were prepared so that Co-Cu-B/(g-C_3N_4+Co-Cu-B) ratios were 10, 20, 30, 40, and 50%. Here, the ratio of mole of Co/Cu was adjusted as 3. After g-C_3N_4 adsorbtion to the salts in the solutions for about 4 hours at 400 rpm at room temperature, $NaBH_4$ solution was added drop by drop to the solutions to reduce Co^{+2} and Cu^{+2} ions. The solutions were kept at 0 ˚C during this reduction step to bind boron easily. Then, the solid parts in the solutions were filtered. They were washed with distilled water and ethanol a lot of times to remove the unwanted impurities. Finally, the solid catalysts were dried in the oven at about 90 ˚C under inert N_2 gas for about 4 hours. As a result, five new g-C_3N_4@Co-Cu-B catalysts containing different amounts of metals were obtained. The best metal ratio and the best wt% NaOH ratio were tried to be determined by testing these catalysts. Then, temperature effect and reusability experiments were conducted by using the before-founded best ratios as reaction conditions. In the experiments, 50 mg catalyst and 1.5 wt% $NaBH_4$ in 10 ml solutions were used.

The g-C_3N_4@Co-Cu-B catalyst synthesis and hydrolysis reaction -in which this catalyst is used- processes were shown in Figure 1. These processes were similar to the system in our previous research, where g-C_3N_4@Co-B-F catalyst was synthesized [2].

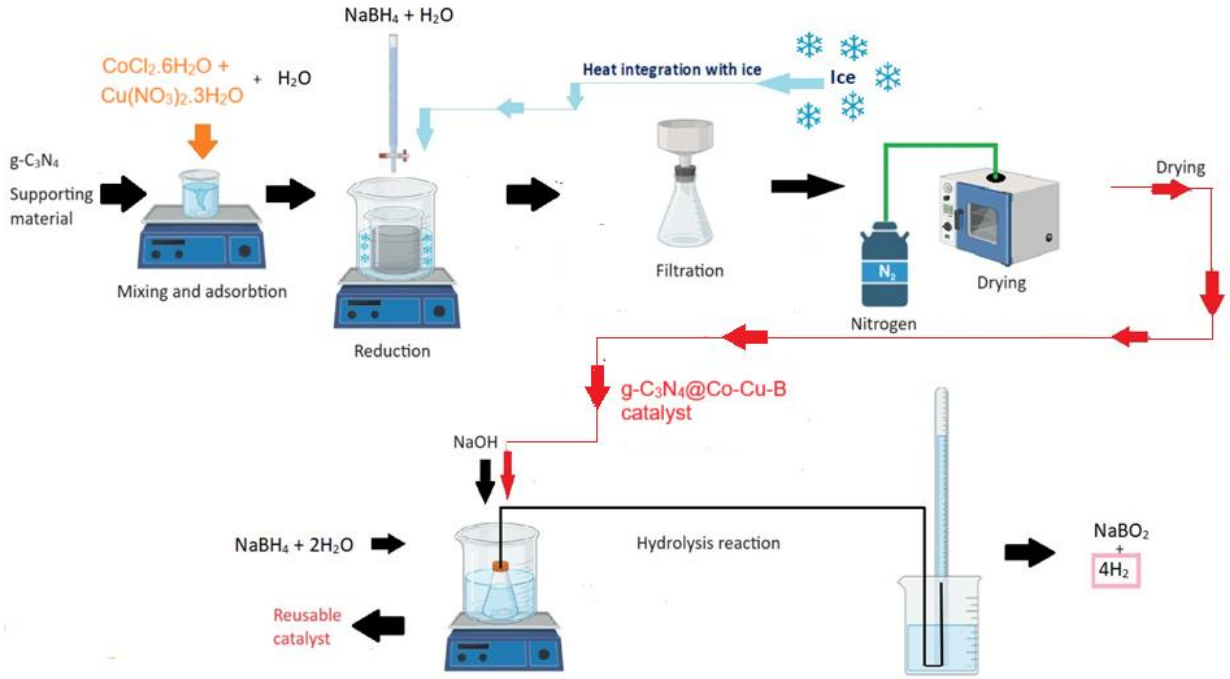

Fig. 1. The synthesis of g-C_3N_4@Co-Cu-B catalyst and the using of this catalyst in $NaBH_4$ hydrolysis processes

3. RESULTS AND DISCUSSION

3.1. The Effect of Metal Ratio, NaOH Concentration, Temperature on Hydrolysis of Sodium Borohydride In the Presence of g-C_3N_4@Co-Cu-B Catalyst and Reusability Tests of This Catalyst

The results of the experiments to determine the best conditions of hydrolysis reactions, temperature effect, and reusability were shown in Fig. 2.

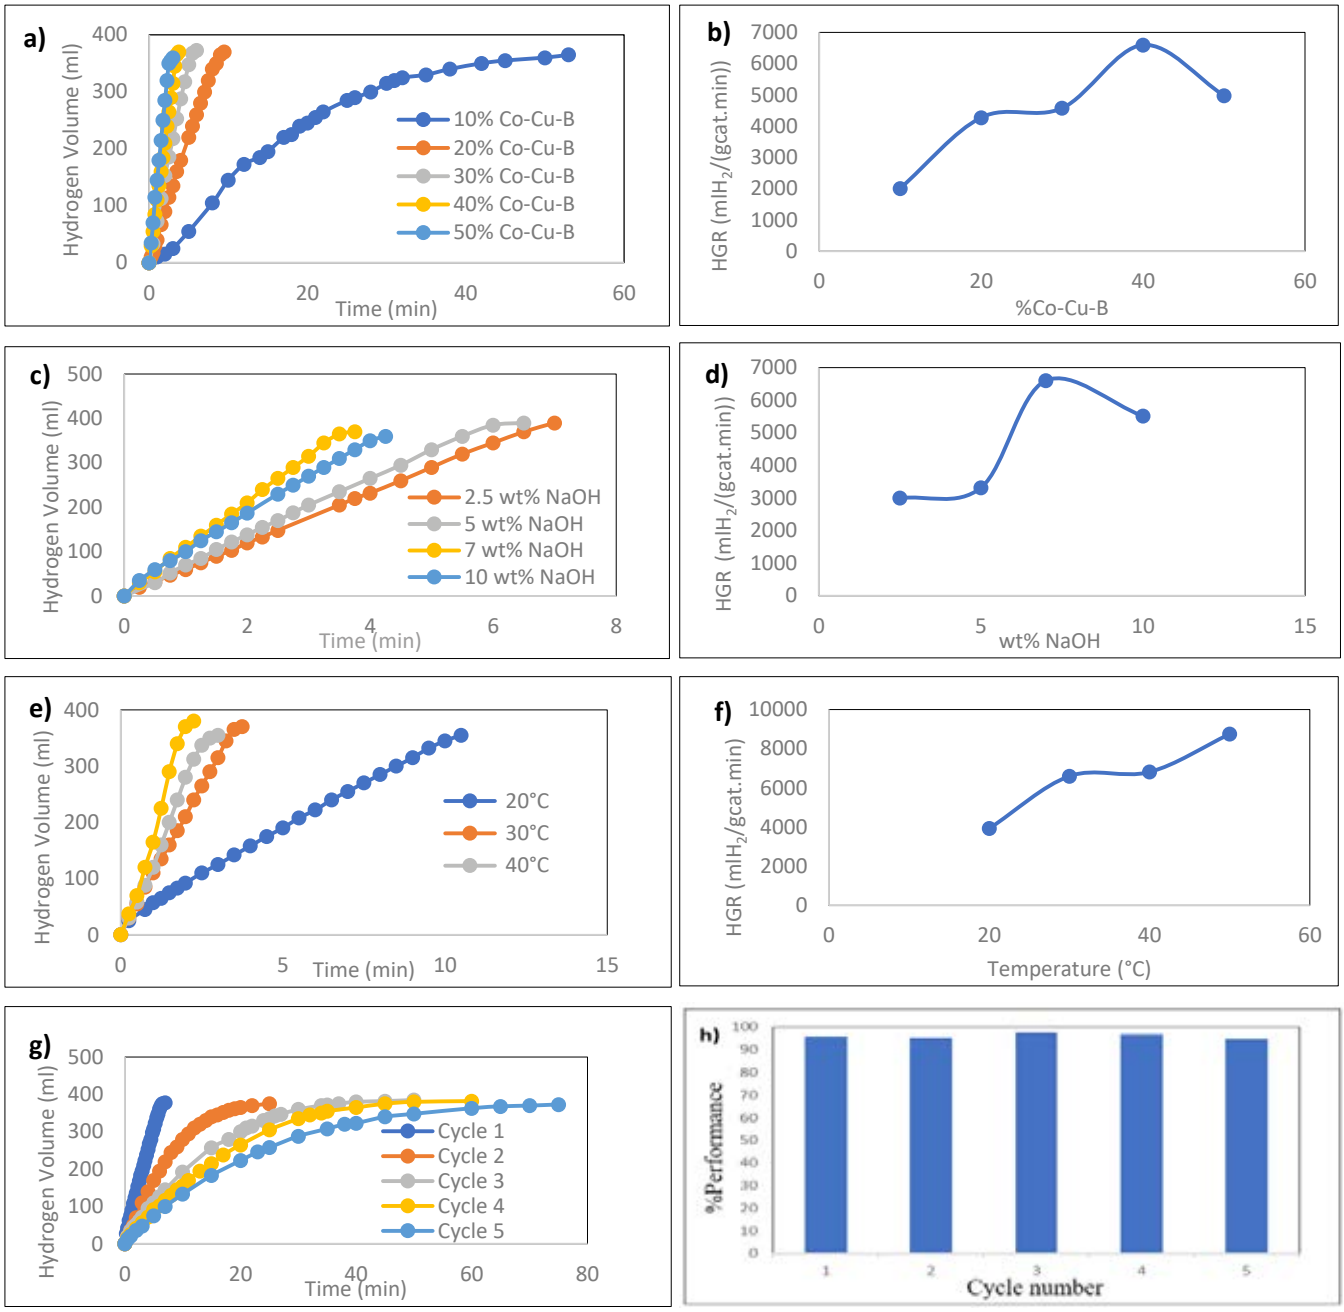

Fig. 2. When g-C_3N_4@Co-Cu-B catalyst was used in hydrolysis of $NaBH_4$, a-b) The effect of metal ratio in the catalyst - a) H_2 production, b) HGR values (NaOH = 7 wt%, T = 30 °C) ; c-d) The effect of NaOH concentration - c) H_2 production, d) HGR values (metal ratio = 40 wt%, T = 30 °C) ; e-f) The effect of temperature - e) H_2 production, f) HGR values (metal ratio = 40 wt%, NaOH = 7 wt%) ; g-h) The reusability tests - g) H_2 production, h) %Performance (metal ratio = 40 wt%, NaOH = 7 wt, T = 30 °C)

Hydrogen volumes as a result of $NaBH_4$ hydrolysis for each metal ratio were seen in Fig. 2a. Then, hydrogen generation rate (HGR) values were calculated for each metal ratio, and they were given in Fig. 2b. According to that, the best ratio of Co-Cu-B/(g-C_3N_4+Co-Cu-B) was determined as 40% which gives high HGR value. Next experiments were continued with the catalyst having this 40% ratio. According to Fig. 2c and 2d, 7 wt% NaOH was determined as the best NaOH concentration for hydrolysis of $NaBH_4$ in the presence of g-C_3N_4@Co-Cu-B catalyst. Then, according to Figs. 2e and 2f, an increase in HGR values was observed from 3925.35 to 8747.5 $mlH_2/g_{cat}.min$ at from 20 °C to 50 °C as expected. The reason for this is that the hydrolysis reaction is faster in high temperatures. Finally, as seen in Figs. 2g and 2h, the expected teoric H_2 gas volume was almost obtained even if five cycles of experiments were completed. Thus, the catalyst performance was said to be close to 100% even if the reactions were slower at each cycle.

3.2. Characterization Results

SEM, EDX and XRD characterization results of g-C_3N_4@Co-Cu-B catalyst were shown in Fig. 3.

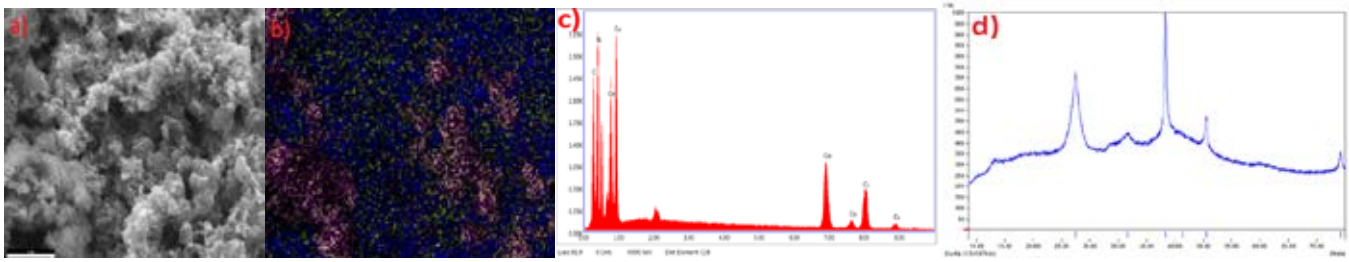

Fig. 3. g-C_3N_4@Co-Cu-B catalyst's a) SEM image (15 kV, 10000x); b) overlapped EDX image (purple:carbon, white:nitrogen, blue:cobalt, yellow-green:copper); c) EDX spectra; d) XRD spectra (Cu-Ka)

As seen in Fig. 3, the SEM image of the catalyst showed that Co-Cu-B particles were dispersed on g-C_3N_4 particles. With the help of the EDX mapping, the presence of each element (C,N,Co,Cu) was verified in the structure of the catalyst. In XRD spectra, as 2theta is about 30-40, Co and Cu peaks were observed as expected.

4. CONCLUSIONS

According to the results obtained from the experiments and characterization, it was concluded that g-C_3N_4@Co-Cu-B catalyst was successfully fabricated, and this catalyst showed a good performance with its reusability and high HGR values like 6598 mlH_2 min^{-1} g_{cat}^{-1}. Thus, g-C_3N_4@Co-Cu-B was acceptable as an appropriate catalyst for $NaBH_4$ hydrolysis in industrial applications.

ABSTRACT

This study focuses on the preparation of boron-doped nickel electrodes and the evaluation of their hydrogen production activity under alkaline conditions. Electrodes were fabricated using electroplating, optimizing the electrolyte composition with nickel salts (Nickel Chloride ($NiCl_2 \cdot H_2O$), Nickel Sulfate ($NiSO_4 \cdot H_2O$)) and boric acid (H_3BO_3, 2–6 wt.%). The influence of key experimental parameters, including H_3BO_3 concentration (2–4 wt.%), applied voltage (4–5 V), and bath temperature (20–60°C), was investigated for electrode preparation. The coating efficiency and hydrogen production performance of the electrodes under alkaline conditions were analyzed. Results indicated that B-doped Ni electrodes electroplated with 20 g/L H_3BO_3 at 4.5 V and 60°C exhibited optimal activity. Additionally, the impact of electrolyte composition was examined by varying the sodium hydroxide to potassium hydroxide (NaOH:KOH) ratio as 1:0, 2:1, 1:1, 1:2, and 0:1. Hydrogen production studies demonstrated that electrodes achieved enhanced performance %630 in the presence of pure KOH as the electrolyte.

1. INTRODUCTION

Energy is crucial for enhancing the quality of life and sustaining modern society. As the global population grows, energy demand rises. While traditional sources like oil, coal, and natural gas have dominated electricity generation, environmental concerns and fossil fuel depletion are driving a shift toward renewables [1]. Hydrogen energy offers a promising alternative as a clean, abundant, and efficient energy carrier. Although not a primary energy source, hydrogen can be produced through methods such as water electrolysis and hydrocarbon processing [2]. Water electrolysis, particularly when powered by renewable energy, is an attractive option [3]. This process, occurring in electrolyzers with electrodes, an electrolyte, and a power supply, involves splitting water into hydrogen and oxygen through the following reactions:

Anode Reaction: $2OH^-_{(aq)} \rightarrow H_2O_{(l)} + \frac{1}{2}O_{2(g)} + 2e^-$ (1)

Cathode Reaction: $2H_2O_{(l)} + 2e^- \rightarrow H_{2(g)} + 2OH^-_{(aq)}$ (2)

Alkaline electrolyzers are widely used due to their efficiency, low operating temperatures, and scalability. These systems typically use potassium hydroxide (KOH) or sodium hydroxide (NaOH) as the electrolyte, making them cost-effective for industrial hydrogen production [4]. Graphite electrodes are preferred for anodes due to their chemical resistance, conductivity, and affordability, though they may degrade over time, requiring maintenance. For cathodes, materials such as stainless steel, platinum, and nickel are commonly used. Stainless steel is favored for its durability, corrosion resistance, and electrochemical stability in alkaline environments. The formation of a chromium oxide (Cr_2O_3) layer further enhances its longevity. Nickel plating is often applied to stainless steel cathodes to improve corrosion resistance and electrocatalytic performance [5].
Nickel electroplating is a widely used industrial process that enhances durability, corrosion resistance, and conductivity. It requires an electrolyte containing nickel precursors and often boric acid (H_3BO_3), which stabilizes pH, enhances conductivity, and is environmentally friendly [6]. The electrolysis process begins by preparing the electrolyte solution and positioning the electrodes. A power supply is then connected, with the cathode linked to the negative terminal and the anode to the positive terminal.
Hydrogen serves as an energy carrier, efficiently storing and transporting energy, making it essential for future energy systems. It is classified into gray, blue, turquoise, and green hydrogen based on production methods. Green hydrogen, produced through electrolysis powered by renewable energy, is the most sustainable option. Alkaline water electrolysis remains the most widely used method for large-scale hydrogen production due to its high efficiency and ability to generate high-purity hydrogen.

This study explores hydrogen production via alkaline electrolysis using a boric acid-added electrolyte, a nickel-plated stainless steel cathode, a graphite anode, and a power supply. Boric acid was selected as a pH stabilizer, while nickel plating improved the corrosion resistance and efficiency of the stainless steel cathode. Various experimental conditions, including boric acid concentration, temperature, and voltage, were examined to assess their impact on electrode performance. The electrodes were weighed before and after coating, and their surface characteristics analyzed via optical microscopy. Additionally, pH variations in the nickel bath were monitored. The goal was to determine optimal conditions for efficient plating and hydrogen production. Alkaline electrolysis presents a sustainable approach to future energy needs. Optimizing the electrolytic process and electrode materials enhances hydrogen production efficiency, supporting the transition to renewable energy. The combination of graphite and nickel-plated stainless steel electrodes with boric acid-added electrolytes is crucial for improving electrolysis performance, ensuring durability and cost-effective hydrogen generation.

2. MATERIALS AND METHODS

Electrodes were fabricated using electroplating, optimizing the electrolyte composition with Nickel Chloride ($NiCl_2 \cdot H_2O$), Nickel Sulfate ($NiSO_4 \cdot H_2O$), and Boric Acid (H_3BO_3) within a concentration range of 2–6 wt.%. The influence of key experimental parameters, including H_3BO_3 concentration (2–4 wt.%), applied voltage (4–5 V), and bath temperature (20–60°C), was systematically investigated to optimize electrode preparation. For electrode deposition, 316L stainless steel plates were used as the substrate, while 99% pure nickel strips served as the cathode during electroplating. Prior to coating, the substrates were pretreated with hydrochloric acid in an ultrasonic bath to ensure surface cleanliness. Electroplating was performed at an optimized voltage of 4–5 V under controlled conditions. The coating efficiency and hydrogen production performance of the electrodes under alkaline conditions were analyzed by weight change and optic microscope. Table 1 presented the experimental conditions of sample electrodes. Ni-plated electrodes were tested with 30% wt. KOH solution at room temperature with 2.3V. Additionally, the impact of alkaline electrolyte composition on hydrogen generation was examined by varying the NaOH:KOH ratio at 1:0, 2:1, 1:1, 1:2, and 0:1 at room temperature with 2.3V.

Table 1. Electroplating experiment parameters

Experiment/ Electrode	Temperature, °C	Voltage, V	H_3BO_3, g/L

2	20	4.5	30
3	20	5	40
4	40	4	30
5	40	4.5	40
6	40	5	20
7	60	4	40
8	60	4.5	20
9	60	5	30

3. RESULTS AND DISCUSSION

This study investigates the use of boron additives in electrode preparation and their impact on hydrogen production activity in alkaline electrolyzers. It examines the relationship between electrode performance and the composition of alkaline electrolytes, focusing on the effects of different concentrations and ratios of NaOH and KOH on hydrogen production efficiency. The research aims to answer two key questions: how boron doping during electrode preparation influences activity in alkaline electrolysis and how varying alkaline agent concentrations affect hydrogen production performance. It is hypothesized that boron-doped electrodes enhance hydrogen electrolysis efficiency and that the concentration and ratio of alkaline agents play a significant role in optimizing hydrogen production. Fig.1 showed the electrode preperation conditions and its electroplating efficiency and hydrogen production activity. As it could be clearly seen from the Fig.1a, electrode prepared under conditions 60 °C, 4.5 V and 20 g/L H_3BO_3 showed the highest efficiency value. Research has shown that boron content positively influences the process up to a certain level, specifically between 30-40 g/L. However, it can hinder efficiency beyond this range, particularly at lower temperatures, as observed with the 5th and 7th electrodes. This limitation may stem from the impact of boron additives on the conductivity of the electrolyte. To determine the optimal conditions, it would be beneficial to further analyze the interactions between temperature, voltage, and boron content.

Subsequently, all electrodes were subjected to the alkaline electrolysis process. A 2.3 V direct current was applied to an electrolyte solution containing 30% potassium hydroxide (KOH) to investigate hydrogen production efficiency. Figure 1c illustrates the relationship between gas produ5ction and time, demonstrating that the optimized coatings positively influenced the hydrogen production rate

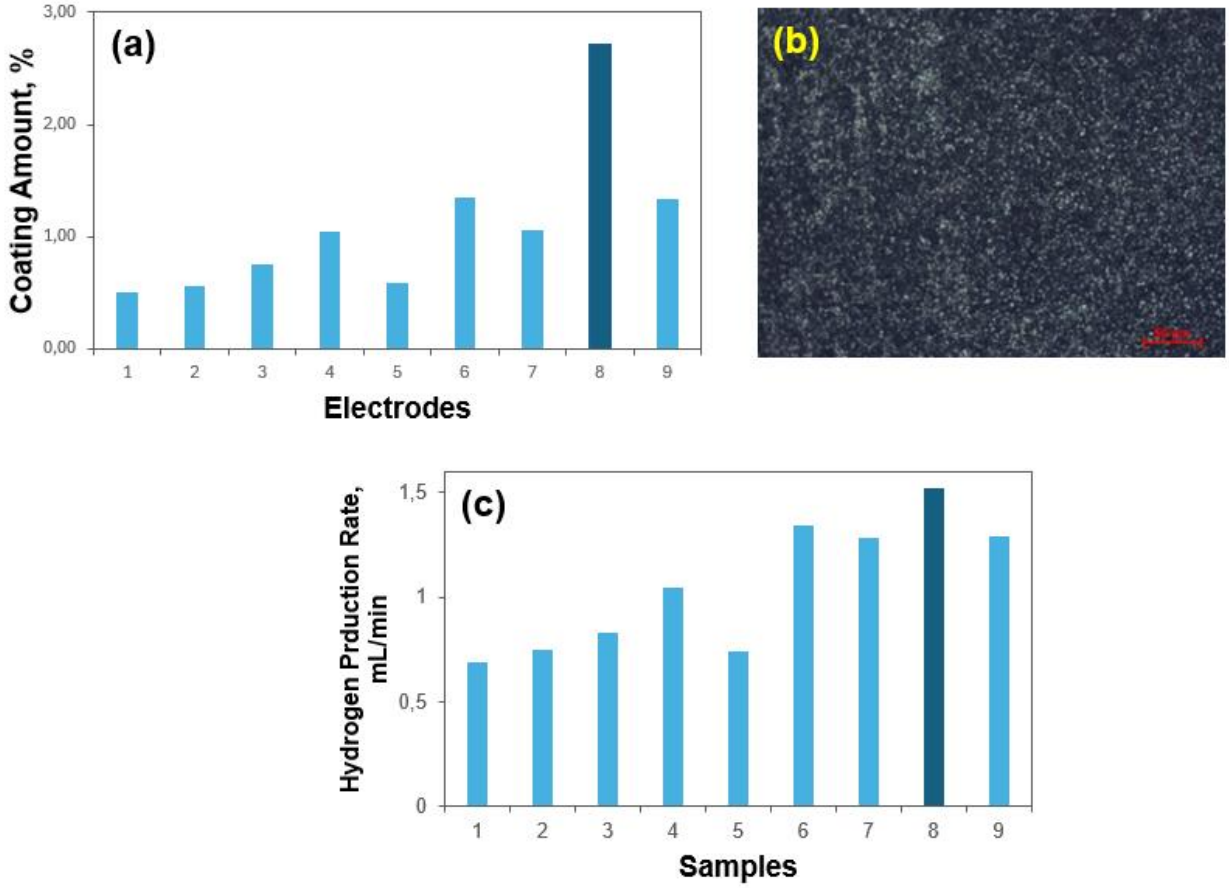

Fig. 1. Experimental results: (a) Electro-plating efficiency, (b) optic microscope image of 8th sample and (c) hydrogen production activity

The electrode prepared under optimized conditions (Electrode No. 8) was also tested to evaluate the effect of the alkaline electrolyte content. To further analyze variations in hydrogen production rates, experiments were conducted using sodium hydroxide (NaOH) solutions in combination with KOH. Five different electrolyte compositions were prepared: 30% KOH, 20% KOH-10% NaOH, 15% KOH-15% NaOH, 10% KOH-20% NaOH, and 30% NaOH. During these experiments, hydrogen production was measured to assess the effect of electrolyte composition. According to Figure 3, solely KOH exhibits superior ionization properties compared to NaOH. As the reaction progresses, the number of available electrons decreases, leading to a slowdown in the reaction rate due to the consumption of water molecules. Additionally, as the hydroxide concentration increased, the performance of KOH remained consistently high. The fourth and fifth electrolyte samples produced similar results, indicating that increasing the NaOH ratio had a limited effect on hydrogen production performance.

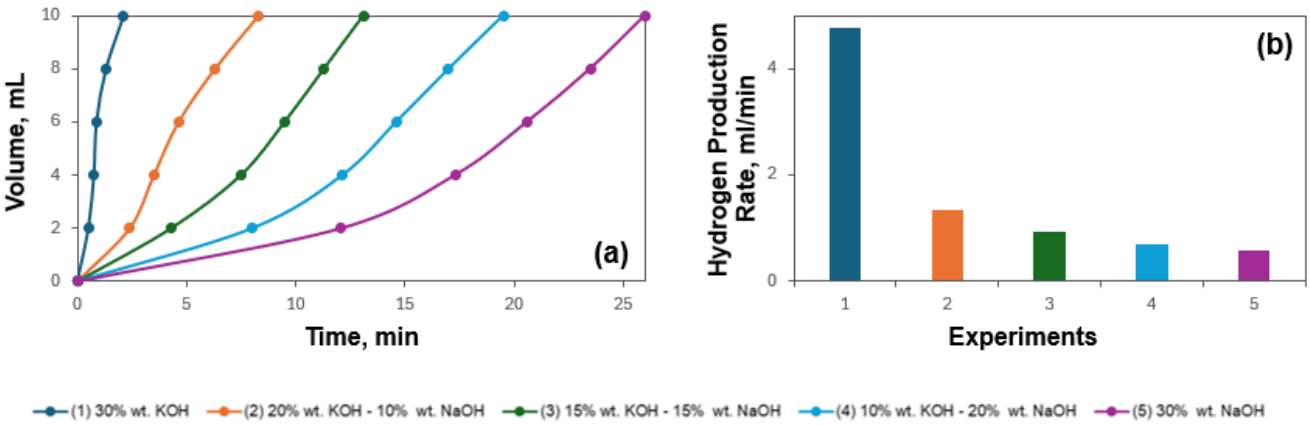

Fig. 2. (a) Comparison of various alkaline electrolyte performances (b) Hydrogen production activity

4. CONCLUSIONS

Alkaline water electrolysis powered by renewable energy sources like solar and wind presents a viable alternative to fossil fuel-based hydrogen production. This study focused on optimizing boron-doped nickel (Ni-B) electrodes for enhanced hydrogen generation efficiency in alkaline electrolyzers. The results demonstrated that boron doping, electrolyte composition, and electroplating conditions significantly impact electrode performance.. Optimal electroplating was achieved using 20 g/L H_3BO_3 at 4.5 V and 60°C, where excessive H_3BO_3 concentrations beyond 30 g/L led to reduced coating thickness. Additionally, KOH showed superior ionization properties compared to sodium hydroxide (NaOH), although NaOH remains a more economical and accessible alternative. By balancing voltage, H_3BO_3 concentration, and electrolyte composition, the efficiency and longevity of nickel-based electrodes can be enhanced, making hydrogen production more sustainable and cost-effective. Future research will explore advanced Ni-based electrode materials, such as Ni-Co Ni-Fe and Ni-Ru alloys, to improve long-term stability in flow-type electrolyzers. Additionally, integrating microbial electrolysis with alkaline electrolysis offers a dual benefit of hydrogen generation and wastewater recycling, further reducing costs and environmental impact.

ABSTRACT
Geothermal energy provides base-load power to the grid and serves as a critical renewable and clean energy source. To encourage investment in these risky, long-term projects, governments often offer feed-in tariff mechanisms and special incentives. However, these tariffs are typically available for only 10 to 15 years, after which electricity prices are determined by open market rates. To address revenue challenges from low market prices, energy storage emerges as a solution, allowing electricity to be stored during low-price periods and sold during peak demand. This study explores energy storage for geothermal electricity through hydrogen (H_2) production, underground storage, and re-electrification. A case study of the Alaşehir geothermal field is presented, featuring a conceptual model that generates geothermal power from basement metamorphic rocks and uses sandstone formations for hydrogen storage. A stochastic Monte Carlo simulation accounts for uncertainties such as reservoir storage potential, costs, and re-electrification efficiency. Results show that storing energy via hydrogen during low-demand periods and re-electrifying it during peak demand nearly doubles revenue, leveraging fluctuations in open-market electricity prices.
Keywords: electricity, geothermal, hydrogen, prices, underground storage

1. INTRODUCTION
Geothermal energy is considered a renewable, environmentally friendly, and sustainable energy resource, providing base-load power, meaning it operates 24/7 throughout the year. Renewable Energy Promotion Mechanism (YEKDEM) that was introduced in September 2005 (No: 5346, Issued Date: May 10, 2005) and it was run until September 2020 provided by Turkish government. This legislation provides incentives for the use of renewables in power generation such as feed-in tariffs, purchase guarantees, connection priorities, lowered license fees, license exemptions in exceptional circumstances and various practical conveniences in project preparation and land acquisition [1]. The guaranteed prices were 105 USD per MW, with an additional incentive of 0.7 USD per MW for the use of domestic equipment, applicable for ten years after the commissioning of the power plant. Recently, the government announced an extension of the tariff purchase period for geothermal energy to 15 years, with a floor price of 100 USD and a ceiling price of 120 USD per MW. Over the last two decades, installed geothermal capacity of Turkiye has increased from 15 MW to 1,726.8 MW, driven by these incentives and feed-in tariff mechanisms. However, after the guaranteed period, selling prices are determined by open market rates. Electricity open market prices in Turkiye fluctuate over the years due to factors such as global war risks, economic crises, and pandemic outbreaks. Open market prices fluctuate hourly, ranging from 30 to 57 USD over the past three years, making energy storage during low prices and selling at peak times a viable strategy to secure long-term cash flow.
This study investigates using geothermal reservoirs for hydrogen production and storage in Turkiye's Alaşehir geothermal field. By storing hydrogen in sandstone formations and supporting the grid during peak demand, it mitigates electricity price fluctuations and stabilizes cash flow in long-term projects. A probabilistic Monte Carlo simulation assesses impacts of uncertain factors, including reservoir temperature, power plant technology, hydrogen recovery, and market prices.

2. MATERIALS AND METHODS
The study begins with an evaluation of the hydrogen production and storage capacity of the Alaşehir geothermal field. Subsequently, the re-electrification of hydrogen to meet peak demand is examined. Storage capacity of Alaşehir field in Manisa, Turkiye can be assessed using Eq. (1).

$$\mathrm{H_{mass}} = \emptyset \times \mathrm{S_g} \times \mathrm{A} \times \mathrm{h} \times \frac{P}{Z \times R \times T} \times M_{H_2} \quad (1)$$

The source of parameters in Eq. (1) are from well testing data and drilling operations in the field. Z-factor is calculated from equations of state (e.g., Peng-Robinson). Eq. (1) employs a deterministic approach, but due to the heterogeneity and anisotropy of tectonically active geological formations, a stochastic approach is necessary. Monte Carlo simulation, implemented in Excel, addresses parameter uncertainties. The triangular distribution, often used with limited data, defines the probability density function using minimum, maximum, and most likely values.
In the Alaşehir field, the Menderes Metamorphic Unit serves as the reservoir rock for the geothermal system. It consists of marble, schist, and quartzite. The geothermal potential of the field is initially assessed using the heat-in-place method. As shown in Fig. 1, the Menderes Metamorphic Unit forms the basement of the field and represents a productive section for geothermal applications. It is overlain by the Çaltılık and Hamamdere Formations, which are composed of sandstone and conglomerates, making them suitable candidates for hydrogen storage. Therefore, in this conceptual model, the metamorphic rocks are utilized for geothermal power generation, while the produced hydrogen is stored in the Çaltılık

and Hamamdere Formations.

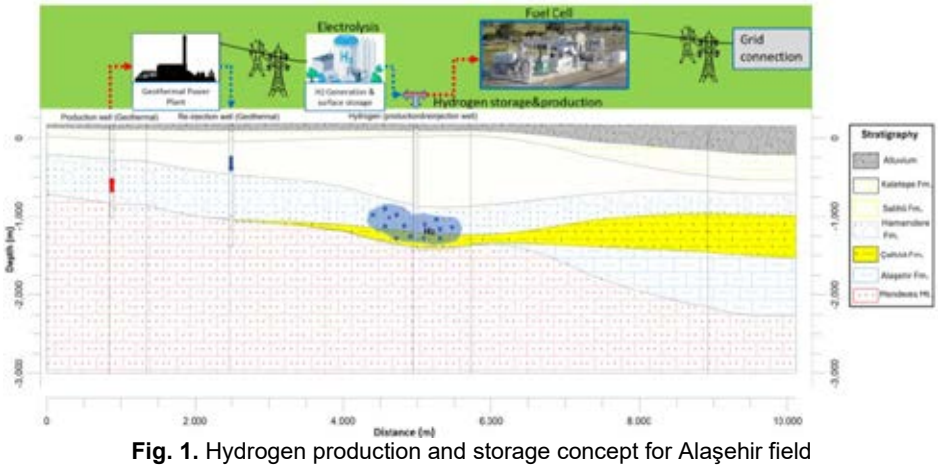

Fig. 1. Hydrogen production and storage concept for Alaşehir field

Fig. 2. A double flash combined geothermal power plant in Alaşehir field

We use Eq. (2) to calculate the mass of hydrogen produced annually from geothermal-sourced electricity. Eq. (3) calculates the cost of hydrogen production and storage, while Eq. (4) calculates the re-electrification from the fuel cell.

$$M_{hm} = Power\ Generation(\frac{kW}{hr}) \times \frac{1825\ hr}{365\ day} \times \frac{365\ day}{year} \div \frac{kW}{H_2(kg)} \quad (2)$$

$$\sum C_{hp} \times M_{hm} + \sum C_{hs} \times M_{hm} \quad (3)$$

$$\sum \eta_{FC} \times M_{hm} \times P_{electricity} \quad (4)$$

The electricity output (E_{elec}) from the fuel cell is given by Eq. (5):

$$E_{elec} = \frac{H_{mass} \times E_H \times \eta_{FC}}{3600} \times 1000 \quad (5)$$

Hydrogen generation and liquefaction utilize energy input and heat supply from geothermal power plants, such as binary (ORC units) and combined (flash and binary) geothermal power plants. Fig. 2 presents the operational scheme of a combined geothermal power plant in Alaşehir field.

3. RESULTS AND DISCUSSION

The Alaşehir field's electricity production capacity, based on Akın [2], is estimated at 103 MW (minimum), 183 MW (most likely), and 335 MW (maximum) per hour for 30 years. Using 2024 market prices, the lowest-priced hours (03:00–07:00 AM) and highest-priced hours (17:00–21:00 PM) were selected for daily hydrogen production and re-electrification, totaling 1,825 hours annually. H_2 is produced during low-price periods and sold at peak demand, with price differences of 30 USD (maximum), 25 USD (most likely), and 20 USD (minimum) per MWh used to estimate profits. H_2 production and storage costs were reviewed. Studies report production costs ranging from 0.979 to 2.615 USD/kg H_2 [3]. Operating

costs for geothermal-assisted electrolysis are about 2.04 USD/kg H_2 [4]. Considering Alaşehir's geothermal resource, production costs of 3 USD (maximum), 2.3 USD (most likely), and 1.6 USD (minimum) per kg H_2 were used. Geological storage costs were set at 5% (maximum), 3.5% (most likely), and 2.5% (minimum) of total hydrogen costs [5]. Energy consumption for hydrogen production was reported between 50–60 kW/kg H_2 [6-7].

Table 1. Costs for hydrogen production and underground storage

Parameters	Minimum	Mean	Maximum	Distribution
Power generation potential of Alaşehir field, MW/hr	103	183	335	Triangular
Power consumption for hydrogen production, kW/kg H_2	50	55	60	Triangular
Hydrogen production costs, USD/kg	1.6	2.3	3	Triangular
Underground storage costs, USD/kg	0.07	0.11	0.16	Triangular
Additional price during Peak demand of electricity, USD/MW	20	25	30	Triangular
Hydrogen production time in a year, hr	1825	1825	1825	Uniform
Re-electrification efficiency, %	40	50	60	Triangular

Table 2. Parameters for underground hydrogen storage

Parameters	Minimum	Mean	Maximum	Distribution
Area, km^2	20	30	40	Triangular
Thickness, m	500	1000	1500	Triangular
Porosity, fraction	0.15	0.20	0.35	Triangular
Reservoir Temperature, K	373.15	398.15	423.15	Triangular
Reservoir Pressure, MPa	10	15	20	Triangular
Gas saturation, fraction	0.15	0.20	0.3	Triangular
Z factor of Hydrogen	1.0300	1.0462	1.062	Triangular
R-Universal gas constant, J/(mol\K)	8.314	8.314	8.314	uniform
MH2 is hydrogen molecular weight, g/mol	2.016	2.016	2.016	uniform

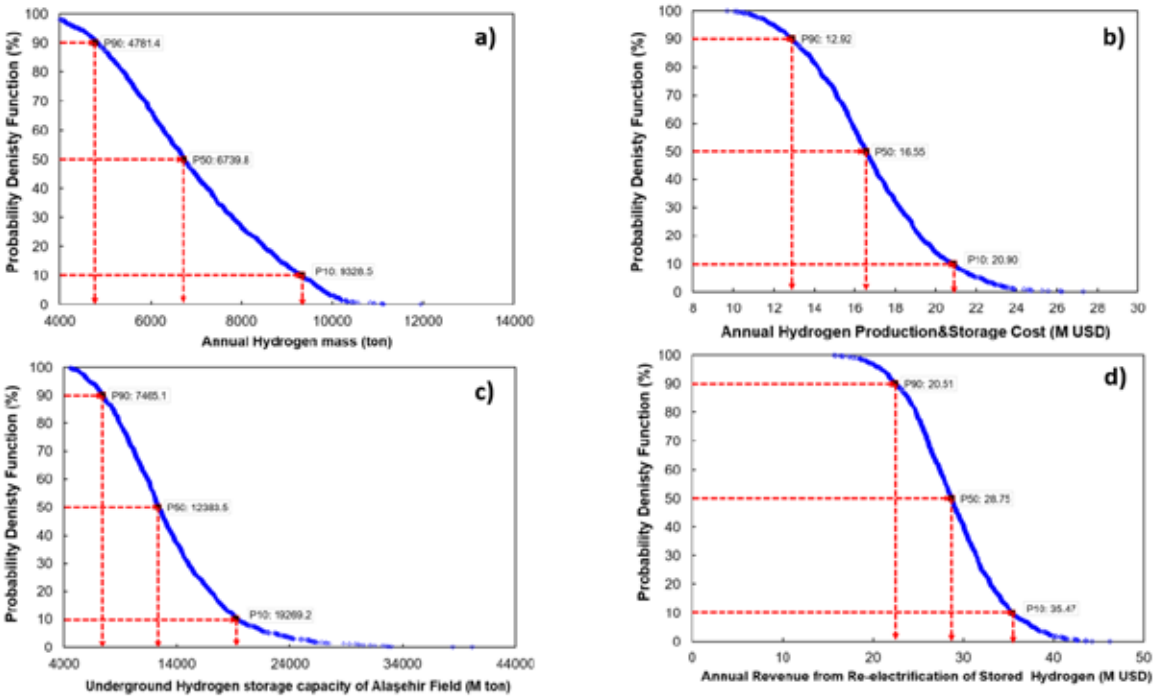

Fig. 3. a) Monte Carlo Simulation results of annual H_2 production capacity **b)** Monte Carlo simulation results for cost of annual production and underground storage **c)** Monte Carlo simulation results of underground H_2 storage capacity **d)** Monte Carlo simulation results for annual revenue from re-electrification of stored H_2 in Alaşehir field

A Monte Carlo simulation of Eq. (2) used a triangular distribution for most variables and a uniform distribution for production time (see Fig. 3). Fig.3-a shows results: proven capacity (90% certainty) is 4,781.4 tons, probable capacity (50%) is 6,739.8 tons, and possible capacity (10%) is 9,328.5 tons of H_2. Using Eq. (3), hydrogen production potential (Fig. 3-a), and data from Table 1, a Monte Carlo simulation assessed the costs of hydrogen production and underground storage in the Alaşehir field. Results (Fig.3-b) show annual costs of 12.92 million USD (90% certainty), 16.55 million USD

(50%), and 20.90 million USD (10%). The study evaluated the Alaşehir field's underground hydrogen storage capacity to determine its suitability for storing produced hydrogen. Using well test data, stratigraphy, and geological formations, parameters influencing pore volume were selected (Table 2). Based on findings by Dehury et al. [8], gas saturation values after brine displacement were set at 0.15 (minimum), 0.2 (most likely), and 0.3 (maximum). The Z factor interval was calculated using the Newton-Raphson method in Python. A Monte Carlo simulation (Eq. 1) with a triangular distribution for uncertain parameters yielded a proven storage capacity of 7,465.1 million tons, sufficient for all hydrogen production (Fig. 3-b). H_2 produced in the Alaşehir field can be stored in sandstone and conglomerate formations above the geothermal reservoir. Re-electrification is feasible using gas turbines or fuel cells, with fuel cells offering higher efficiency (60–80%) compared to gas turbines (30–40%). Waste heat recovery from fuel cells can boost efficiency to 80–90%. Among fuel cells, PEMFCs are favored for their low operating temperature and 40–60% efficiency, while SOFCs provide higher efficiency but face maintenance challenges due to high operating temperatures. Using Eq. (5) in a Monte Carlo simulation (Table 1), annual re-electrification revenue is estimated at 20.51 million USD (90% certainty), nearly double the 12.92 million USD cost of hydrogen production and storage (Fig. 3-b). This demonstrates the cost-effectiveness of hydrogen-based energy storage during low-demand periods and re-electrification during peak demand. Further analysis should evaluate capital investments in infrastructure and well completion for full feasibility.

4. CONCLUSIONS

This study investigated hydrogen production, storage, and re-electrification in the Alaşehir geothermal field, demonstrating that energy storage through hydrogen production and underground storage, followed by re-electrification via fuel cells, can mitigate price fluctuations and enhance project feasibility. The Monte Carlo simulation showed that the field has hydrogen production capacities of 4,781.4 tons (90% certainty), 6,739.8 tons (50%), and 9,328.5 tons (10%), with annual re-electrification revenue of 20.51 million USD at 90% certainty, significantly improving revenue due to market price fluctuations.

NOMENCLATURE

A	Reservoir area, m^2
C_{hp}	Cost of hydrogen production
C_{hs}	Cost of hydrogen storage
E_{elec}	Electricity generation from 1 kg of hydrogen kW per hour
E_H	Energy content from 1 kg of hydrogen equals to 119.96 MJ
H	Reservoir thickness, m
H_{mass}	Total hydrogen mass to be stored, kg
η_{FC}	Fuel cell efficiency ranging between 40 and 60 %
M_{H2}	Hydrogen molecular weight, 2.016 g/mol
M_{hm}	Mass of hydrogen, kg/year
P	Reservoir pressure, Pa
$P_{electricity}$	Open market electricity prices
$Ø$	Effective porosity, fraction
R	Universal gas constant, 8.314 J/(mol·K)
S_g	Gas saturation, fraction
T	Reservoir temperature, K
Z	Compressibility factor, dimensionless

ABSTRACT
Hydrogen, recognized as an energy carrier, can compromise the structural integrity of metals by contributing to hydrogen embrittlement, which reduces their mechanical strength. Examining only fracture behavior is insufficient to comprehend hydrogen embrittlement, prompting this research to focus on deformation processes. To investigate this, slow strain rate testing (SSRT) was conducted on both hydrogen-charged and uncharged specimens, accompanied by *in situ* scanning electron microscopy (SEM) and electron backscatter diffraction (EBSD) to monitor real-time deformation. When hydrogen penetrated the austenitic stainless steel (ASS) 304 at lower strain levels than the uncharged specimen, it activated the formation of strain-induced martensite (SIM). The hydrogen precharged specimens exhibited a more significant degree of SIM even at equivalent strain levels. These SIM, linked to dislocation activity, were further studied using single crystal (SX) superalloys, which almost deform only dislocation slip. It was found that hydrogen induced secondary slip at lower strains, which led to dislocation pinning and an increase of dislocation density, thereby facilitating the formation of stacking faults earlier in the deformation process. As with interstitial elements, hydrogen modifies dislocation motion, promotes stacking fault at lower strains, and activates fracture initiation. The hydrogen effects on the deformation process was directly related to the hydrogen amount absorbed by the ASS 304. By examining the deformation process, predictive models were established to quantify the loss of tensile properties based on hydrogen embrittlement mechanism. This research offers critical insights into understanding and mitigating the reduction of mechanical properties in metals exposed to hydrogen.

Keywords: Hydrogen embrittlement, *in situ* EBSD, deformation behavior, predicted mechanical properties, stacking fault

1. INTRODUCTION
Hydrogen is increasingly regarded as a sustainable energy carrier due to its non-carbon emissions during use. However, the phenomenon of hydrogen embrittlement remains a significant challenge for hydrogen application to metallic materials, as it degrades their mechanical properties. This degradation of strength and ductility is primarily due to hydrogen permeation into the metal. Several models, including hydrogen enhanced decohesion (HEDE), hydrogen enhanced localized plasticity (HELP), and nanovoid coalescence, have been proposed to explain these phenomena [1].

While much of the focus has traditionally been on fracture-based studies, recently, research has shifted to understanding the influence of hydrogen on the deformation process. In face-centered cubic (FCC) metals, the effects of hydrogen have been explored in relation to dislocation mobility [4], deformation via stacking faults [5], and the occurrence of SIM [6]. For example, Barnoush et al. [7] noted that hydrogen reduces the energy required for dislocation initiation during deformation, as demonstrated by nanoindentation experiments. Similarly, Yamada et al. [8] and Pontini [9] observed that hydrogen increases deformation via stacking fault (SFE) in FCC structures. San Marchi [10] examined the role of hydrogen in either enhancing or inhibiting phase transitions in metals. Additionally, Chen et al. [11] documented an increase in dislocation density in pure Pd after hydrogen precharging. Multiple interpretations have been suggested for when hydrogen embrittlement occurrs. In this study, the aim was to investigate the various factors that govern hydrogen embrittlement during the deformation process. To assess how hydrogen influences the mechanical properties of FCC materials, the study evaluated the hydrogen embrittlement and deformation process of two kinds of FCC metals (ASS and Ni-based superalloy).

2. EXPERIMENTAL PROCEDURE
2.1 Materials
To assess how hydrogen affects fracture and the deformation process, two distinct materials were selected: a commercial grade of ASS (STS 304) and a Ni-based single crystal superalloy. The superalloy composition is as follows: 7.0Cr-6.2Al-7.5Co-1.5Mo-0.15Hf-6.5Ta-3.0Re-5.0W, with nickel being the primary component. The orientation of the Ni-based superalloy was aligned along the <101> crystallographic direction, which encourages the development of Lüders bands, offering a clearer view of hydrogen influence on the dislocation motion during unidirectional slip.

2.2 Hydrogen Precharging Techniques

Two techniques for hydrogen precharging were employed: electrochemical hydrogen absorption and thermal hydrogen exposure. In the electrochemical method, the specimens were immersed in a 3% NaCl electrolyte at 70°C with a current density of 100 mA/cm² for a period of three days, followed by tensile testing performed within 10 minutes. For the thermal method, specimens were exposed to hydrogen gas at a temperature of 250°C under various pressures for a duration of 4 days, then stored at -80°C to prevent any hydrogen release before testing. Hydrogen content was quantified using thermal desorption spectroscopy (TDS, HTDS-003, R-DEC), and the tensile tests were conducted at a cross-head speed of 2 µm/s, in compliance with ASTM G142, using a tensile testing module (DDS 003, Kammrath & Weiss, Fig. 1a).

2.3 *in Situ* SEM/EBSD and Microstructural Observations

To examine the hydrogen effects on the deformation process, *in situ* SEM (Fig. 1b, c) and EBSD (Fig. 1d) were utilized. During tensile testing, microstructural changes were recorded at set intervals within the SEM. For enhanced electron backscatter intensity in the EBSD system, the specimens were positioned on a 40° pre-tilt stage, with the testing specimen holder inclined at 30°. This setup resulted in an overall tilt angle of 70°, ideal for observing the deformation process. Additionally, crystallographic variations were analyzed using EBSD (Nordlynano, Oxford Instruments). Fracture morphology was further investigated on the broken specimens using SEM, X-ray diffraction, and EBSD to provide a comprehensive understanding of the fracture mechanisms.

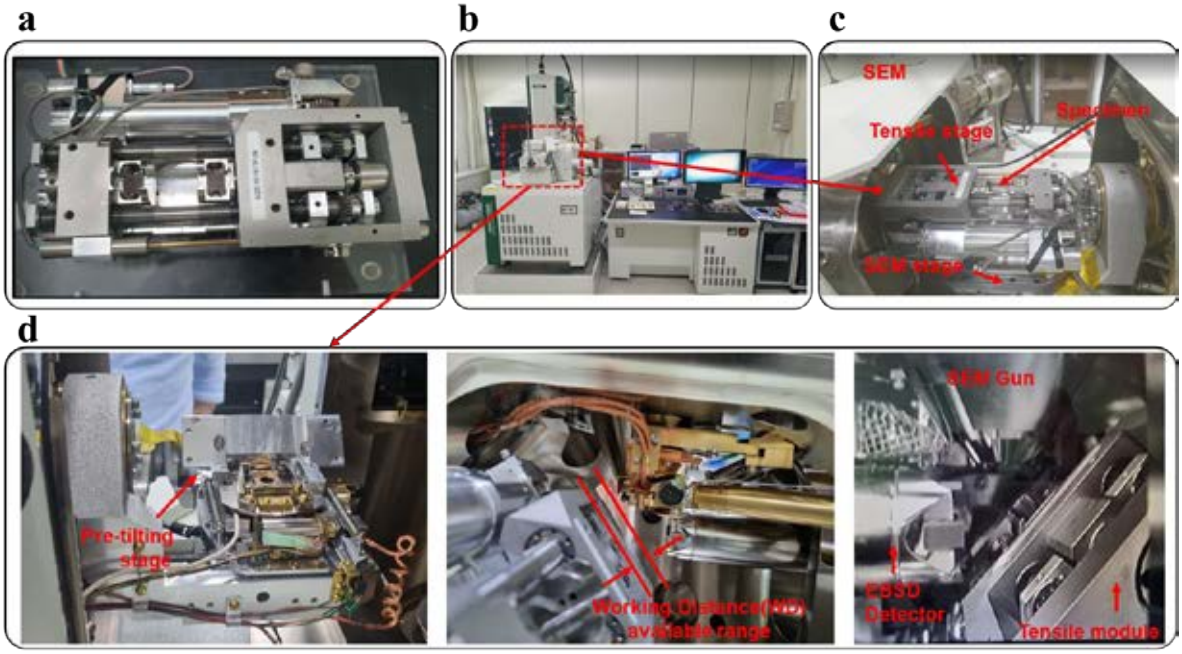

Fig. 1 Evaluation of hydrogen embrittlement system, mechanical deformation module(a), scanning electron microscopy (SEM)(b), *in situ* SEM system(c), and *in situ* EBSD system(d)

3. RESULTS AND DISCUSSION

3.1 Alternation of fracture and deformation via hydrogen on STS 304.

In STS 304, although both hydrogen charging methods produced similar fracture microstructures, notable differences were verified in the deformation. As shown in Fig. 2a, the mechanical properties of hydrogen precharged specimens were reduced. In the case of electrochemical hydrogen precharging (304-E, Fig. 2b), grain boundaries were accumulation sites, while in the case of gaseous hydrogen exposure (304-G, Fig. 2c), hydrogen was mainly trapped within the grains (lattice). Despite these differences in deformation process, the similar fracture mechanisms were verified in both hydrogen precharging methods (Fig. 2d). SIM induced fracture was started at twin boundary due to the prepared site in both methods. The deformation process was influenced by where the hydrogen was trapped, particularly in the low-angle boundaries (Fig. 2e). In the electrochemical method (304-E), where hydrogen gathered at the grain boundaries, the deformation until 700 µm closely resembled that of the uncharged specimen (304-N). However, for the gaseous method (304-G), where hydrogen was accumulated at lattices, the early deformation until 700 µm was distinctly altered. Additionally, SIM observed after fracture highlighted the hydrogen-induced stacking fault process during SSRT (Fig. 2f). In the 304-E specimens, where hydrogen diffusion was restricted, a noticeable difference in SIM fraction between the edge and center were observed. Thus, this study confirms that hydrogen precharging induces significant changes in both fracture and deformation process in STS 304.

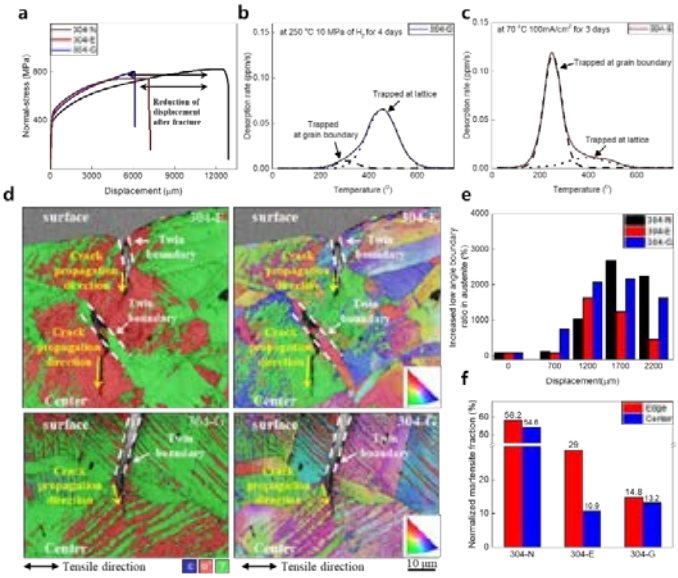

Fig. 2 Effects of hydrogen on deformation and fracture. (a) displacement-stress curve, (b) desorption behavior for 304-E, (c) desorption behavior for 304-G, (d) microstructural fracture mechanism, changes of low angle boundary(e) and SIM (f) of deformation behavior via *in situ* EBSD [].

3.2 Changes of slip Systems via hydrogen

Previous studies have demonstrated that hydrogen affects deformation by increasing low-angle boundary formation and SIM, which correlates with a rise in dislocation density. To investigate this further, the effects of hydrogen on the deformation process were studied using a Ni-based SX superalloy, which has a unidirectional slip system. After exposure to a 10 MPa hydrogen environment for 4 days, the hydrogen content was measured at 173 ppm. The reduction in ductility was found to correlate directly with the hydrogen content (Fig. 3a). The deformation progression for hydrogen precharged specimens is illustrated in Figs. 3b and c. Initially, microstructure deformed with unidirectional dislocation slip (b-1), followed by secondary slip (b-2). As strain increased, the secondary slip was more marked (b-3), leading to fracture at the cross site of the two kinds of slip (b-4). In the hydrogen-precharged specimens (Fig. 3c), both dislocation slips (primary and secondary) were activated at 4.9% (c-1). As strain increased, the secondary slips intensified (c-2, c-3), and fracture similarly occurred (c-4).This confirms that hydrogen promotes the activation of cross slip, resulting in an increase of dislocation density in FCC metallic material.

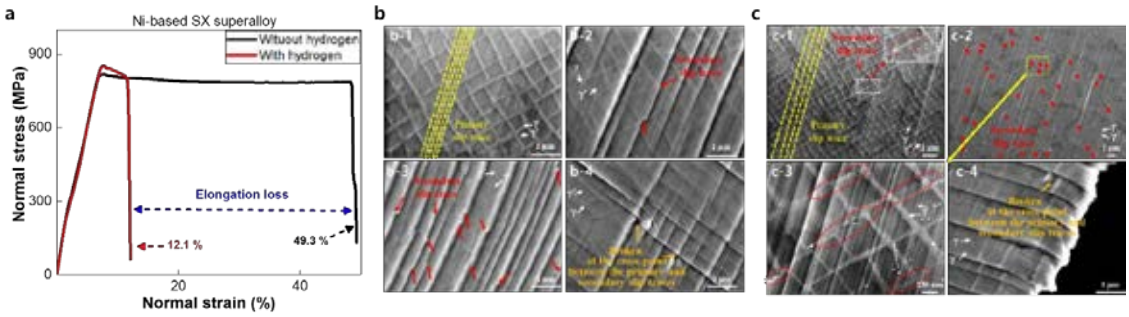

Fig 3. Hydrogen induced dislocation slip in Ni-based single crystal superalloy. (a) reduction of fracture strain by hydrogen embrittlement, (b) evaluation of deformed microstructure of specimens without hydrogen at 4.9%(b-1), 19.7%(b-2), 39.4%(b-3), 49.3%(b-4), and (c) evaluation of deformed microstructure of specimens with hydrogen at 4.9%(c-1), 9.3%(c-2,3), 12.8%(c-4).

3.3 Predictive tensile properties on hydrogen embrittlement in STS 304

The main contributors to hydrogen embrittlement in STS 304, as identified in this study, are SIM formation and the increase of dislocation density due to hydrogen. To examine these effects, tensile properties of specimens with different hydrogen contents were evaluated. As the hydrogen content increased, the fracture elongation reduced (Fig. 4a). Two trends were observed in the phase fraction (Fig. 4b). Additionally, once the phase fraction saturated, an increase in grain orientation spread (GOS) was noted (Fig 4c). This rise of GOS value also indicated a higher dislocation density. This nature was clearly evident during the deformation process, as predicted by the Olson-Cohen model (Fig. 4d). In specimens with low hydrogen content (Region 1), the SIM observed after fracture was matched in the Olson-Cohen model (similar to the uncharged state), whereas, in Region 2, the SIM fraction remained constant, but the activation of

cross slip due to hydrogen led to SIM appearing through lower strain levels, resulting in elongation loss. Based on these observations, a model was developed to predict fracture elongation as a function of hydrogen content (Fig. 4e).

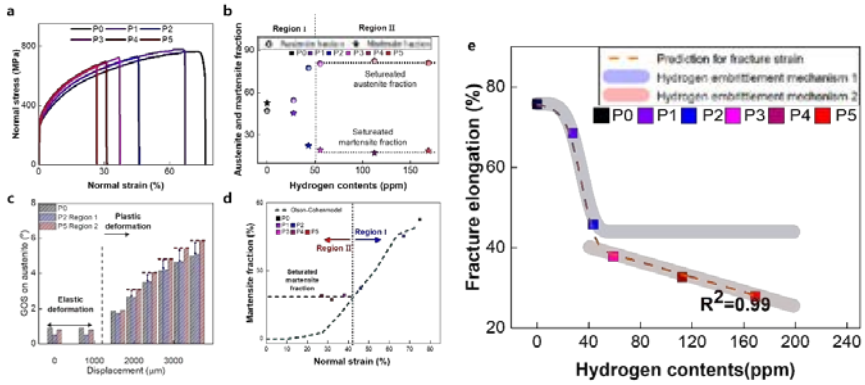

Fig. 4 Predictied various hydrogen embrittlement in STS 304 according to hydrogen contents. (a) evaluation of SSRT, (b) phase fraction after fracture, (d) changes of GOS during the deformation (e) matching various hydrogen precharged specimens in Olson-cohen model, and (f) prediction of fracture elongation on hydrogen embrittlement.

4. CONCLUSIONS

This study investigated the hydrogen embrittlement mechanism of FCC metal, with the following key findings:

1) The fracture behavior of STS 304, resulting from hydrogen embrittlement, was primarily driven by decohesion, which occurred due to differences in hydrogen solubility and was linked to SIM formation.
2) In FCC metals, the increase in dislocation density by hydrogen was attributed to the activation of secondary slip.
3) The model for prediction of tensile properties was developed to predict fracture elongation as a function of hydrogen content, based on the identified mechanisms for the two types of hydrogen embrittlement.

ABSTRACT

The effects of hydrogen addition to methane fuel on the flame parameters and methane reactivity were numerically studied in this paper. A lab-scale tube burner forming a central fuel jet in the coflow oxidizer mixture was employed. The hydrogen addition to methane fuel was adjusted in such a way that the hydrogen ratio varied from 10% to 40% on molar base. The inlet temperature and composition of the high-temperature coflow oxidizer mixture were kept constant in order to evaluate the pure effects of hydrogen addition. The results show that the maximum flame temperature slightly increases from 1670K for the pure methane case to 1738K for the 40% hydrogen addition case, due to mild combustion behavior occurring from the high-temperature diluted oxidizer. However, hydrogen addition makes methane fuel more reactive by getting it reacted in a shorter axial distance and eliminates the temperature jump, which is formed for the pure methane case. Hydrogen addition increases the OH radical concentration in the flame and enchances the mixing rate of the reactants due to the increased axial momentum of the central fuel jet, which shifts the combustion flame upstream of the burner and makes it more stable.

Keywords: Hydrogen addition, Methane fuel, Mild combustion

1. INTRODUCTION

The population of our world is increasing every year and the energy demand from all of the sectors is also increasing accordingly. The energy industry still relies heavily on fossil fuels in our day. Hydrocarbon fuel shortage is likely to be the main problem to be faced in the near future. Therefore, the utilization of alternative fuels and efficiency optimization studies on the current energy systems are intensely conducted to remedy the possible energy shortage. One of the methods to increase thermal efficiency of combustion systems is the application of mild combustion regime. Mild combustion can be defined as a slow reaction process of a fuel under diluted hot oxidizer conditions. With this combustion regime, an increased flame volume with uniform temperature distribution can be formed and the overall heat transfer rate from the combustion flame to the surroundings can be enhanced. However, combustion stability issues can occur under mild conditions, since the chemical time scale is comparable with turbulence or the mixing time scale. Some of the research studies related to mild and diluted combustion are reviewed. Tu et al. [1] conducted CFD studies to investigate the mild combustion behavior of hydrogen and methane fuel mixtures. Their results indicated that CO_2 diluent was a better option to obtain mild conditions than H_2O diluent. Erete et al. [2] performed some experimental studies to reveal the effects of CO_2 dilution of methane fuel on the flame parameters such as flame length and lift-off height. Fordoei et.al [3] numerically studied on the effects of hydrogen addition to methane on the flame parameters under CO_2 dilution conditions of the oxidizer mixture. EDC combustion model was used in their study. The obtained results reported a reduction in the ignition delay time of fuel with the increasing hydrogen addition ratio. Fordoei et. al [4] conducted some series of numerical studies for the CO_2 diluted oxidizer-methane combustion cases. They analysed CH_2O species distribution in the flame to measure its mild behavior. Schluckner et.al [5] compared the results obtained from the flamelet models, EDC model and EDM for the oxy-fuel combustion case in a natural gas combustor. Their results reported that the partially premixed flamelet model showed the best performance for NO_X emission predictions. In this paper, the effects of hydrogen addition to methane fuel, under the CO_2 diluted coflow hot oxidizer conditions in a tube burner, on the central methane fuel reactivity and flame parameters are numerically investigated using non-premixed combustion model with the steady flamelet approach. The physical and chemical effects of hydrogen addition on the flame parameters are revealed. The improvement in the combustion stability of methane fuel with the increasing hydrogen addition ratio is evaluated.

2. COMPUTATIONAL DETAILS

In this paper, a combustion tube from the study of Brokes and Moss [6] was utilised as the combustion volume. Fluent code was used as the computational tool. This burner originally measures 1m in length and 0.155m in diameter. However, the tube length was extended to 2m in this paper for the purpose of the diluted combustion flame analysis. The burner has a central fuel injector, which measures 4.07mm in diameter, and a coflow oxidizer annulus inlet with the same size of the burner diameter. The tube burner is modelled as a 2D non-premixed type and axisymmetric one, and presented in Fig.1. It should be noted that the gravity is applied towards the reactants inlet.

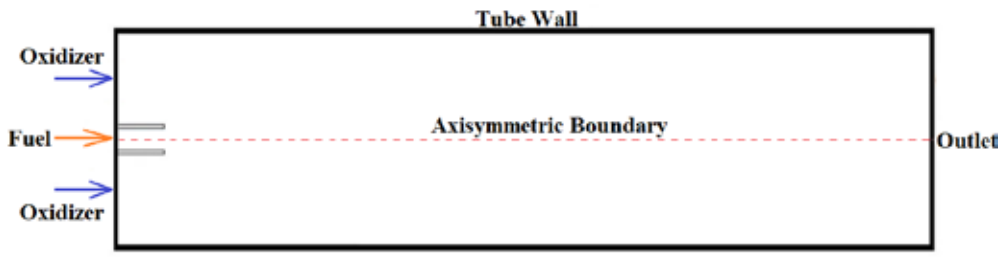

Fig. 1. 2D Modelling of Tube Burner

In this numerical study, the methane fuel inlet rate was taken as 0.000172 kg/s, which corresponded to 8.6 kW thermal load. The oxidizer inlet rate was adjusted to have an excess coefficient ratio of 4 for methane fuel. The fuel inlet temperature and oxidizer inlet temperature were kept constant as 290K and 1000K, respectively. In addition, the oxidizer was adjusted to have a composition of 12% O_2, 20% CO_2 and 68% N_2 on molar base in order to sustain diluted or mild combustion conditions. Five different cases were studied in this paper by changing the hydrogen addition ratio to methane from 0% to 40% on molar base by 10% step, while keeping the methane flow rate constant. For the simulations in the combustion tube, the governing equations related to mass, momentum and energy conservation were solved and they are given in Eq. (1), Eq. (2) and Eq. (3) respectively [7].

$$\frac{\partial \rho}{\partial t} + \nabla.(\rho \mathbf{v}) = 0 \tag{1}$$

$$\frac{\partial (\rho \mathbf{v})}{\partial t} + \nabla.\rho \mathbf{v}\mathbf{v} = -\nabla.P + \rho \sum_{i=1}^{N} Y_i f_i \tag{2}$$

$$\frac{\partial (\rho h)}{\partial t} + \nabla.(\rho \mathbf{v} h) = \nabla.[\frac{k_t}{c_p} \nabla h] + S_h \tag{3}$$

Here in these equations, ρ is density (kg/m^3), **v** is velocity vector (m/), P is stress tensor (N/m^2), h is enthalpy (kJ/kgK), Y_i is mass fraction of i_{th} species, f_i is force acting on i_{th} species (kJ/kg), k_t is thermal conductivity (kW/mK), c_p is specific heat (kJ/kgK), t is time (s) and S_h represents the source term for radiation . The radiation intensity equation was also solved to take into account the radiation heat transfer mechanism in the combustion flame and to the surroundings from the flame [8]. The equations were solved by Reynolds averaging. Therefore, standart k-ϵ turbulence modelling [8] was chosen to close the equation system. For the chemical modelling of the simulations, the non-premixed combustion model with the steady flamelet approach was used. For this purpose, the averaged mixture fraction conservation equation [8] was solved and it is given as;

$$\frac{\partial (\rho \bar{f})}{\partial t} + \nabla.(\rho \mathbf{v} \bar{f}) = \nabla.(\frac{\mu_t}{\sigma_t} \nabla \bar{f}) \tag{4}$$

In this equation, $\bar{f}$ is the averaged mixture fraction, μ_t is turbulent viscosity (kg/ms) and σ_t is a constant. The mean scaler variables such as density, temperature and species mass fractions are calculated taking into account of turbulence-chemistry interaction by Eq. (5) [8] and tabulated prior to the numerical simulations.

$$\bar{\emptyset} = \int \emptyset(f, \bar{H}) P(f)\, df \tag{5}$$

In Eq. (5), P(f) is the β type probability density function, which is a function of $\bar{f}$ and the averaged mixture fraction variance ($\overline{f'^2}$). Therefore, a conservation equation for $\overline{f'^2}$ [8] was also solved together with the averaged mixture fraction formulation. The scaler variable $\emptyset$ is a function of f and this function is set with the use of flamelet equations. GRI-Mech 3.0 reaction mechanism [9] was used in the flamelet equation calculations. All of the equations were discretized and numerically solved using Fluent code. The steady state assumption was made for all the cases. Coupled method was chosen for pressure-velocity coupling. Second order scheme and second order upwind scheme were used for pressure and equation discretization, respectively. Discrete Ordinates was utilised for the radiation modelling and wsggm-domain based was used for the absorption coefficient [8]. The adiabatic wall condition was assigned for the burner walls. Around 600000 meshing elements were used for the flow volume, since further increment in the meshing elements did not give any significant change in the central axial temperature values. The mathematical modelling and numerical parameters were validated with the experimental data of Brokes and Moss [6] for the methane-air case. However, it could not be presented in this paper.

3. RESULTS AND DISCUSSION

The obtained results from the simulations as the temperature variations in the combustion tube are presented in Fig.2.

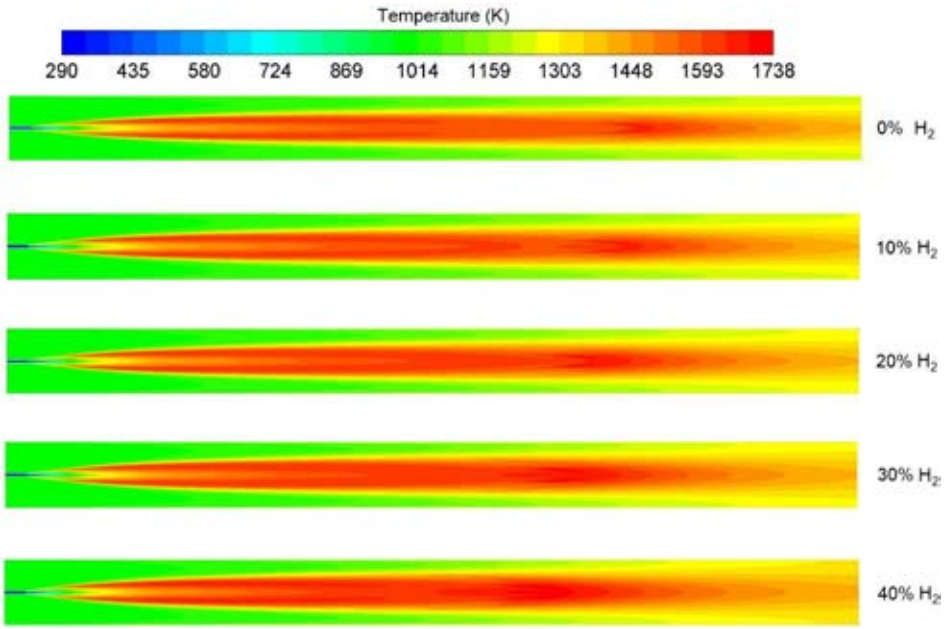

Fig. 2. Temperature Variations in Tube Burner

The axial variations in the centre of the tube burner related to the temperature, excess oxidizer coefficient (EOC) for methane fuel and OH radical mole fraction are plotted in Fig.3 for some of the cases. The total flow rate variations of the unreacted methane fuel in the tube burner according to the different axial positions are also outlined in Fig.3.

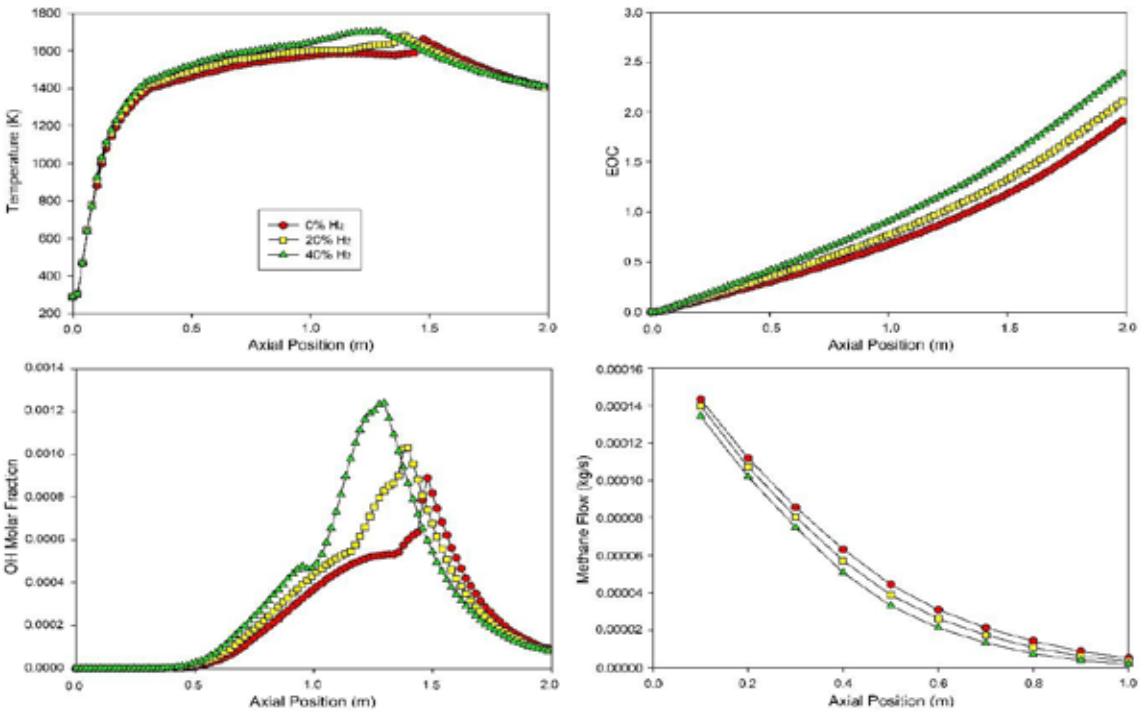

Fig. 3. Variations in Flame Parameters for Different Hydrogen Addition Ratios

The results show that hydrogen addition enhances the mixing rate of the reactants. EOC parameter for methane fuel shows an increasing trend at any axial position with the increasing hydrogen addition ratio. This occurs due to the

increasing axial momentum of central fuel jet with hydrogen addition. This can be classified in the physical effects of hydrogen addition to methane. The hydrogen addition also increases the molar fraction of OH radical, which is the most effective on decomposition of CH_4 molecule. This increment in OH radical is both due to the better mixing of the reactants and the chemical effects of hydrogen molecule, which form OH and H radicals, as hydrogen molecule is reacted with O radicals. Fig.2 and Fig.3 show that the flame uniformity is improved with the hydrogen addition. The maximum flame temperature point is shifted towards the reactants inlet and therefore the temperature jump formation for the pure methane case is eliminated. The temperature jump is formed due to the poor mixing of the reactants in more than half length of the burner for the pure methane case under diluted oxidizer conditions. The poor mixing of the reactants causes scarcity in the necessary radicals for decomposition of methane fuel, up to some point close to the outlet section. The enhanced mixing rate of the reactants and formation of OH, H and O radicals by hydrogen addition contribute to the acceleration of the methane reaction rate and the temperature jump formation is eliminated accordingly. Therefore, in general, the reactivity of methane fuel is determined to be enhanced with hydrogen addition. Fig.3 proves that the flow rate of methane fuel in the tube at the different axial points is reduced, which indicates that methane fuel is reacted in shorter axial distance with the hydrogen addition. The maximum flame temperature does not significantly increase with the hydrogen addition, due to the diluted oxidizer and mild combustion behaviour of the flame. It increases from 1670K for the 0% hydrogen addition case to 1738K for the 40% hydrogen adition case, which will not contribute significantly on the NO_X formation rate in the flame. It is determined that hydrogen addition to methane can offer solutions to stability issues under diluted or mild combustion conditions, while the flame temperature increase by hydrogen addition can be limited to prevent the NO_X emission formation.

4. CONCLUSION

The following conclusions can be achieved from this study;

- Hydrogen addition to methane slightly increases the maximum flame temperature due to diluted or mild combustion conditions. The maximum flame temperature increases from 1670K for the case without hydrogen addition to 1738K for the case with 40% hydrogen addition ratio.
- Hydrogen addition to methane improves the mixing rate of the reactans for the central fuel jet burners.
- The flame uniformity and stability are improved with hydrogen addition to methane fuel. The temperature jump formation for the pure methane combustion case under diluted oxidizer conditions is diminished with hydrogen addition. This is an indication of the increased reactivity of methane fuel under diluted oxidizer conditions.
- Hydrogen fuel contributes to the methane fuel reactivity by changing both physical and chemical properties of the combustion flame.

ABSTRACT
Europe, like other agricultural regions in the world, through waste resulting from agriculture and energy potential. In fact, achieving a circular economy will require agriculture to use various forms of valorization of important energy waste, remaining one of the most important. The use of pyrolysis technologies and especially gasification allows obtaining H_2 in high proportions. If for wood mass the results of gasification are significant, both in terms of flow rates and quality of synthesis gas, with electrical power achievements of the order of MW, for agricultural biomass they are for now only achievements, at the pilot stage level. The paper presents the current study of the performance of gasification of agricultural residual biomass, highlighting the possibilities of obtaining green H_2. To this end, experimental tests are also presented for the characteristics of residential agricultural biomass in the European Union (EU). The paper also contains a simulation of the green H_2 country through the gasification of agriculture in the EU, with which it also refers to the costs associated with production.

Keywords: Gasification, Agricultural Biomass, Green Hydrogen, Energy

1. INTRODUCTION

The achievement of a society without CO_2 emissions will also have to include the agricultural sector, where agricultural waste could constitute an important energy potential, with a final reflection in the achievement of a circular economy. Despite all the technological advances in recent times, including the use of fermentation, agriculture still delivers an enormous amount of waste, possibly to be recovered as energy. Current ecological requirements no longer allow their direct combustion, generating CO_2 [1], [2], [3].

EU agriculture, represented by France, Germany, Italy, Romania, Poland, Spain, Hungary and England, mainly produces cereals, maize and sunflower, but also vines and fruit trees, all of which can be used as primary fuel for gasification. For the period 2016 – 2021, these 8 countries produced an annual average of 109.63 million tonnes of wheat grains, 50.39 million tonnes of maize grains and 56.70 million tonnes of sunflower seeds [1], [2]

For the first 15 EU countries, the cultivated areas included: wheat: $21.6 \cdot 10^6 ha$; maize: $7.14 \cdot 10^6 ha$; sunflower: $3.91 \cdot 10^6 ha$. For these crops, the waste of the countries, [2], [3], [4]: wheat straw: $3.2 - 4.0\ t/ha$; maize stalks: $5.8\ t/ha$; corn cobs: $0.7\ t/ha$; sunflower stalks: $1.8\ t/ha$; vine tails and orchard branches: $0.25 - 0.38\ t/ha$.

Comparing this waste to the cultivated area in the EU results in considerable quantities, of which about 40% have internal use, the remaining 60% can be used for energy production [2], [4]. To define the energy characteristics of plant biomass, the easiest analysis can be used, the technical one, which includes in gravimetric percentages the moisture content, W; the volatile content V; the fixed carbon content, C_f and the ash content, *A*.

$$W + V + C_f + A = 100\% \quad (1)$$

The gasifier gas consists of the components H_2, CO, CO_2, CH_4 and N_2 (in air gasification, nitrogen is dominant, reaching around 50%), has a calorific value corresponding to the proportion of the respective gases. This gas, through combustion, from the components CO, CO_2 and CH_4 forms CO_2, so the respective installations will have to be coupled to a CO_2 capture installation (see subchapter 5).

2. TECHNOLOGICAL CHARACTERISTICS OF FUEL GAS PRODUCTION THROUGH GASIFICATION

Gasification is a source of thermochemical processes that leads to the transformation of a primary solid fuel into a synthesis gas (gasogen). The heat required to carry out thermochemical processes comes from an internal source (combustion of the primary fuel), from an external source, or from a combination of these. Gasogens in the first category are called autonomous and are exclusively applicable to plant biomass. The combustion agent can be air, oxygen-enriched air, less often oxygen, but also steam (in which case the heat introduced by the steam represents an external heating source).

Gasification includes the following characteristic steps:

- removal of water (W) from the primary fuel (drying). The process ends at a temperature in the range of $105 - 200^0C$;
- pyrolysis, obtained by heating the fuel in the absence of an oxidizing agent, characterized by the removal of volatiles (V), the process ends in the range of $450 - 700^0C$;

- combustion of carbon with the formation of a high-temperature reactive zone;
- realization of the conversion equations, with the formation of synthesis gas (gasogen).

In the pyrolysis zone, the first part of the synthesis gas composition is formed from the fuel, consisting of: H_2, CO, CO_2, CH_4, N_2. Combustion includes the reactions, [1]:

$C + O_2 = CO_2$ (exothermic reaction) (2)

$C + H_2O = CO_2 + H_2$ (endothermic reaction) (3)

The main reduction reaction (endothermic):

$CO_2 + C = 2CO$ (4)

Hydrogenation reactions (exothermic):

$C + 2H_2 = CH_4$ (5)

$H_2O + CO = CO_2 + H_2$ (6)

Methanation reactions (exothermic):

$C + 3H_2 = CH_4 + H_2O$ (7)

$CO_2 + 4H_2 = CH_4 + 2H_2O$ (8)

The combustion Eq. (1) represents the main heat source and the temperature level is ensured by the amount of air (excess air) admitted. The hydrogenation Eq. (6) and Eq. (7) form the amount of H_2 gas, along with that formed in the pyrolysis process from the composition of the synthesis gas. The hydrogenation reactions highlight the importance of water vapor (H_2O). A classification of gasification plants is shown in Fig. 1.

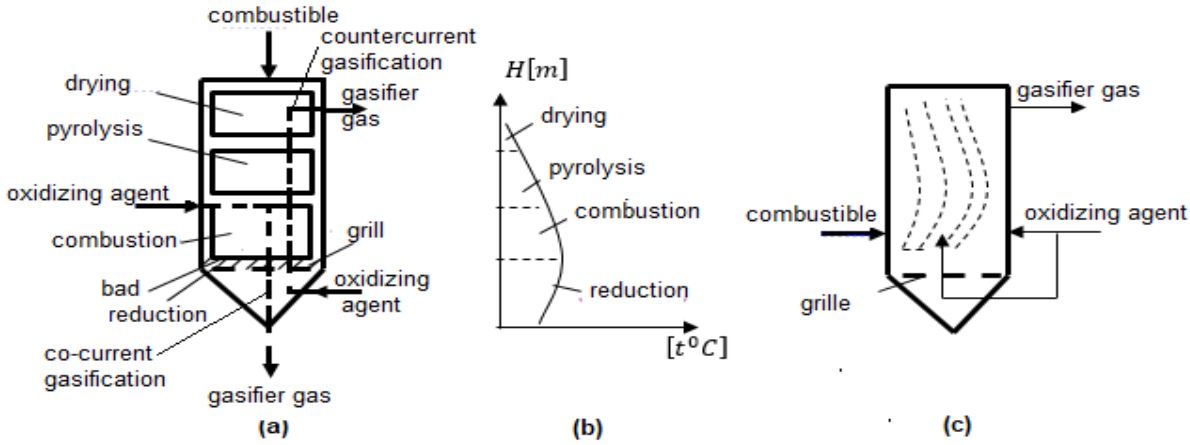

Fig. 1. Construction and functional principles for gasification plants
a – fixed bed gasifier (in co-current or downcurrent and countercurrent, respectively); b – temperature evolution in the gasifier body; c – gasifier with fluidized state and flow in the stream

Fluidized bed or flow-through gasification plants provide higher flow rates and therefore higher thermal power than fixed bed plants, but these plants are currently only applicable to primary fuels made from woody biomass.

Synthesis gas (gasifier gas), in air gasification, includes the following components:

$H_2 + CO + CO_2 + CH_4 + N_2 = 100$ (9)

The gaseous component CO_2 is strongly reduced with the increase in the state temperature, at temperatures above 950^0C, having subunit values ($CO_2 < 1\%$), so that the gasifier gas will contain the combustible components (H_2, CO, CH_4) in a proportion of about $44 - 49\%$.

3. STATUS OF ACHIEVEMENTS OF VEGETABLE BIOMASS GASIFICATION FACILITIES

Achievements in the field of agricultural biomass gasification are currently at the level of low powers, usually below 1MW, but with the advantage of a synthesis gas with a sufficiently high calorific value. Agricultural biomass gasification requires air as an oxidizing agent, provided that it is gradually distributed in the combustion zone, because the temperature in the layer must not exceed $850 - 900^0C$, especially in the case of cereal straw, to avoid the grill clogging [1], [2], [3], [5].

The best results for agricultural biomass - as a primary fuel are presented by gasifiers with a fixed bed and downward circulation – Fig. 1, both due to the control of the reduction reactions that lead to the formation of H_2 and CH_4, and because they thermally destroy the tar formed in the pyrolysis operation, which is forced to travel through the fixed bed. Good results were also obtained with a hybrid gasifier, between those with downward and upward circulation, namely the cross-circuit gasifier, Fig. 2, in which the biomass has a downward flow, and the gas a lateral (transverse) one.

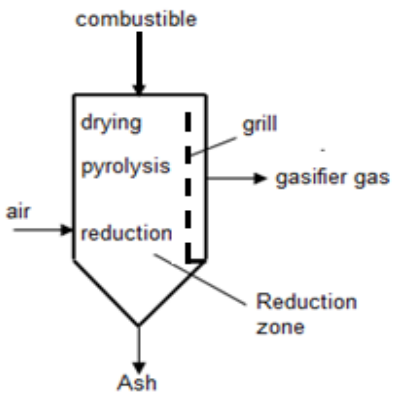

Fig. 2. Cross-circuit gasifier diagram

From the data in the paper [6], regarding the gasification of vegetable biomass, it results the presence of carbon in minute quantities in the discharged ash, below 1%, as well as for hydrogen sulfide and hydrochloric acid. Regarding tar, it can be included in the category of bituminous oil. Regarding the dimensions of vegetable biomass, the advantage of pelletization was found (the dimensions obtained are for a diameter of 5-6 mm and a length of 20 - 25 mm), even compared to briquettes. Special attention is also paid to the use of vegetable biomass in the form of chips (average diameter 2 - 5 mm), for a humidity controlled at 10-12 %. Regarding the efficiency of the vegetable biomass gasification process, it was in the range of 61-73 %, above that achieved with municipal waste, [7], [8].

The amount of gasifier gas, characterized by the ratio of its gaseous components, demonstrates: $CO/CO_2 = 1.3 - 1.5$, and $H_2/CO = 0.45 - 0.75$. These data are especially for Asian plant biomass (Thailand, Malaysia, India), in Europe research is still in its infancy, [9], [10].

4. EXPERIMENTAL TESTS OF GASIFICATION OF EUROPEAN VEGETABLE BIOMASS

These tests were carried out at the POLITEHNICA Bucharest, with a 4KW pilot gasifier, for dominant vegetable biomass in EU agriculture. The tests aimed to achieve a high H_2 content in the synthesis gas. For this purpose, the following was achieved: fixed bed gasification with descending circulation; gradual air distribution (on 0.35 of the gasifier height); an increased constructive height/thickness ratio; humidity control in the range of 10-20%; fixed bed temperature control; biomass size control. Agricultural biomass was represented by the dominant waste, namely: cereal straw (in the form of chopped or pellets), corn stalks (in the form of chopped), vine ropes, walnut shells [5]. The pilot gasifier has the characteristic dimensions [1], [3], [4]: internal diameter, $\Phi = 88mm$, height $400\,mm$, primary fuel flow $1kg/h$. Fig. 3 shows a picture of the complex gasification installation.

Fig. 3. Appearance of the 4 KW pilot gasifier.

The gasification of a wide range of plant biomass is presented in Table 1.

Table 1. Experimental test results

Biomass	Technical analysis, %				t_r^* [°C]	R_{H_2}
	W	V	C_f	A		
Cereal straw	9.8	72.0	12.6	5.6	850	0.62
Cereal straw pellets	8.7	70.0	15.9	5.4	850	0.49
Chopped corn stalks, **	13.3	67.5	13.1	6.1	870	0.61
Chopped vine strings, **	8.7	67.5	17.9	5.9	900	0.44
chopped fruit tree branches, **	14.2	66.2	13.1	6.5	885	0.59
Walnut shells, **	9.1	66.0	18.8	6.1	900	0.42

*) with t_r the steady state temperature was noted; **) particle size within the limits of 3 – 5 mm.

The H_2/CO ratio in the gasifier gas was denoted by R_{H_2}. The gasification installation includes air supply systems (Einhell TC $\frac{190}{2418.165}$ $l/_{min}$). The fixed layer temperature measurement and control system (thermocouple type "S" PtRh 10% - Pt, Φ 6, l = 500 mm, vertically immersed from the outside of the plant into the fixed layer, indicator device type SREN 61326 – 1:2013. The average calorific value of the gasifier gas was between $5.4\ and\ 7.6\ MJ/m_N^3$. Experimental tests with agricultural waste in the EU have demonstrated the production of a gasifier gas with a high H_2 content, on average about 13 – 31% (for air gasification).

5. CAPACITY TO PRODUCE AND USE H2 PRODUCED BY GASIFICATION OF AGRICULTURAL BIOMASS

For a first estimate of the annual potential of agricultural biomass that can be gasified in the EU, only cereal, corn and sunflower crops were considered, resulting in the following quantities of waste (see subchapter 1):

- wheat: $21.6 \cdot 10^6 ha \cdot 3.6\ t/ha = 77.76 \cdot 10^6\ t/year$;
- maize: $7.14 \cdot 10^6 ha \cdot 5.8\ t/ha = 41.41 \cdot 10^6\ t/year$;
- sunflower: $3.91 \cdot 10^6 ha \cdot 1.8\ t/ha = 7.04 \cdot 10^6\ t/year$.

This results in a total of $126.21 \cdot 10^6\ t/\text{year}$ of agricultural vegetation waste, of which 40% is considered to be internal consumption, resulting in an amount of $75.72 \cdot 10^6\ t/\text{year}$ for energy. The gasification test data demonstrated a gasifier gas production of $2 - 2.8\ m_N^3/kg$ biomass, so that the total annual potential becomes: $(151.4 - 212.0) \cdot 10^9\ m_N^3/\text{year}$. This gasifier gas can be considered impure hydrogen, being similar to the current energy stage of transition to a decarbonized economy with the use of mixing, H_2 in CH_4. This gasifier gas can be used by direct combustion either in an internal combustion engine or in an electrical and/or thermal energy generator. For an average content of 16% green H_2 in the gasifier gas, a productive potential of $(24.1 - 33.9) \cdot 10^9 m_N^3/\text{year}$ results, in mass units approximately $(2.4 - 3.3) \cdot 10^5 t/\text{year}$. The cost of green hydrogen produced by gasification is lower than that produced by photosynthesis based on wind energy $(3.40 - 11.04\ EUR/kg)$, or solar energy $(3.50 - 10.04\ EUR/kg)$, having the value $(1.84 - 6.44\ EUR/kg)$, on average it can be considered $(4.14\ EUR/kg)$ [9].

6. CONCLUSIONS

The paper presents the economic and ecological importance of using agricultural waste for the production of green hydrogen through gasification. For the current stage of transition to a neutral economy in terms of CO_2 emissions, gasifier gas represents a comparative solution to the one expected for the use of the $H_2 - CH_4$ mixture in proportions of up to 10-15%. Current analytical and experimental data indicate a high potential for green hydrogen, with a lower price than that obtained through electrolysis based on renewable energy. The paper also mentions the need to continue research into the gasification of agricultural residual biomass, for the construction of higher power plants.

ABSTRACT

This study conducts a numerical investigation into the exhaust emissions of a hydrogen-diesel dual-fueled medium-speed marine diesel engine, focusing on the impact of varying fumigated hydrogen mass fractions while keeping diesel injection mass constant. Employing advanced computational models, including the RNG k-ε turbulence model and the SAGE combustion model, the analysis examines the combustion process and the exhaust emissions, including nitrogen oxides (NO_x), carbon monoxide (CO), carbon dioxide (CO_2) and unburned hydrocarbons (UHC). The findings reveal that NO_X and CO_2 emissions enhances increasing fumigated hydrogen mass fractions, whereas UHC emissions exhibit a comparatively stable behavior and CO emissions first decreased then increased. The lowest values of maximum NO_X, UHC, CO and CO_2 emissions are 810, 1392, 4433 and 49683 ppm, respectively. The optimum fumigated hydrogen mass fraction is chosen as 0.0001 according to lowest NO_X, UHC and CO_2 emission values and 0.0002 according to lowest CO emission value. This research not only enhances the understanding of dual-fuel combustion processes but also provides valuable insights for the development of sustainable marine engine solutions in alignment with global emissions regulations.

Keywords: Numerical investigation, Medium-speed marine diesel engine, Exhaust emissions, Fumigated hydrogen mass fractions

1. INTRODUCTION

The maritime transportation sector plays a pivotal role in the global economy, with over 80% of international trade reliant on ships for the movement of goods across vast distances [1]. This heavy reliance on shipping logistics is mainly backed by the use of internal combustion engines (ICE), which are essential for about 98% of the entire merchant fleet, allowing these ships to effectively move goods to different places worldwide [2]. This sector contributes approximately 10% of the total emissions produced by the transportation sector and accounts for 2.9% of overall emissions [3], thus rendering it crucial to identify alternatives that ensure maritime transportation is both economically and environmentally sustainable. Indeed, the maritime sector predominantly relies on fossil fuels, exhibiting a 20% escalation in greenhouse gas emissions over the preceding decade [1]. In this sense, international merchant ships must obey the emission regulations defined by the International Maritime Organization (IMO) [4], which have become stricter over the years [5]. While multiple strategies may be contemplated for realizing a near zero-carbon future, it is anticipated that ICEs will persist in their predominance within maritime applications for an extended period, owing to their superior torque, efficiency, and weight characteristics, which align with the operational requirements and structural design of vessels [6]. One of these strategies is the usage of alternative fuels, such as hydrogen or ammonia, in diesel engines, which offer promising potential for reducing greenhouse gas emissions while maintaining the performance standards required in marine operations [7].
Recent advancements in hydrogen/diesel dual-fuel engines have garnered significant attention for their potential to reduce emissions while improving fuel efficiency in the maritime sector. By adopting hydrogen as a complementary fuel, these engines realize a decrease of nearly 50% in CO_2 emissions alongside traditional diesel systems [8]. Nonetheless, obstacles remain, particularly with respect to ignition properties and combustion stability across varying hydrogen mass fractions. Also, the transition towards dual-fuel technology entails significant infrastructure investment and modifications to current vessels, raising issues about its economic practicality and enduring feasibility in fulfilling strict International Maritime Organization (IMO) regulations [9]. As the sector navigates these challenges, ongoing scholarly inquiry seeks to optimize dual-fuel technologies to effectively reconcile performance with ecological obligations.
This research aims to examine numerically exhaust emissions in medium-speed marine diesel engine with a constant diesel injection mass and five different fumigated hydrogen mass fractions in-cylinder. By developing a comprehensive numerical model for simulating hydrogen combustion, this study seeks to identify optimal hydrogen mass fractions that minimize exhaust emissions without compromising engine performance, thereby offering valuable insights for engine manufacturers and ship operators in the pursuit of more sustainable maritime operations.

2. MODEL SETUP

In various R&D fields, CFD softwares are widely used for simulations. This study developed a numerical model of the

MAN Diesel L32-40 medium-speed marine diesel engine using CONVERGE Studio v3.2. To reduce analysis time and operational volume, a sector geometry representing the full engine was utilized. The sector geometry is shown in Fig. 1, and the engine's specifications under full load are listed in Table 1.

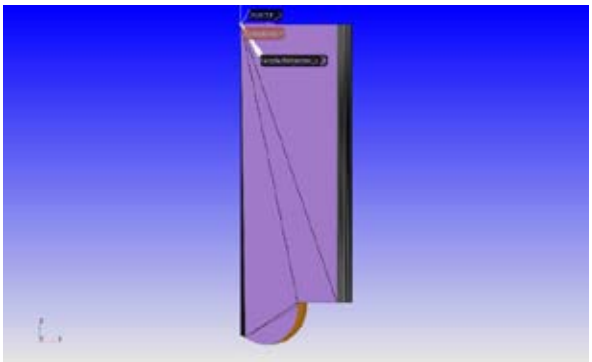

Fig. 1. MAN 32/40 medium speed marine diesel engine sector geometry

Table 1. MAN 32/40 engine specifications

Parameters	Value
Compression ratio	22.0
Engine speed (rpm)	750
Bore (mm)	320
Stroke (mm)	400
Connecting rod length (mm)	533
Diesel nozzle hole diameter (mm)	0.259
Diesel injection temperature (K)	341
Number of diesel injector	1
Number parcels of per nozzle	5000

The primary computational models utilized in this simulation include the RNG k-ε turbulence model [10], which is widely adopted in engineering, and the modified KH-RT model [11] for spray breakup. The Frossling Correlation model [12] is employed for evaporation simulation, while the SAGE model [13] is used for combustion, integrating a chemical reaction kinetic mechanism with a solver to address the combustion of the computational fuel. This study combines ammonia and n-heptane mechanisms, substituting n-heptane for diesel due to their comparable combustion properties. The chemical reaction mechanism, based on Xu et al. [14], consists of 69 species and 389 reactions, yielding satisfactory predictions for the skeletal mechanism.

3. RESULTS AND DISCUSSION

3.1. Model validation

All computational analyses were conducted using CONVERGE Studio v3.2, utilizing cell counts of 50,000, 75,000, and 100,000, derived from base grid dimensions of 4.82413 mm, 4.214267 mm, and 3.82892 mm, respectively. The Mean Absolute Percentage Errors (MAPE) were calculated for each scenario based on experimental data, yielding values of 18.62%, 17.25%, and 17.48% for the respective cell counts. Consequently, Case-2 (75000 cell count) was determined to be the most favorable solution based on MAPE results.

3.2. Exhaust emission characteristics

A study was conducted to analyze the fluctuations NO_X, UHC, CO and CO_2 emissions in relation to crank angle, utilizing five various fumigated hydrogen mass fractions (0.0001, 0.0002, 0.0003, 0.0004, 0.0005). The fluctuation of NO_X emissions in relation to the crank angle is illustrated in Figure 2(a). As the fumigated hydrogen mass fraction increases, NO_X emissions also rise due to changes in combustion characteristics and reaction pathways. Hydrogen's rapid flame velocity and broad flammability spectrum alter the combustion environment, promoting NO_X generation [15]. The maximum NO_X emission recorded is 903 ppm at a 0.0005 fumigated hydrogen mass fraction, with end-of-cycle values of approximately 810 ppm, 821 ppm, 852 ppm, 874 ppm, and 903 ppm for mass fractions ranging from 0.0001 to 0.0005. The variation of unburned hydrocarbon (UHC) emission with respect to the crank angle is shown in Figure 2(b). As the fumigated hydrogen mass fractions increase, UHC emissions remain relatively constant due to the complex interactions of hydrogen's combustion properties with other fuels and combustion conditions [16,17]. The maximum UHC emission recorded is about 1392 ppm at full fumigated hydrogen mass fractions, with end-of-cycle HC emission values ranging

from 1.1142 ppm to 1.1601 ppm for fumigated hydrogen mass fractions between 0.0001 and 0.0005.

Figure 2(c) exhibits how carbon monoxide (CO) emissions vary with the crank angle. As the fumigated hydrogen mass fractions increase, CO emissions first decreased due to improving combustion efficiency and increasing flame temperatures, which aids in converting CO to CO_2 [18] and after a certain threshold, additional hydrogen may result in incomplete combustion, causing CO emissions to increase again [19]. The maximum CO emission values range from 4433 ppm to 4547 ppm for fumigated hydrogen mass fractions between 0.0001 and 0.0005. Additionally, the end-of-cycle HC emission values vary from 4.6534 ppm to 7.9344 ppm within the same range of hydrogen mass fractions.

Figure 2(d) exhibits how carbon dioxide (CO_2) emissions vary with the crank angle. As the mass fractions of fumigated hydrogen rise, there is a corresponding increase in CO_2 emissions due to improving combustion efficiency by increasing flame temperature and leading to a more complete combustion of the carbon-based components [20]. Both the maximum CO_2 emission and the end-of-cycle HC emission values range from 49683 ppm to 49819 ppm for fumigated hydrogen mass fractions between 0.0001 and 0.0005.

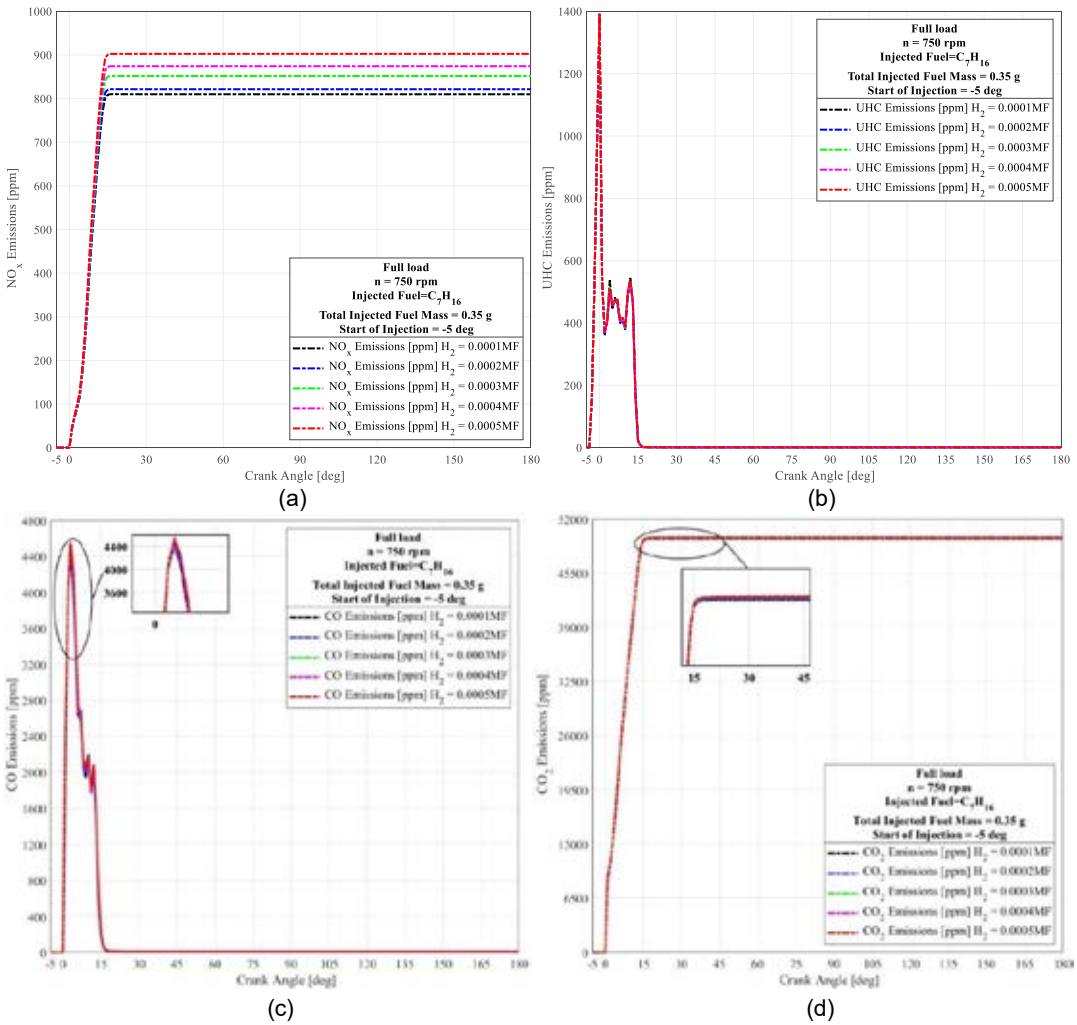

Fig. 2. The variation of exhaust emissions on crank angle degree (a) NO_X (b) UHC (c) CO (d) CO_2

4. CONCLUSIONS

The study conducted on the fluctuations of NO_X, UHC, CO, and CO_2 emissions in relation to crank angle, influenced by various fumigated hydrogen mass fractions, yielded the following main findings:

- All analyses were performed using CONVERGE Studio v3.2, with cell counts of 50,000, 75,000, and 100,000, determining Case-2 (75,000 cell count) to be the most favorable based on Mean Absolute Percentage Errors (MAPE) of 17.25%.
- A direct correlation was observed between the increase in fumigated hydrogen mass fractions and NO_X emissions, with a maximum emission recorded at 903 ppm for a mass fraction of 0.0005.
- UHC emissions remained relatively constant across varying hydrogen mass fractions, with a maximum emission of

approximately 1392 ppm noted at full fumigation.

- CO emissions initially decreased with increasing hydrogen mass fractions due to enhanced combustion efficiency, but later increased beyond a certain threshold, with maximum values ranging from 4433 ppm to 4547 ppm.
- CO_2 emissions increased alongside the fumigated hydrogen mass fractions, reflecting improved combustion efficiency, with maximum values ranging from 49683 ppm to 49819 ppm.

These findings highlight the complex interactions between hydrogen fumigation and combustion emissions, emphasizing the importance of optimizing hydrogen mass fractions for improved emission control.

ABSTRACT
The work addressed the combustion technology of the $H_2 - CH_4$ mixture for high values of up to 40% for H_2. The work developed previous theoretical and experimental studies. Starting from these, a diffusion burner was developed, with five nozzles for gas intake, each surrounded by coaxial air intake. The burner was mounted on a stand, built for this purpose, which achieved a controlled and stable mixing for CH_4 and H_2 components. The flame developed in free space. During the tests, a proportion of 17.25% and 40% for H_2 was used. The flames obtained were very stable, without vibrations and pulsations, with the first dominant part of H_2 combustion. The results obtained will represent a basis for future research and experimental testing.

Keywords: Methane, Hydrogen, Mixture, Diffusive Combustion, Cylindrical Flame

1. INTRODUCTION

The increase in the percentage of H_2 in CH_4 will have to be studied sequentially, each step raising the issue of the transition from the dominance of the combustion characteristic by CH_4 to the dominance of the H_2 component. Up to a mixing ratio of 10% for H_2, even 15%, as practice has shown, the flame is practically CH_4. As a result, for the proportion of the mixture below 15%, the combustion of premixes with air can be used, even with the full preservation of methane burners. In addition, a very simple technology can be used, represented by burners with self-aspiration of air. The main problems for the combustion process are represented by [1], [2], [3]:
- flame return for the technology of combustion of the gas-air premix;
- the correlation between the flame entry velocity for gas and air in the case of their separate admission, also called diffusive flame.

The combustion velocity of hydrogen amplifies these aspects, which is about 8 times higher than that of methane. The combustion velocity is perpendicular to the flame front and in the opposite direction to the flow. A stable flame is characterized by the equality of the flow velocity with the air velocity. In addition, other essential parameters intervene, such as temperature, turbulence, excess air (the ratio between the real air in the jets and the stoichiometric one). The main problem is the stability of combustion, represented by the correlation between the flow velocity in the jet that defines the flame and the combustion velocity.
Figure 1 presents a synthetic sketch of the constructive - functional variants of burners for the $CH_4 - H_2$ mixture, [4].

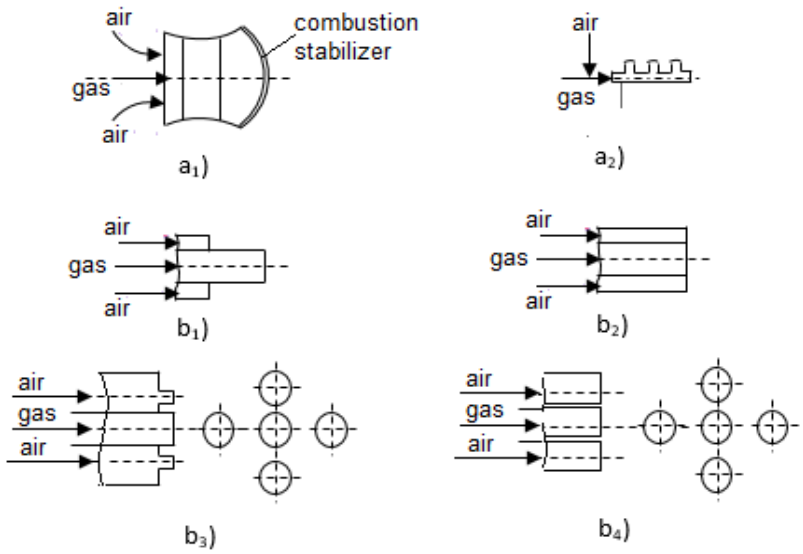

Fig.1. Construction variants for $CH_4 - H_2$ mixture burners.
a - with air premix: a_1 – with self-aspiration, a_2 – forced premix;
b – diffusion burners with separate gas-air jets: b_1 and b_2 – with coaxial jets, b_3 and b_4 – with separate jets.

2. COMBUSTION STABILITY CONTROL

The premix burners shown in Fig. 1. have domestic applications (heating, cooking, apartment heating systems). The presented diffusive burner variants (see figure 1) allow for combustion without flame return and thermal powers represented by fuel flows, significantly higher than those with premix do, and their modular construction allows for the achievement of high thermal powers [4].
The combustion of the gas-air premix depends on the kinetic characteristics of the gaseous fuel, which is why it is also called kinetic combustion, with “kinetic burners”, respectively [5], [6]. Diffusive combustion, existing in separate gas-air jets, depends on the diffusive transport of air to the fuel and has a much greater dependence on the gas dynamics of the gas-air mixture than on the energetic (kinetic) characteristics of the gaseous fuel. This gas-dynamic dependence of the gas-air ensemble is even more pronounced for hydrogen, due to the increased air velocity [7], [8], [9].
The very high laminar combustion velocity causes the main gasdynamic problem, of $3.1\,m/s$ for hydrogen, compared to $0.4\,m/s$ for methane. As a result, a mixture between them will have to solve this gap through the gas dynamics of the flame. This aspect is positive, so that at the base of the flame (at the burner exit), there will be hydrogen combustion, and at the periphery methane combustion [4].
Theoretically and experimentally for the diffusive flame it is found that the length "L" is little influenced by the exit velocity of the jets from the burner. The diffusion equation of the fuel concentration "C" for the coordinates in Fig. 2, for a symmetrical cylindrical flame is in the form (with D $[m/s]$ the fuel-air diffusion coefficient was noted):

$$\frac{\delta C}{\delta t} = \frac{D}{u}\left(\frac{\delta^2 C}{\delta y^2} + \frac{1}{y}\frac{\delta C}{\delta y}\right) \quad (1)$$

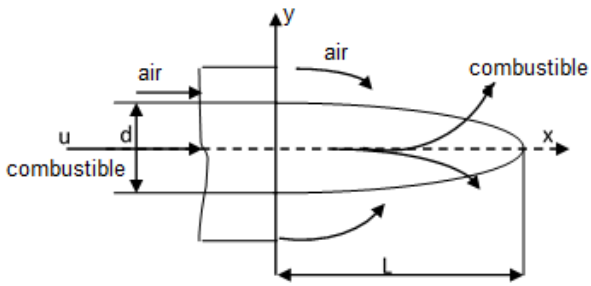

Fig. 2. Diffusion for a cylindrical flame.

A difference appears for the two gaseous components in the mixture $CH_4 - H_2$, where for $H_2 - air$ $D_0 = 6.11 \cdot 10^{-5} m^2/s$ and $CH_4 - air$ where $D_0 = 1.96 \cdot 10^{-5} m^2/s$ (both at 273 K), the diffusion coefficient in air being about 3 times higher for hydrogen than for air. This difference, as well as that of the momentum difference, leads to the combustion of hydrogen in the initial part of the flame, with the combustion of methane pushed towards the axial extremity of the flame.
For turbulent diffusion, governed by the turbulent diffusion coefficient ε, a coefficient proportional to the length of the turbulence ladder and to the turbulence intensity which is proportional to the velocity u, the dependence of the flame length proportional to the nozzle diameter d results.

$$L \sim d\ [m] \quad (2)$$

For a stable flame, the equality between the flow velocity $u\,[m/s]$ and the combustion velocity S_L $[m/s]$ for laminar regime, respectively S_T $[m/s]$ for turbulent regime, must be achieved. For both situations the combustion velocity depends on the fuel concentration C in air expressed in m^3/m^3, Fig.3, where C_{st} is the stoichiometric concentration.

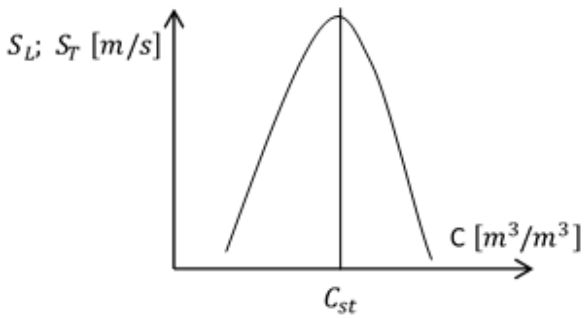

Fig 3. Variation of burning rate with fuel – air concentration.

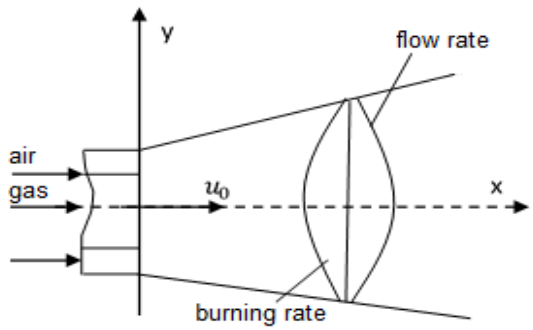

Fig. 4. The stability condition presented globally, as equality between the flow velocity and the combustion velocity which is in the opposite direction.

Finally, for the burning velocity in a jet, a parabolic distribution appears, Fig.4.

Along the axial flow "x" axis, the flow velocity exhibits a hyperbolic decrease $u = \sim\frac{1}{x}$, so the velocity u_0 at the exit of the fuel nozzle must ensure the stability condition $u = S_L$, respectively $u = S_T$. For this condition, the velocity u_0 must comply with condition (3).

$u \geq 10S_T$, respectively $u \geq 10S_L$ (3)

3. METHODOLOGY AND RESULTS OF TESTING THE COMBUSTION OF CH4-H2 FUEL, WITH HIGH H2 CONTENT

Experimental research included the creation of a stand for mixing the two gaseous fuels and a burner that allows combustion with a concentration of H_2 up to 60% in a mixture with CH_4. The burner presented conceptually in Fig. 5 comprises 5 fuel intake modules axially framed by air, and Fig. 6 shows an image of the burner, where $d_1 = 3mm,\ d_2 = 7mm,\ d_3 = 10mm$.

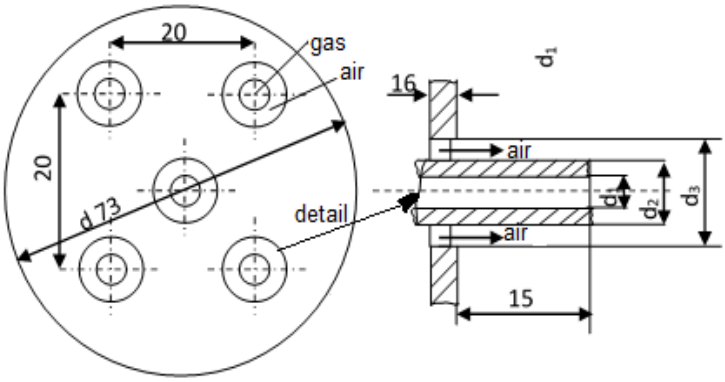

Fig. 5. Burner design.

Fig.6. Image of the burner.

Figure 7 shows a schematic of the stand designed to test the combustion of the $CH_4 - H_2$ mixture with a high H_2 content.

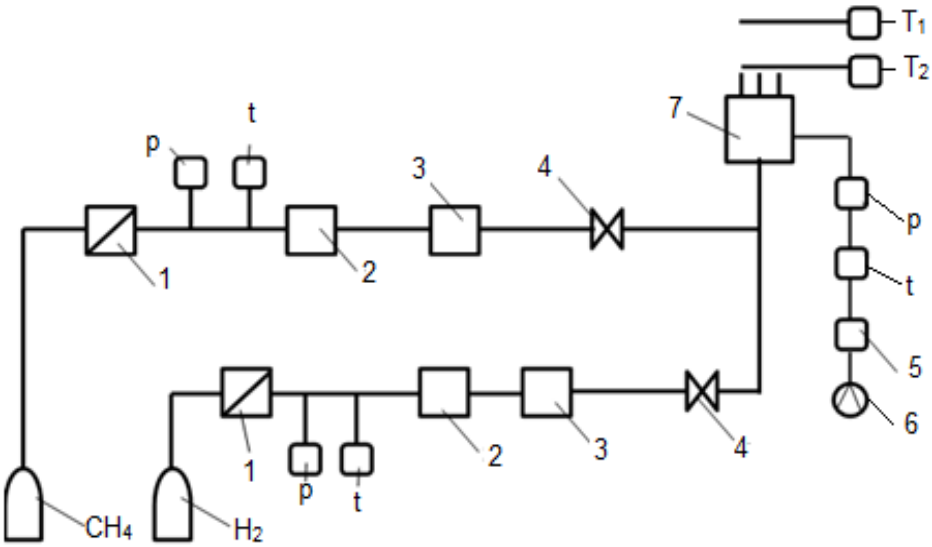

Fig.7. Experimental stand.
1- pressure reducing valve; 2 – flow programmer type Bronkhorst Flow; 3 – combustion process control type EMKOESM 4430; 4 – one-way valve; 5 – flow controller; 6 – air compressor, 7 – burner,
p, t – pressure and temperature measurement; T_1 and T_2 – thermocouples.

An image of the experimental stand is show in Fig. 8. It is worth noting the placement of two thermocouples for measuring the temperature in the flame, type $P_tR_h10\% - P_t(s),\ \Phi\ 6,\ L = 500\ mm, t_{max} = 1400^0C$, with the placement at a distance of 50 mm and 100 mm respectively from the fuel outlet section.

Fig.8. General view of the stand.

Fig. 10. Flame appearance 25% H2.

Fig. 11. Flame appearance 40% H2.

Table 1. Synthetic data of the experiments

No.	CH_4 flow (m^3)	H_2 flow (m^3)	H_2 / CH_4 (%)	Air flow (m^3)	t_1^* (°C)	t_2^* (°C)	CO_2^{**} (%)
1	1.0	0.2	17	10.5	768	907	9.2
2	1.5	0.5	25	16.4	-	928	6.4
3	1.5	1.0	40	17.8	-	986	5.2

*) temperatures at thermocouples T_1 and T_2, (Fig. 7); **) measurements at thermocouple T_2; they are for $O_2 = 3\%$.

Figures 9, 10, 11 show the appearance of the flames for the three situations specified by the data in Table 1, respectively the H_2/CH_4 ratios of 17% (Fig. 9), 25% (fFig. 10) and 40% (Fig. 11), respectively. The analysis of the images identifies by color, the combustion of hydrogen in the immediate area from the exit of the gas nozzles (flame with high transparency), and the combustion of methane for the rest of the flame length (reddish blue flame). During the testing period, no deviations from the combustion present in these figures were noted, this being without vibrations and shocks.

4. CONCLUSIONS

The paper presented the results of experimental tests of methane combustion mixed with hydrogen in proportions of 17%, 25% and 40%. To carry out these tests, it was necessary to create a stand that would allow the desired mixing, a stand equipped with a diffusive combustion burner, which included five gas jets, each framed by a concentric jet of accompanying air. The combustion tests showed perfect combustion, validating the developed burner concept, recommending the diffusive combustion technology as a safe and efficient one. The results obtained will be used to extend research for the combustion of the H_2/CH_4_4 mixture at values for H_2 above the 40% limit reached.

ABSTRACT
The growing demand for efficient energy storage and conversion systems has driven the exploration of advanced electrolytes, including ionic liquids (ILs), for improving hydrogen evolution reaction (HER) and performance of Zn-based batteries. In this study, we investigated the effects of five ILs - four newly synthesized choline-based ILs ([Ch][Sal], [Ch][Sac], [Ch][Ace], [Ch][Lac]) and one commercial IL ([Bmim][BF4]) - as additives to enhance electrolyte performance for both HER and Zn-ion batteries. Electrochemical measurements were conducted to evaluate their impact on HER efficiency and inhibition of Zn dendrite growth in Zn-ion batteries. The addition of ILs significantly shifted the HER onset potential to more positive values, increased the current density and influenced the Tafel´s slopes. In Zn-ion batteries, [Ch][Sac] demonstrated superior performance by stabilizing voltage and inhibiting dendrite growth, while [Ch][Sal] accelerated dendrite formation, leading to faster short-circuiting. These findings highlight the potential of specific ILs to optimize electrochemical processes and open up new possibilities for their application in advanced energy technologies.
Keywords: Ionic liquids, HER, Zn-ion batteries

1. INTRODUCTION

The growing global demand for sustainable and efficient energy solutions has encouraged significant research into the development of advanced materials and systems for energy storage and conversion. Among them, hydrogen evolution reaction (HER) and zinc-based batteries (zinc-air, zinc-ion batteries) have gained considerable attention due to their potential for renewable energy technologies. HER plays an important role in electrochemical water splitting, a key process for clean hydrogen production [1]. Zinc-based batteries are emerging as promising alternatives to lithium-ion batteries, offering safety, cost-efficiency and environmental benefits [2]. However, both systems face challenges that limit their widespread application.

The HER efficiency is often hindered by sluggish reaction kinetics, electrode degradation and limited stability under harsh operating conditions [1]. Similarly, all zinc-based batteries suffer from issues such as dendrite formation, side reactions and insufficient cycling stability, primarily due to the limitations of conventional aqueous electrolytes. The main problem with zinc-based batteries is the formation and growth of dendrites at the anode, which leads to short circuits and battery failure [2]. Addressing these challenges requires innovative approaches in the development of electrolytes that can simultaneously enhance the performance, stability and safety of these systems.

In this sense, ionic liquids (ILs) are pomising electrolyte additives for the activation of HER and the inhibition of dendrite growth in zinc-based batteries. With their unique physicochemical properties such as high ionic conductivity, wide electrochemical stability windows and tunable viscosity, ILs have proven to be promising candidates for advanced electrolyte formulations. The application of ILs as electrolyte additives for HER and zinc batteries is still at an early stage of investigation. 1-butyl-3-ethylimidazolium bromide ([Beim][Br]) and 1,3-diethylimidazolium bromide ([Eeim][Br]) were first investigated as electrolyte additives for HER [3]. In this study, the addition of 2 vol% [Beim][Br] in 8M KOH electrolyte enganced HER, increased the current density and improved the efficiency of alkaline electrolysis compared to the pure 8M KOH electrolyte without the addition of ILs. In another research, HER was investigated in an 8M KOH electrolyte containing small amounts of three salicylate-based ILs: 1-butyl-3-methylimidazolium salicylate ([Bmim][Sal]), 1-(3-hydroxylpropyl)-3-methylimidazolium salicylate ([C3OHmim][Sal]), and imidazolium salicylate ([Im][Sal]) [4]. The addition of salicylate-based ILs resulted in higher current densities and enhanced HER. Furthermore, 1-butyl-3-methylimidazolium tetrafluoroborate ([Bmim][BF4]) and 1-butyl-3-methylimidazolium hexafluorophosphate ([Bmim][PF6]) have been studied as electrolytes for water electrolysis on various electrode materials [5,6]. (Optimal hydrogen production rates were achieved with solutions containing 10 vol% of these ILs, which was attributed to the enhanced ionic conductivity of the electrolyte.

The different ILs were used as electrolyte additives to suppress dendrite growth in zinc-based batteries. For example, [BMIm][OTF] with a very low melting point was used as an electrolyte additive in ZIBs, which in this case operate at a low temperature of -30°C [7]. The mixture of [EMIm][BF4] and Zn(BF4)2 has also been used as an electrolyte for effective dendrite inhibition [8]. It should be emphasised that the application of ILs as electrolyte additives for differente

electrochemical devices is still at an early stage of investigation.

In this work, we investigated for the first time the application of five ILs as electrolyte additives for HERs and ZIBs; two commercially available ILs (1-butyl-3-methylimidazolium tetrafluoroborate [Bmim][BF4] and choline acetate [Ch][Ace]) and three newly synthesised ones: choline-based iLs (choline salicylate [Ch][Sal], choline saccharinate [Ch][Sac] and choline lactate [Ch][Lac]).

2. MATERIALS AND METHODS

2.1. Synthesis of ILs and electrolyte preparation

The syntheses of ILs were performed according the procedure described in references: [9,10,11]. These ILs are:

- 1-butyl-3-methylimidazolium tetrafluoroborate [Bmim][BF4] (commertial, Acros Organics),
- choline salicylate [Ch][Sal],
- choline saccharinate [Ch][Sac],
- choline acetate [Ch][Ace] (commertial, Acros Organics) and
- choline lactate [Ch][Lac].

1M Na_2SO_4 for HER and 1M $ZnSO_4$ for Zn-ion batteries were used as the base electrolytes. To study the impact of various ionic liquids, each was dissolved in 1M Na_2SO_4 or in 1M $ZnSO_4$ solution at a concentration of 5 g L^{-1}. The resulting electrolyte solutions were labeled with abbreviations representing the respective ionic liquids to facilitate identification and comparison during the analyses.

2.2. Electrochemical measurements

All electrochemical measurements were performed in three- and two-electrode configurations. For all measurements BioLogic SP-150 potentiostat was used and all measurements were conducted at room temperature.

HER was examined in neutral 1M Na_2SO_4 electrolyte, without and with addition of ILs. Measurements was perfomed in three-celectrode configuration with Pt as counter electrode, Ag/AgCl as reference electrode and Au as working electrode (diameter of Au electrode was 0.16 cm). Linear sweep voltammetry (LSV) was performed in potential range from -0.5 V to -2 V vs. Ag/AgCl, with scan rate of 20 mV s^{-1}.

ZIB and dendrite formation was investigated in 1M $ZnSO_4$ electrolyte without and with addition of ILs. For this investigation measurements was performed in two-electrode configuration. The setup included two parallel Zn plates, each with a surface area of 0.25 cm^2, separated by a 1 mm gap to ensure a uniform distance. The prepared electrodes were immersed in glass vials containing 100 µL of electrolyte. The plating and stripping processes (i.e. dendrite growth) were investigated using the Galvanostatic Cycling with Potential Limitation (GCPL) technique.

3. RESULTS AND DISCUSSION

In the first step of this inevstigation, HER was analysed at an Au electrode in pH-neutral 1M Na_2SO_4 electrolyte, without and with the addition of ILs. As shown in Fig. 1, the hydrogen evolution reaction was influenced by the ILs and all electrochemical parameters are listed in Table 1.

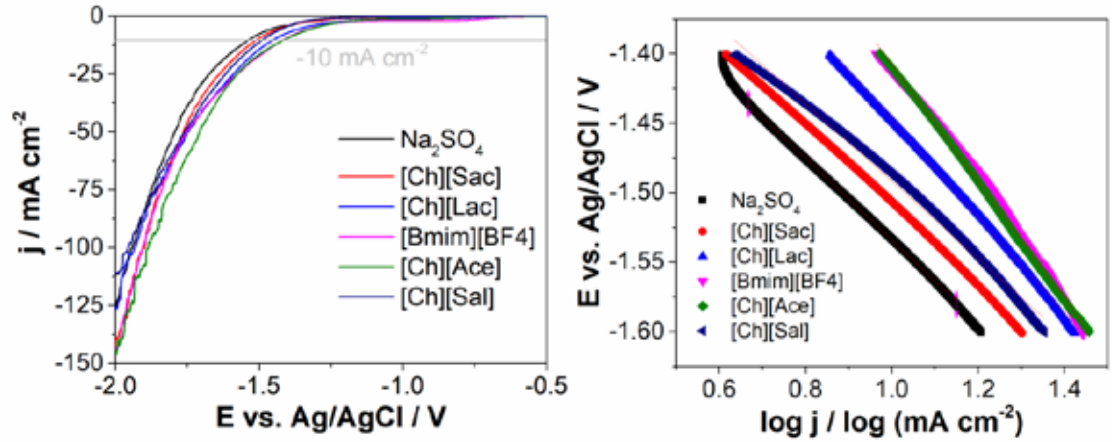

Fig. 1. LSV curves (left) and Tafels plots (right) obtained in all investigated electrolytes

.

The addition of ILs to the Na_2SO_4 electrolyte shifts the onset potential of hydrogen evolution to more positive values compared to the onset potential obtained in pure 1M Na_2SO_4. The onset potentials were evaluated at -10 mA cm^{-2}. The onset potential obtained in 1M Na_2SO_4 electrolyte showed the most negative value (-1.54 V vs. Ag/AgCl). On the other

side, in Na_2SO_4 electrolyte with addition of ILs, the onset potential moves to positive values and follows the order: [Ch][Sac] (-1.51 V), [Ch][Sal] (-1.49 V), [Ch][Lac] (-1.46 V), [Ch][Ace] and [Bmim][BF4] showed almost the same value of -1.42 V.

Table 1. Electrochemical parameters evaluated for HER.

Electrolyte	E_{onset} @ -10 mA cm-2 / V	j@-2 V / mA cm^{-2}	Tafel's slope / mV dec^{-1}
1M Na_2SO_4	-1.54	-122	-294
[Ch][Sac]	-1.51	-140	-298
[Ch][Sal]	-1.49	-112	-278
[Ch][Lac]	-1.46	-126	-347
[Ch][Ace]	-1.42	-146	-422
[Bmim][BF4]	-1.42	-143	-418

Furthermore, the addition of ILs additives showed a significant influence on the current density (j). The j value (at -2 V vs Ag/AgCl) value was lowest for [Ch][Sal], followed by Na_2SO_4 electrolyte without addition of ILs (Table 1). On the other side, the j values increase with the addition of ILs to the electrolyte. Additionally, to the HER investigation, a Tafel analysis was performed. As can be seen from Table 1 and Figure 1, the Tafel jumps vary between the electrolytes. A higher value of the Tafel´s slope was evaluated for the electrolyte [Ch][Ace], while the lowest value was determined for the electrolyte [Ch][Sal].

These values demonstrate the beneficial impact of the addition of ILs to the electrolyte on HER efficiency. We assume that the addition of ILs changes the conductivity of the electrolyte, which may be favourable for HER.

In addition to this research, a 1M $ZnSO_4$ solution with added ILs was investigated as a potential electrolyte for Zn-ion batteries. The study aimed to address the main issue of zinc dendrite growth, which is a major problem in all types of Zn batteries. The plating/stripping processes and dendrite formation were investigated using the Galvanostatic Cycling with Potential Limitation (GCPL) technique at a current density of 10 mA cm^{-2}, 2.5 mAh cm^{-2}, Figure 2.

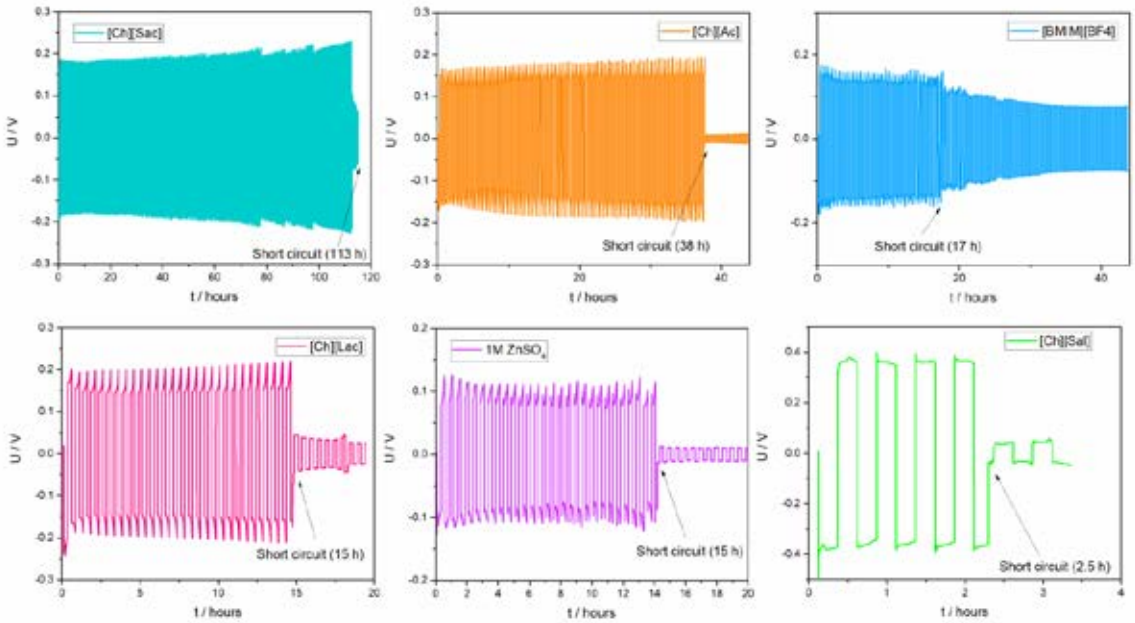

Fig. 2. Zn plating/stripping performances at 10 mA cm^{-2}, 2.5 mAh cm^{-2}.

The stability of the overpotential (Fig. 2) was highest for the [Ch][Sac]-based electrolyte. In contrast, the other IL-based electrolytes exhibited deviations of the overpotential from their initial values over time. As the number of cycles increased, the overpotential gradually fade, which may be attributed to rapid growth of the Zn dendrites on the electrode surface. Figure 2 also shows that the short circuit between the two Zn electrodes occurred faster in the $ZnSO_4$ electrolyte containing [Ch][Sal]. This suggests that the [Ch][Sal]-based electrolyte accelerates dendrite growth, while [Ch][Sac] inhibits dendrite growth.

A notable difference between the electrolytes was observed in short-circuiting behaviour (i.e. dendrite growth): [Ch][Sac] effectively inhibited dendrite formation, while [Ch][Sal] significantly accelerated dendrite growth. In the case of the ionic liquids [Ch][Sac], the [Sac] anion acts as a traffic aid for Zn^{2+} and as a passive layer on the electrode surface and therefore inhibits dendrite formation [12].

4. CONCLUSIONS

This study demonstrated the dual functionality of ILs in enhancing HER and inhibiting the growth of zinc dendrites in Zn-based batteries. The addition of ILs to the electrolyte shifted the initial HER onset potential to more positive values, improved the current density and affected the Tafel slopes, confirming their ability to enhance HER efficiency. Among the investigated ILs, [Ch][Sac] exhibited superior performance for Zn-ion batteries by effectively stabilizing the overpotential and suppressing dendrite growth due to its unique interaction with Zn ions. In contrast, [Ch][Sal] promoted rapid dendrite formation, highlighting the critical role of IL composition in determining electrolyte behaviour. These results underline the potential of tailored ILs as versatile additives to improve both the HER efficiency and stability of Zn-based batteries. Further research of IL-electrolyte interactions is essential to optimize these systems for practical applications in sustainable energy technologies.

ABSTRACT
The hydrogen evolution reaction (HER), the oxygen evolution reaction (OER) and the oxygen reduction reaction (ORR) are essential for renewable energy applications like water splitting, fuel cells and metal-air batteries. This study explores the synergistic effects of combining V_2O_5 electrode material with 1-butyl-3-methylimidazolium salicylate ([Bmim][Sal]) as an additive to an ionic liquid electrolyte. Electrochemical measurements in 0.1 M KOH, with and without [Bmim][Sal], reveal enhanced performance for HER and OER. The addition of [Bmim][Sal] shifts HER and OER onset potentials to more favourable values, indicating improved catalytic activity. Furthermore, ORR studies demonstrate an increased current density and a transition to a direct four-electron pathway in the presence of [Bmim][Sal]. These findings highlight the potential of [Bmim][Sal] as a promising electrolyte additive to optimize the electrochemical performance of V_2O_5 electrodes for sustainable energy technologies.
Keywords: HER, OER, ORR, V_2O_5, ionic liquids.

1. INTRODUCTION

The hydrogen evolution reaction (HER), the oxygen evolution reaction (OER) and the oxygen reduction reaction (ORR) are critical electrochemical processes in renewable energy technologies such as water splitting, fuel cells and metal-air batteries [1]. HER facilitates hydrogen production and provides a clean and sustainable energy carrier, while OER is essential for the production of oxygen in water splitting, which is often hindered by slow kinetics and high overpotential. Similarly, ORR plays an important role in energy conversion in fuel cells and requires efficient and durable catalysts to ensure high performance. ORR and OER are crucial electrochemical processes in rechargeable metal-air batteries (such as Zn-air, Al-air, etc.). However, all these reactions are very slow, which significantly limits the application of electrochemical devices. As a result, current research is focussed on the development of new materials (electrocatalysts) and advanced electrolytes that can improve the efficiency and kinetics of these reactions.

Carbon materials occupy a significant place in the field of catalysis. It can be used as a support, but also it will show good catalytic properties by doping, functionalization or introduction of defracts [2]. Materials such as graphene, carbon nanotubes and porous carbon structures have been extensively studied for their ability to enhance catalytic performance when doped with heteroatoms (e.g. N, S or P) or functionalized with transition metal nanoparticles. Furthermore, various metal oxides have gained significant attention as electrocatalysts for these reactions due to their unique electronic structures, high stability and tunable catalytic properties. In the last years, the use of V_2O_5 for applications in electrocatalysis for HER, OER and ORR has gained considerable importance. V_2O_5 materials exhibit high OER performance due to the multivalent states of V and the abundant V=O groups, which enhance the active intermediates (OOH*) by modulating the V valence electron structure and stabilizing the oxygen sites [3]. On the other side, their intrinsic HER performance remains limited due to the weak H* adsorption at the V centre, hindering the rate-determining step at the electrode–electrolyte interface [4]. Beside, HER and OER, V_2O_5 was also used for ORR. In this context, ORR on V_2O_5 electrode materials predominantly follows a two-electron pathway leading to the generation of hydrogen peroxide [5].

Besides the development of new electrode materials, the design of novel electrolytes is another approach to improving electrochemical performance. The most popular approach is application of ionic liquids (ILs) as new, versatile electrolytes [6]. ILs are organic salts that remain in a liquid state at room temperature and consist of large organic cations and inorganic or organic anions. They are used as electrolytes in electrochemistry due to their high ionic conductivity, their wide electrochemical potential window and their stability and are therefore suitable for various applications. However, application of ILs as electrolytes or electrolyte additives is still at an early stage of research.

In this paper, we combined V_2O_5 electrode material with 1-butyl-3-methylimidazolium salycilate ([Bmim][Sal]) as an electrolyte additive to improve HER, OER and ORR.

2. MATERIALS AND METHODS

2.1. 1-butyl-3-methylimidazolium salycilate synthesis and electrolyte preparation

1-butyl-3-methylimidazolium salycilate (abbrev. [Bmim][Sal]) was prepared according the procedure described in reference [7]. 0.1M KOH was used as electrolyte, without and with addition of [Bmim][Sal] in concentration of 1%. 0.1M KOH with addition of IL was noted as 0.1M KOH+ [Bmim][Sal].

2.2. Electrode preparation and electrochemical measurements

The working electrode was prepared by mixing V_2O_5 (purity 99.6%, Sigma Aldrich) with carbon black (Vulcan, Cabot Corporation) in a mass ratio of 1:0.5. The resulting mixture was dispersed in a binder solution and sonicated for 2 hours at room temperature. The binder solution was consised of 0.2% chitosan in 1% aqueous acetic acid solution [8]. The reason for using this binder solution instead of the most commonly used Nafion is the negligible toxicity of chitosan. A 5 µL aliquot of the dispersed solution was applied to a rotating disc electrode made of glassy carbon (surface area: 0.07 cm^2) and dried under an IR lamp.

All electrochemical measurements were performed using a BioLogic SP-150 instrument at room temperature. The electrochemical cell consisted of a platinum counter electrode, an SCE reference electrode and a modified glassy carbon rotating disc electrode as the working electrode (as described above). All potentials were related to the reversible hydrogen electrode (RHE) using the formula $E_{RHE}=E_{SCE}+0.242+0.059pH$. For HER and OER studies, linear sweep voltammetry (LSV) was recorded at a scan rate of 50 mV s^{-1}. For ORR, cyclic voltammetry (in N_2- and O_2-saturated electrolytes) was recorded at a scan rate of 50 mV s^{-1} within the potential range of 1.1 to 0.27 V versus RHE. LSV was performed at different rotation speeds (from 500 to 2000 rpm) with a scan rate of 50 mV s^{-1} within the potential range of 1 to 0.27 V vs. RHE.

3. RESULTS AND DISCUSSION

The electrocatalytic properties of V_2O_5 in a 0.1 M KOH solution with the addition of [Bmim][Sal] for HER and OER were first explored. Fig. 1 represents LSV curves for HER (left) and OER (right) in 0.1M KOH without and with addition of [Bmim][Sal] ionic liquid.

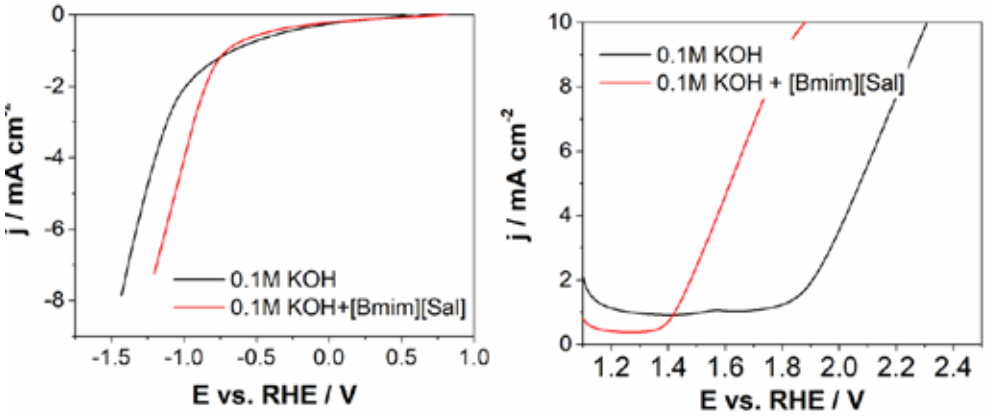

Fig. 1. LSV curves of V_2O_5 in pure 0.1M KOH and 0.1M KOH with addition of [Bmim][Sal] for HER (left) and OER (right).

As can be seen form Figure 1, HER and OER in pure 0.1M KOH (without addition) started at -1.1 V and 1.9 V, respectively. These results showed that V_2O_5 electrode material is active for HER and OER. In comparison with literature data, for example for cobalt-doped carbon OER starts at around 1.6 V vs. RHE [9] implying that V_2O_5 in pure 0.1M KOH electrolyte has suitable electrocatalytical activity towards OER. On the other side, electrocatalytical activity towards HER is slighty lower when compare to carbon-based materias (where HER starts arund -0.5 V vs. RHE depending on electrolyte concentration and material properties).

On the other side, addition of ionic liquid [Bmim][Sal] showed positive impact on both HER and OER. The onset potential of HER move to positive values (-0.8 V), while OER potential moves from 1.9 V to 1.4 V vs. RHE.

ORR was investigated by CV and LSV in N_2 and O_2 saturated electrolyte, without and with addition of [Bmim][Sal]. As can be seen in Figure 2, the V_2O_5 electrode material showed no oxido-reduction peaks in N_2-saturated electrolytes. On the other side, in electrolytes saturated with O_2, oxygen reduction peaks occur in both electrolytes. These results clearly show that the V_2O_5 electrode material is active for oxygen reduction.

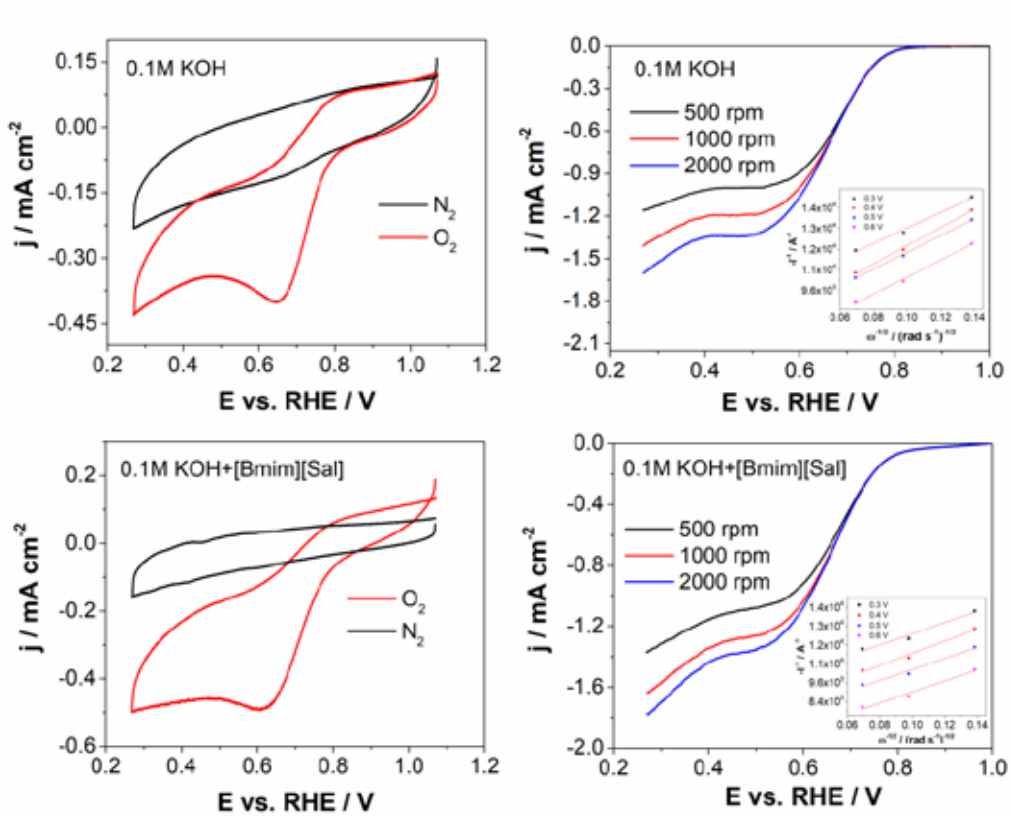

Fig. 2. CVs and LSVs with inserted Kouteky-Levich plots for V_2O_5 electrocatalysts in 0.1M KOH and 0.1M KOH electrolyte with addition of [Bmim][Sal].

No significant differences were found between the two electrolytes with regard to the initial and peak potential of oxygen reduction. The oxygen reduction starts in both cases begins at 0.85 V vs. RHE, with the reduction peak occurring around 0.75 V vs. RHE. However, the current density of the reduction peak is higher in the electrolyte containing [Bmim][Sal]. This increase could be attributed to the increased conductivity of the electrolyte and increased solubility of O_2 in the electrolyte with the addition of [Bmim][Sal].

In order to get insight into the kinetics of oxygen reduction at V_2O_5 electrodes in two investigated electrolytes. The Koutecky-Levich plots are represented in Figure 2 (inset diagrams). Details of the Koutecky-Levich analysis can be found in reference [9]. The number of exchange electrons during the ORR can be determined from the slope of the Koutecky-Levich plot. It is known that the ORR can occur via two pathways: the direct four-electron pathway (which is favourable in electrochemical devices) and the indirect two-step two-electron electro pathway (which is unfavourable in electrochemical devices). In the case of a pure 0.1 M electrolyte, the ORR at the V_2O_5 electrode occurred via the two-step two-electron pathway, which is in agreement with the literature. The average number of exchange electrons in the potential range of 0.6 to 0.3 V vs. RHE was calculated to be 2.4. In contrast, the Koutecky-Levich analysis for the electrolyte with [Bmim][Sal] showed that the average number of exchange electrons in the same potential range is 3.7, which corresponds to the direct four-electron pathway. It can be concluded that the addition of IL (i.e. [Bmim][Sal]) has no influence on the electrochemical parameters, such as the onset ponetial, but this addition has an influence on the oxygen reduction pathway.

4. CONCLUSIONS

The integration of [Bmim][Sal] with V_2O_5 electrodes significantly improves their electrochemical performance for her, oer and orr. the ionic liquid reduces the overpotentials of her and oer and promotes the favourable four-electron pathway in ORR, demonstrating its ability to improve efficiency and kinetics. This approach underlines the potential of ionic liquid additives to revolutionize energy conversion processes and open a pathway to more efficient and sustainable renewable energy technologies. Further studies on optimization and long-term stability are recommended to advance practical applications.

ABSTRACT

With the advancement of industry and technology, addressing and solving the increasing energy demand has become one of the most critical challenges for humanity. To meet this demand, current chemical process technologies have shifted their focus toward hydrogen-based energy systems where hydrogen serves as an energy carrier, transferring energy from various sources to practical applications. This study involves the synthesis of metal-organic frameworks (MOFs) to be used as adsorbents for hydrogen purification applications. Among the thousands of MOF varieties, MOF-74 was selected for this project due to its high surface area, pore volume, and thermal stability. MOF-74 was synthesized in various forms by modifying temperature and duration parameters using the solvothermal method, followed by purification processes. Characterization was conducted using XRD, FT-IR, and SEM analyses. The results from XRD and SEM analyses confirmed the formation of the Zn-MOF-74 structure. Furthermore, the carbondioxide (CO_2) adsorption capacities of the MOFs were examined, with the highest CO_2 adsorption capacity observed at 120°C.

Keywords: MOF, Solvothermal Method, Adsorption

1. INTRODUCTION

The increasing industrialization and technological advancements have made the rising energy demand a significant issue. To address this demand and reduce greenhouse gas emissions, chemical process technologies have shifted their focus towards hydrogen energy. Despite being the most abundant element in the universe, hydrogen gas is produced from hydrogen-containing raw materials such as hydrocarbons, biomass, and water. For industrial applications, hydrogen needs to be purified. This purification process eliminates impurities such as carbon dioxide in hydrogen gas, enabling the production of high-purity hydrogen required for applications like fuel cells [1,2].

Commercial hydrogen purification methods include pressure swing adsorption (PSA) [1,2]. Traditional adsorbents include organic materials like activated carbon and inorganic materials like zeolites. While activated carbon exhibits high adsorption capacity, it has an irregular structure. On the other hand, zeolites have a regular structure but are limited in terms of stability and diversity [3,4]. Metal-organic frameworks (MOFs) are emerging porous materials composed of metal ions or metal clusters coordinated with organic linkers. MOFs stand out for their applications in adsorption, catalysis, sensing, drug delivery, and renewable energy. They offer advantages such as high surface area, tunable porosity, good selectivity, chemical stability, and flexible structures, allowing performance customization. These materials have significant potential in adsorption processes [4,5].

In this study, Zn-MOF-74 was synthesised by the solvothermal method at different temperatures (100, 110 and 120 °C) to investigate the effect of synthesis temperture and characterized with XRD, FTIR and SEM. CO_2 adsorption tests were carried out at 25 °C in a fixed bed reactor to determine the CO_2 adsorption capacity.

2. MATERIALS AND METHODS

2.1. Synthesis MOF-74

In this study, the synthesis process was carried out using the solvothermal method. 1.065 g of zinc nitrate hexahydrate (Carlo Erba Regents) and 0.234 g of 2,5-dihydroxyterephthalic acid (Abcr, 97%) were dissolved in 22.5 ml of dimethylformamide (DMF, Carlo Erba Regents, 99.9%). The mixture was subjected to sonication for 30 minutes. The mixture was then placed in a Teflon-lined autoclave reactor and heated in an oven for 24 hours. The obtained sample was washed with DMF and methanol (Sigma Aldrich, 99.7%) using vacuum filtration. Afterward, the sample was washed twice with methanol by centrifuging at 6000 rpm for 45 minutes at 24-hour intervals. Following the washing steps, it was dried in an oven at 105°C for 24 hours. Synthesized MOF labeld as Zn-T-24 where T represents the synthesis temperature.

2.2. Characterization

X-ray diffraction (XRD) analysis of the crystal structure was performed using a Rigaku XRD MiniFlex 600 device operating with Cu-Kα, at a scanning angle of 0.02°, a scan rate of 4°/min, and in the 2θ range of 5°–45°. The Fourier Transform

Infrared Spectroscopy (FTIR) analysis was conducted using a Thermo Scientific Nicolet IS10 FTIR in the scanning range of 525–4000 cm^{-1}, with a scanning speed of 64 and a resolution of 4 cm^{-1}. Surface morphology was analyzed using a ZEISS-SUPRA 50 VP scanning electron microscope (SEM). Energy Dispersive X-ray Spectroscopy (EDS) analysis was carried out to determine the elemental composition of Zn-MOF-74.

2.3. Carbon Dioxide Adsorption

The adsorption process was conducted using a stainless-steel tubular continuous-flow reactor with a length of 45 cm, an inner diameter of 0.8 mm, and an outer diameter of 1.2 mm. Zn-MOF-74 was fixed in place with two layers of glass wool, forming a fixed bed. For activity studies conducted using the continuous-flow tubular reactor, pure carbon dioxide was used at a flow rate of 0.2 L/min for 40 minutes per experiment. Before each experiment, Zn-MOF-74 was activated in an oven at 100°C for 1 hour. The adsorption capacity of the adsorbent can be calculated using the following equation:

$$CO_2\ Adsorption\ capacity\ \left(\frac{mmol}{g}\right) = \left(\frac{W_{before\ CO_2\ adsorption} - W_{after\ CO_2\ adsroption}}{W_{adsorbent}\ x\ MW_{CO_2}}\right) x\ 1000 \quad (1)$$

3. RESULTS AND DISCUSSION

Experiments were conducted at three different temperatures, maintaining a constant synthesis duration of 24 hours. SEM images of the synthesized structures are presented in Fig. 1. (a) synthesis at 100°C, (b) 110°C, and (c) to 120°C. Examination of the SEM images revealed that, although the Zn-MOF-74 structure formed at 100°C and 110°C, the temperatures were below the appropriate synthesis temperature, leading to the presence of structures that had not yet fully formed. In contrast, the morphological structure observed in the SEM images of Fig. 1., corresponding to synthesis at 120°C, aligns with the Zn-MOF-74 structure reported in the literature**.**

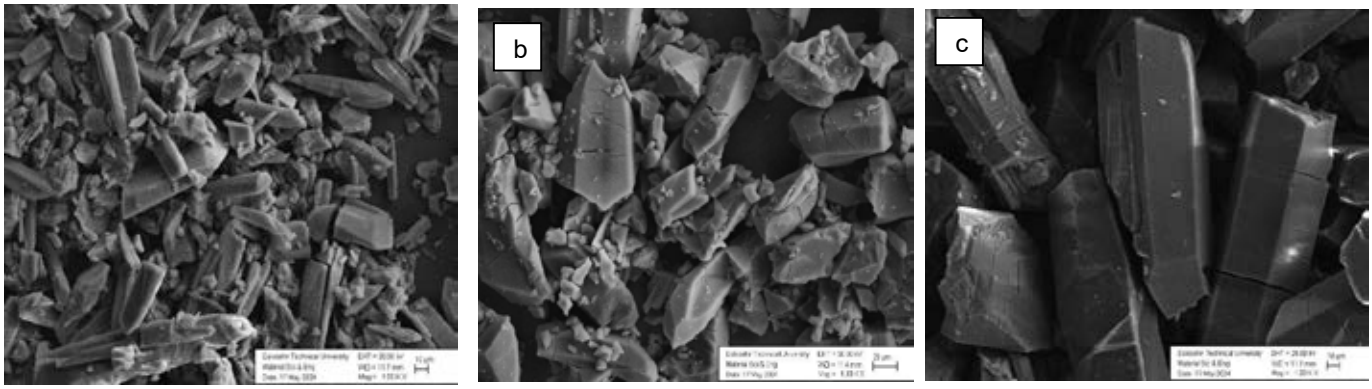

Fig. 1. SEM images for MOF-74 synthesized at different temperature, (a) 100°C (b) 110°C (c) 120°C

FTIR spectras of synthesized MOFs are given on Fig. 2. Examination of these spectra reveals that the region between 3000 cm^{-1} and 3500 cm^{-1} corresponds to the stretching and vibration region of RNH_2 groups. The peak observed around 1500 cm^{-1} corresponds to the stretching and vibration of CH_2 groups. These spectra indicate that DMF has not been completely removed.

Fig. 3. presents the XRD patterns of three different syntheses of Zn-MOF-74 conducted at 120°C, 110°C, and 100°C, each with a synthesis duration of 24 hours. Peaks marked with a ★ symbol indicate the presence of Zn-MOF-74. The small peaks observed in the Zn-120-24 pattern confirm the existence of MOFs. These peaks are not observed in the Zn-100-24 and Zn-110-24 patterns. The synthesis conducted at 120°C yielded a pattern most consistent with the literature.

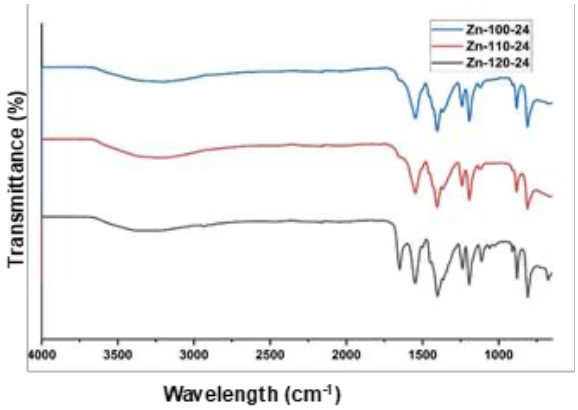

Fig. 2. FTIR spectras of MOF-74

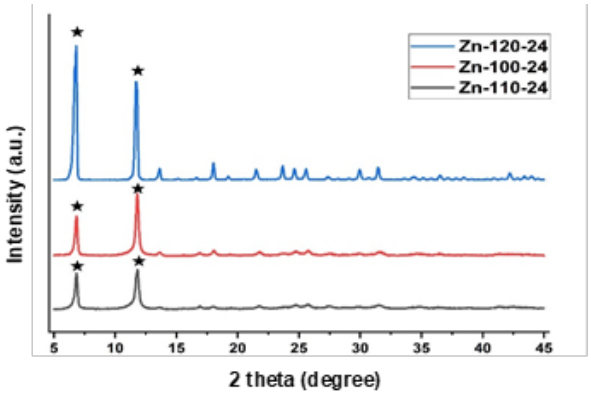

Fig. 3. XRD patterns of MOF-74

CO_2 adsorption capacities of Zn-MOF-74 structures with synthesized different temperatures were determined. The calculated values are presented in Table 1. As a result of incremental temperature increases of 10°C, it was found that the adsorption capacity increased by 0.19 mmol/g when the synthesis temperature was raised from 100°C to 110°C, and by 0.81 mmol/g when comparing 110°C to 120°C. The highest CO_2 adsorption capacity obtained with Zn-120-24 as 2.33 mmol/g and these result inlined with literature data [5,6]

Table 1. The adsorption capacities of Zn-MOF-74 synthesized at different temperatures for 24 hours

Synthesis Temperature (°C)	CO_2 adsorption capacities (mmol/g)
100	1.33
110	1.52
120	2.33

4. CONCLUSIONS

In this study, the effect of synthesis temperature on the structural and adsorption properties of Zn-MOF-74 was systematically investigated. Three different temperatures (100°C, 110°C, and 120°C) were evaluated while maintaining a constant synthesis duration of 24 hours. SEM analysis revealed that although the Zn-MOF-74 structure began to form at 100°C and 110°C, the structures were not fully developed at these temperatures. In contrast, the morphology observed at 120°C corresponded well with the Zn-MOF-74 structure reported in the literature, indicating optimal synthesis conditions. XRD analysis indicated that the characteristic peaks of Zn-MOF-74 were more clearly observed at 120°C, aligning well with literature data. In comparison, smaller and less distinct peaks were observed at 100°C and 110°C. CO_2 adsorption measurements highlighted the effect of synthesis temperature on adsorption capacity. At 120°C, the maximum adsorption capacity was determined to be 2.33 mmol/g. As observed in other characterizations, the highest

CO_2 adsorption capacity was also achieved at 120°C. In future studies, Brunauer-Emmett-Teller (BET) analysis will be conducted to further investigate the surface area and porosity characteristics of the material.

ABSTRACT
This paper provides a detailed analysis of a stand-alone photovoltaic (PV) system implemented in Constanta, Romania, designed to deliver sustainable energy for residential use. Utilizing PVsyst software, the system's design and performance were evaluated over one year. The system comprises a 5.75 kWp PV array, 48 lead-acid batteries (12V, 1200 Ah total), and an MPPT-equipped inverter. The simulation results show an annual energy production of 8.13 MWh and a specific yield of 1414 kWh/kWp/year. Key performance metrics include a performance ratio (PR) of 40.71% and a solar fraction (SF) of 98.46%, indicating a high level of solar energy utilization.
The study highlights that significant energy losses are attributed to storage inefficiencies and environmental factors. Economic analysis demonstrates the potential for long-term cost savings and energy independence, despite high initial investment costs. Findings suggest that optimizing storage capacity and reducing system losses are critical to enhancing overall efficiency and reliability.
This research contributes to the understanding of deploying solar technologies in high-insolation regions and underscores the need for customized energy solutions tailored to regional characteristics. Future work will focus on integrating advanced storage technologies and intelligent energy management systems to maximize performance and economic benefits. The results provide valuable insights for policymakers and stakeholders aiming to advance renewable energy adoption and reduce reliance on conventional power sources in similar geographic settings.

Keywords: Stand-alone photovoltaic system, Solar energy, Renewable energy, Energy storage, Performance ratio.

1. INTRODUCTION

The global demand for sustainable and renewable energy solutions has been on a significant rise, driven by the urgent need to mitigate climate change, reduce greenhouse gas emissions, and enhance energy security. Among the various renewable energy sources, solar power stands out as a particularly attractive option due to its abundance, sustainability, and decreasing cost of technology [1]. The sun provides an inexhaustible source of energy, making solar power a critical component in the transition towards greener energy systems. As countries worldwide strive to reduce their carbon footprints, the deployment of solar photovoltaic (PV) systems has become increasingly widespread [2].
In this context, regions with substantial sunlight exposure are ideally positioned to harness solar energy efficiently. Constanta, a city located on the Black Sea coast in Romania, is one such region that benefits from a high solar irradiance, making it an excellent location for implementing solar power systems [3]. This geographic advantage provides a unique opportunity to explore the effectiveness and viability of stand-alone solar power systems in meeting local energy demands.
This study focuses on evaluating the performance of a stand-alone solar power system installed in Constanta to cater to the energy needs of a residential setup. By examining key metrics such as system performance, energy savings, cost-effectiveness, and reliability, this research aims to provide comprehensive insights into the operational viability of solar installations in similar geographic locations. The findings from this study not only contribute to the understanding of solar energy's potential in residential applications but also offer valuable data for future projects aiming to optimize the integration of solar technologies in urban and semi-urban environments [4].
Furthermore, the study addresses the technical challenges and economic considerations associated with stand-alone solar systems, including storage solutions, load management, and system sizing. Understanding these factors is crucial for developing efficient solar installations that can operate independently of the grid while maximizing energy output and minimizing costs. As the world moves towards a more sustainable energy future, the results of this study could play a vital role in shaping energy policies and investment strategies in solar technologies for regions with similar solar potential to Constanta [5].

2. SYSTEM CONFIGURATION

The stand-alone solar system in Constanta was designed with the following specifications: Location: Constanta, Romania (Latitude 44.22° N, Longitude 28.63° E, Altitude 5 m). PV Array: Consists of 23 PV modules, model 8.250MSGB, with a total nominal power of 5.75 kWp. The modules are mounted with a tilt of 30° and azimuth of 0° to optimize solar exposure. Battery Storage: Comprises 48 units of lead-acid batteries (12V, 100 Ah each) configured to provide a total storage capacity of 48 V / 1200 Ah. Controller and Converter: Utilizes a Universal controller with MPPT (Maximum Power Point Tracking) technology, ensuring high conversion efficiencies (97% maximum and 95% European

efficiency). Fig. 1. Illustrates the flow of energy in a PV system, showing the connections between the PV array, backup generator, batteries, and the user load, with a regulator managing the energy distribution and battery charging/discharging processes.

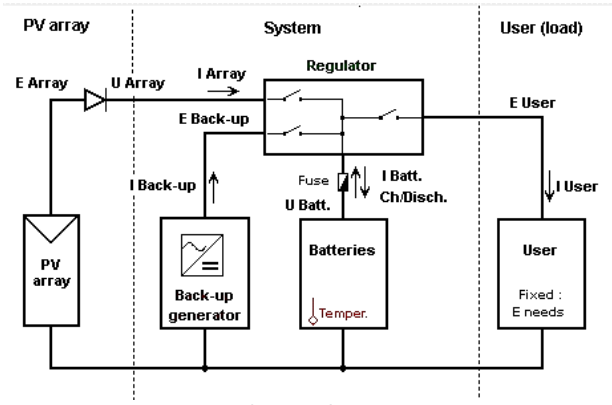

Fig. 1. Overall System Diagram

3. SIMULATION PARAMETERS AND METHODS

The PVsyst software was used to simulate the system's performance over a year, accounting for local meteorological data and specific load requirements. Key parameters such as global horizontal irradiation, module temperature, and load profiles were integrated into the simulation to derive accurate energy production and consumption metrics [6].

Table 1. presents monthly data on global and diffuse irradiance, temperature, and wind velocity, showing seasonal variations with peak solar irradiance and temperatures in the summer months, while wind velocity remains relatively consistent throughout the year [7].

Table 1. Metrological data

Month	Global Irradiance (kWh/m²/month)	Diffuse Irradiance (kWh/m²/month)	Temperature (°C)
January	43.2	19.3	-1.0
February	69.6	35.1	1.5
March	110.0	51.3	6.7
April	142.5	58.1	11.8
May	181.5	75.2	17.9
June	195.9	81.8	21.8
July	203.8	82.7	23.7
August	178.3	69.4	23.1
September	125.1	57.2	17.1
October	85.0	37.5	11.9
November	45.9	24.9	5.6
December	34.7	20.1	0.4
Year	**1415.5**	**610.6**	**11.7**

Table 2. Summarizes household energy consumption by detailing the power usage, daily operational hours, and daily energy consumption of various appliances, including lighting, electronics, domestic appliances, refrigeration, washers, ventilation, and standby devices.

Table 2. House hold load

Appliance	Power (W)	Daily Use (h/day)	Daily Energy (Wh/day)	Notes
Lamps (LED)	10	6.0	600	10 lamps using 10W each, used for 6 hours daily.
TV / PC / Mobile	100	6.0	1200	2 devices using 100W each, used for 6 hours daily.
Domestic appliances	500	6.0	3000	1 appliance using 500W, used for 6 hours daily.
Fridge / Deep-freeze	0.80	24.0	1598	2 units using 0.80 kWh daily, continuously running.
Dish & Cloth-washers	1000	2.0	2000	1 unit using 1000W, used for 2 hours daily.
Ventilation	1000	24.0	2400	1 unit using 1000W, continuously running.
Stand-by consumers	6	24.0	144	Standby consumption, continuous use.

4. RESULTS AND DISCUSSIONS

Fig. 2. Shows the relationship between the installed PV power and the probability of loss of load (PLOL) for different battery capacities, illustrating how increased battery capacity reduces the required PV power to achieve a specific PLOL. Fig. 3. Shows the average daily state of charge (SOC) of a battery throughout the year, indicating higher charge levels from January to October and significantly lower levels from November to December.

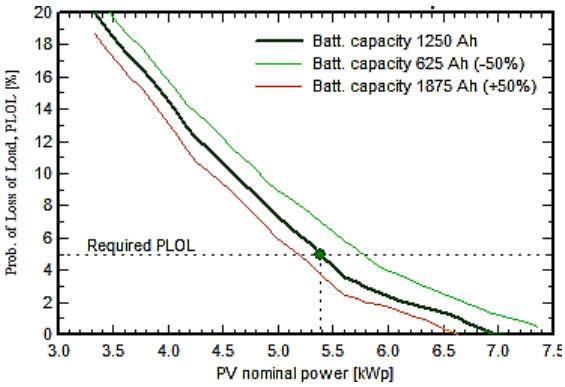

Fig. 2. PLOL as function of the installed PV

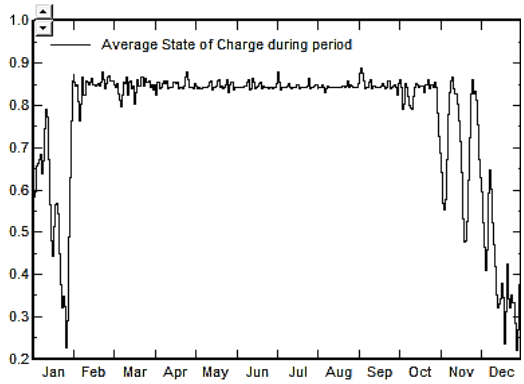

Fig. 3. State of charge daily Distribution

Fig. 4 shows the distribution of effective power output from a solar array throughout the year, with most frequent outputs occurring between 1.5 and 4 kW. Fig. 5. Fig. 4. Array power distribution

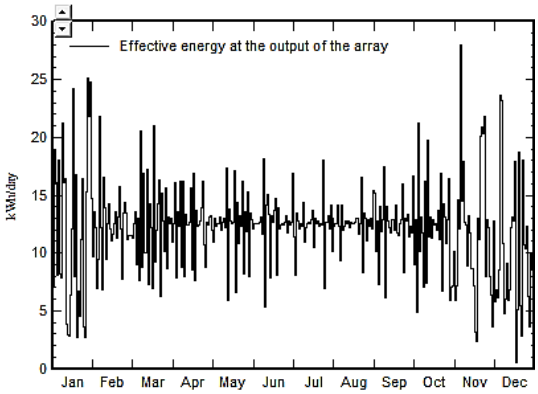

Fig. 5. Daily output energy

Fig. 6. Compares the Performance Ratio (PR) and Solar Fraction (SF) for each month of the year, showing variations in solar energy system efficiency and the proportion of energy load met by solar power. Fig. 7. Illustrates the normalized production and loss factors for a 5.75 kWp solar system across each month, highlighting the distribution of unused energy, collection losses, system losses, and energy supplied to the user.

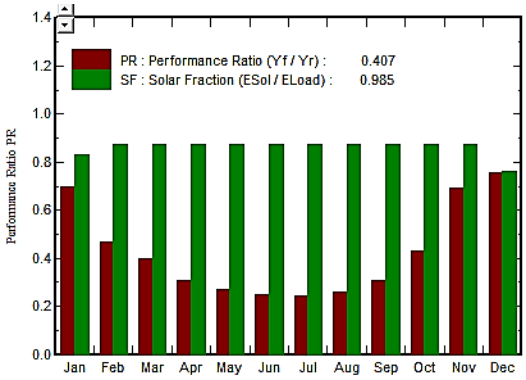

Fig. 6. Performance Ratio and solar fraction

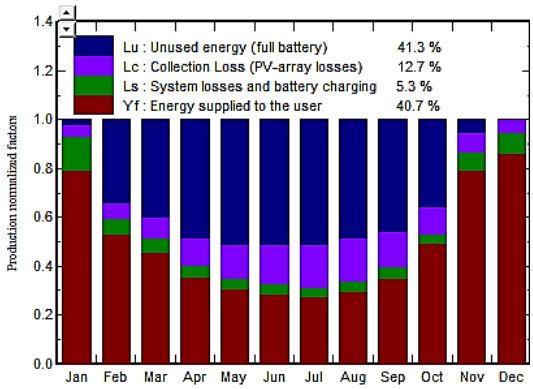

Fig. 7. Normalized production and loss factors

Fig. 8. Displays the normalized daily energy production per installed kWp for a 5.75 kWp solar system, breaking down the energy supplied to the user, unused energy, collection losses, and system losses throughout the year. Fig. 9. Shows the reference incident energy on the collector plane for each month, with the highest energy levels observed in the summer months, peaking in July. The system's performance was evaluated based on several key metrics: Energy Production: The system produced an annual available energy of 8.13 MWh, with a specific production rate of 1414 kWh/kWp/year. Energy Usage and Losses: Of the total energy produced, 3.93 MWh was used to meet the household's energy needs, while 3.99 MWh remained unused due to battery storage limitations. The performance ratio (PR) was calculated at 40.71%, and the solar fraction (SF) was 98.46%, indicating a high level of solar energy utilization.

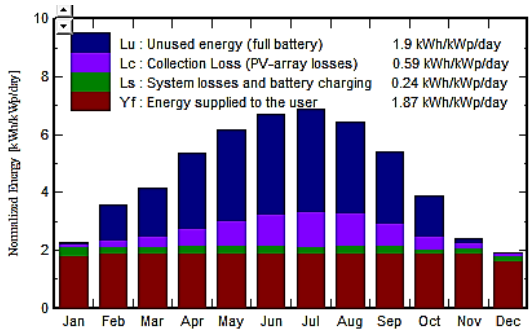

Fig. 8. Normalized productions

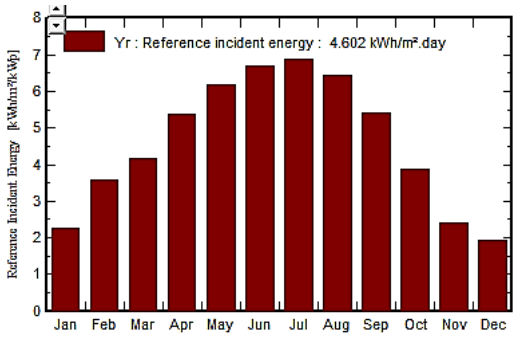

Fig. 9. Reference incident energy

System Losses: Major losses were attributed to unused energy due to full battery conditions (47.3%), followed by PV losses due to irradiance levels (0.7%), temperature effects (6.8%), and wiring losses (2.5%). The results indicate that the stand-alone solar system is capable of meeting the energy demands of a residential setup in Constanta, with minimal reliance on external power sources. However, the high percentage of unused energy suggests the need for optimizing battery capacity or incorporating additional energy storage solutions. The performance ratio indicates potential areas for improvement, such as reducing wiring losses and enhancing battery efficiency.

6. CONCLUSIONS

This study has demonstrated the potential and effectiveness of a stand-alone solar power system in Constanta, Romania, highlighting its viability as a sustainable energy solution for residential setups. The findings reveal that such systems can significantly contribute to meeting energy demands while providing substantial cost savings over time. With Constanta's favorable geographic conditions and high solar irradiance, the solar installation achieved impressive performance metrics, underscoring the region's suitability for solar energy adoption.

The research also underscores the importance of optimizing solar technology integration, particularly in regions with high solar potential. The study's insights into energy savings, system reliability, and cost-effectiveness provide valuable information for stakeholders, including policymakers, investors, and homeowners, interested in transitioning to renewable energy sources. Additionally, the consideration of technical challenges, such as storage solutions and load management, emphasizes the need for a comprehensive approach to the design and implementation of solar power systems.

The successful deployment and performance of the stand-alone solar power system in Constanta confirm the economic and environmental benefits of solar energy in similar geographic contexts. As the world seeks sustainable alternatives to traditional energy sources, this research contributes to the growing body of evidence supporting the adoption of solar power as a key component of future energy strategies.

ABSTRACT
This paper provides an efficient generation of electricity from solar energy, which is crucial in the global transition to renewable sources. A key factor in this process is the optimal positioning of photovoltaic (PV) panels, which capture sunlight and convert it into electrical power. Two primary geometric parameters—tilt (inclination) and azimuth angles—significantly influence conversion efficiency.
This study analyzes the photovoltaic park in Craiova to evaluate how these geometric factors impact energy efficiency. The inclination angle determines the panel's tilt relative to the horizontal plane and is essential for maximizing energy capture throughout the year. Similarly, the azimuth angle, which defines orientation along the north-south axis, plays a vital role in maintaining consistent sunlight exposure and ensuring reliable electricity generation.
Craiova's unique climatic conditions, with seasonal variations and cloudy periods, highlight the need for optimal panel alignment. This study assesses the park's current configurations against optimal theoretical values to provide recommendations for improved efficiency. The zenith angle, which measures the sun's position relative to the vertical, is also introduced to further refine energy capture strategies.
The PVsyst application is used to simulate and analyze various tilt and azimuth scenarios, evaluating their impact on energy output and economic viability. It also includes financial analysis features to estimate amortization costs, considering initial capital expenditures, operational expenses, and projected revenue from energy production. Additionally, integrating a hydrogen system enables surplus solar energy to be converted into green hydrogen, enhancing economic value. This analysis helps determine the payback period and overall return on investment, offering key insights into the feasibility of different configurations.

Keywords: photovoltaic system, solar power, tilt angle, PVsyst, hydrogen system, green hydrogen, optimization.

1. INTRODUCTION

Solar energy plays a crucial role in sustainable electricity generation, with solar cells offering a pollution-free solution. Technological advances have improved efficiency and reduced costs, making photovoltaic (PV) systems more accessible and vital to the transition to renewable energy.
Craiova, with its favorable climate, flat terrain, and extensive agricultural land, presents significant opportunities for solar energy deployment. The region benefits from abundant sunlight, enabling high energy output and offering dual land use for both solar installations and agriculture. This integration can boost productivity and economic gains for local farmers. The availability of large tracts of unused land provides the flexibility to install large-scale solar farms without disrupting existing agricultural activities. Additionally, the region's proximity to infrastructure, such as roads and power distribution networks, facilitates the efficient transmission of generated electricity to the grid [1].
Despite the vast potential of solar energy, it remains underutilized. Strategic planning and optimization of PV systems are essential to fully harness this resource and reduce dependence on fossil fuels. In Craiova, factors such as geographic positioning, climate variations, and system design influence PV efficiency. Seasonal variations in solar radiation levels require adaptive system configurations to ensure consistent performance year-round. Proper installation and maintenance are critical to achieving optimal performance. Regular inspections and cleaning schedules can help maintain panel efficiency by preventing dust accumulation and shading effects, which can reduce energy output [2].
A thorough analysis of PV system configurations, including azimuth and inclination angles, is necessary to maximize energy capture and conversion. The azimuth angle, which determines the orientation of the panels relative to the sun's position, plays a crucial role in maintaining consistent energy generation throughout the day. Similarly, the inclination angle, which sets the tilt of the panels, is essential for optimizing the amount of solar radiation absorbed. Adjusting these angles based on seasonal variations and latitude-specific conditions can significantly enhance energy production. Collaboration with experts ensures the effective implementation of sustainable energy solutions and promotes long-term energy security in Craiova. The energy from the photovoltaic park will be used for hydrogen production via electrolysis, converting water into green hydrogen for storage and various applications, improving energy flexibility and grid stability [3].
The economic viability of solar energy projects in Craiova is influenced by several factors, including initial investment costs, operational expenses, and the potential revenue generated from energy sales. Financial incentives such as government subsidies and tax credits can further improve the return on investment for solar projects. Additionally, partnerships with local stakeholders and investors can help secure the necessary funding to develop large-scale

installations [4].[5].

2. DETERMINING THE ORIENTATION AND TILT ANGLES OF PHOTOVOLTAIC PANELS

The efficiency of photovoltaic (PV) panels in converting solar energy into electricity is largely influenced by their positioning relative to the sun and Earth's surface. Two key factors affecting energy capture are the tilt angle, which determines the panel's inclination to the horizontal plane, and the azimuth angle, which defines orientation concerning the north-south axis.

A comprehensive approach combining mathematical and empirical methods is critical to optimizing energy capture and ensuring the economic viability of solar power systems. Fig. 1 illustrates these key angles and their relationship to the sun's position [7].

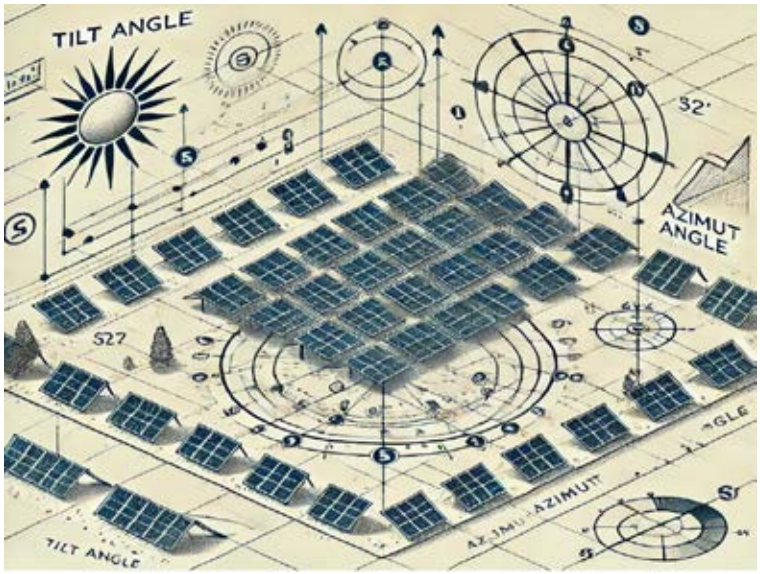

Fig. 1. Angle Diagram for Photovoltaic Panels

Fig. 1 shows the key angles for positioning photovoltaic panels to maximize solar energy capture. It illustrates the tilt angle, which is the panel's inclination to the horizontal plane, and the azimuth angle, which defines its orientation relative to the north-south axis. These angles are essential for optimizing solar exposure and energy efficiency.

3. SYSTEM CONFIGURATION

The photovoltaic park is located in the Craiova area, Olt County, Romania. This facility, with an installed capacity of approximately 3000 kWp, is relatively smaller compared to other solar power plants in the region. It is integrated into the local power grid via a 20 kV distribution line and occupies an area of approximately 12,000 square meters dedicated to photovoltaic panels.

The park comprises 5263 TSP-720-XYZ polycrystalline silicon photovoltaic modules, which are arranged into 10 parallel strings per inverter, with each string consisting of approximately 526 modules. These strings are connected to 10 SUN3000-400KTL-H2 inverters, which are securely mounted on a robust supporting structure.

The inverters enable connection to the national grid through a 0.4/20 kV transformer and an electricity meter, ensuring optimal power transmission efficiency. The entire photovoltaic installation is supported by a corrosion-resistant galvanized steel structure [8]. Surplus energy can be used in a hydrogen production system through electrolysis.

4. SIMULATION PARAMETERS AND METHODS

The simulation study will consider three different scenarios based on different tilt and azimuth angles of the system. In the first scenario, the system will be analyzed with a tilt angle of 30 degrees and an azimuth angle of 70 degrees. The second case will investigate the performance at a tilt angle of 70 degrees with the same azimuth angle. Finally, the third case will use optimized tilt and azimuth angles, specifically tailored for the selected location to maximize efficiency. Following the simulations, the results obtained will be analyzed in detail to assess the impact of these angle variations on the system performance [9].

In this simulation study, PVsyst software was used to determine the optimal tilt and azimuth angles for the photovoltaic system. The values obtained from PVsyst were subsequently verified using the PVGIS application to ensure accuracy. All collected data were then imported into MATLAB, where further calculations were performed to analyze the financial aspects of the project, specifically focusing on determining the investment payback period.

Table 1. Cases analyzed

Case 1:	Case 2:	Case 3: Optimized angles
Tilt angle: 30° Azimuth Angle: 70°	Tilt angle: 70° Azimuth Angle: 70°	Tilt angle: 36° Azimuth Angle: 2°

5. RESULTS AND DISCUTIONS

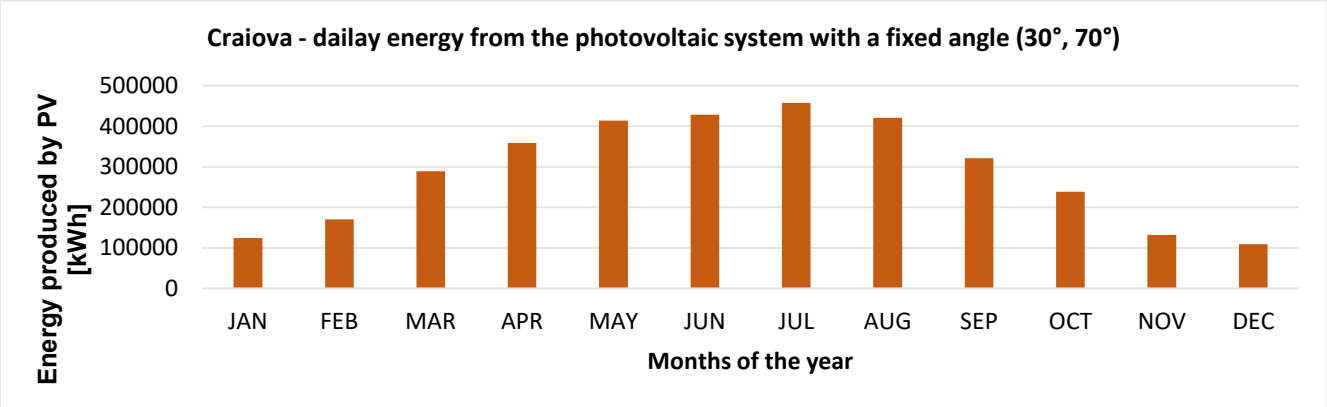

Fig. 2. Craiova - Lunar energy from the photovoltaic system with a fixed angle (30°, 70°)

Fig. 2 provides an overview of the total annual energy production of the system. The photovoltaic system, with an installed panel capacity of 3000 kWp, is capable of generating an annual energy production of 3463062.77 kWh. This production capacity is for the analyzed case 1 which highlights the efficiency of the system in harnessing solar energy to meet the energy demands over a year.

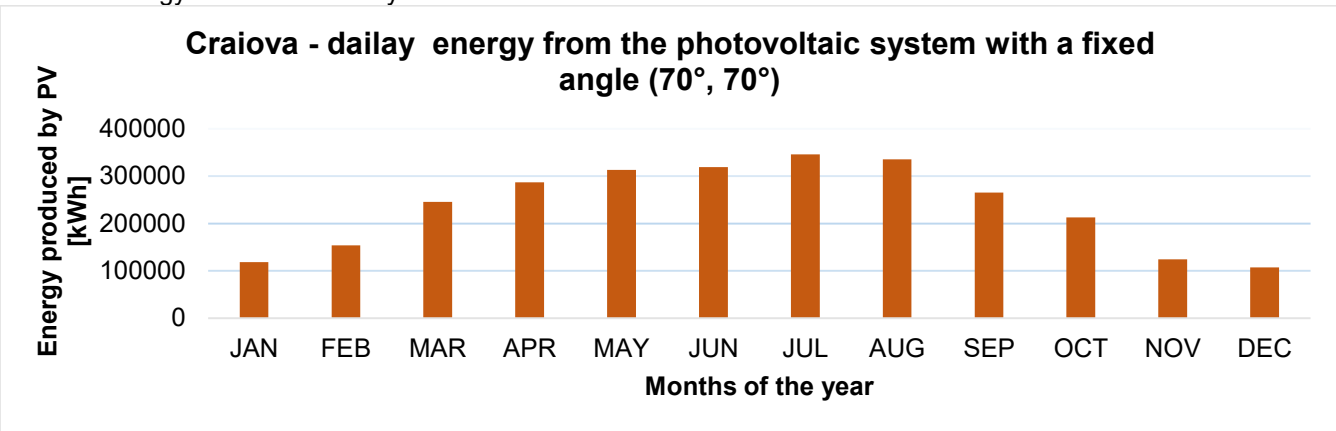

Fig. 3. Craiova - Lunar energy from the photovoltaic system with a fixed angle (70°, 70°)

Fig. 3 presents a summary of the system's total yearly energy output. With an installed panel capacity of 3000 kWp, the photovoltaic system is designed to produce approximately 2830477.79 kWh of energy annually.

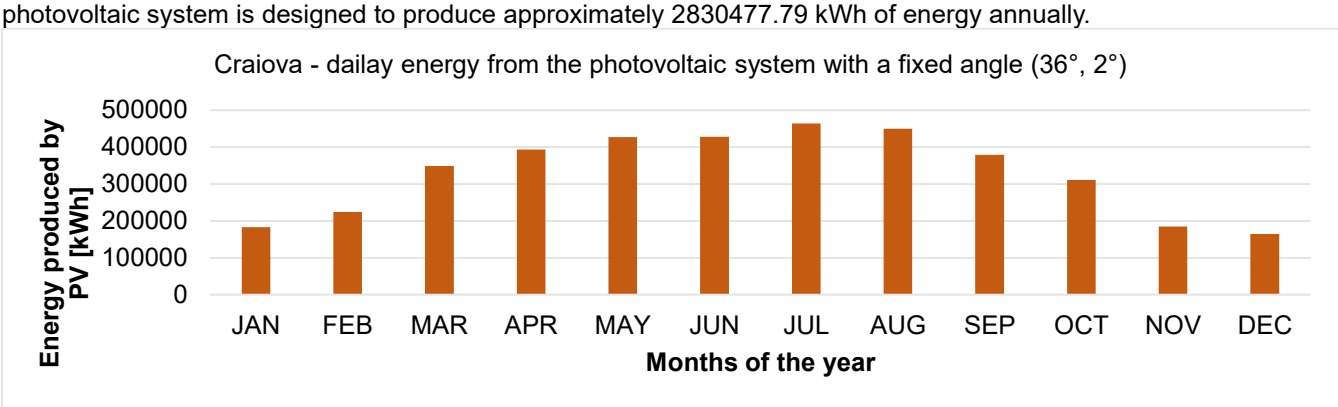

Fig. 4. Craiova - Lunar energy from the photovoltaic system with optimized angles (36°, 2°)

Fig. 4 presents an overview of the system's total annual energy production. The photovoltaic system, with an installed

capacity of 3000 kWp, is expected to generate around 3955381.39 kWh per year. This energy output corresponds to the conditions evaluated in case 3, which represents the optimal scenario, highlighting the system's effectiveness in utilizing solar energy to satisfy annual energy demands.

Table 2. Centralization of total annual energy

Analysis of Craiova:	Case 1: 30°, 70°	Case 2: 70°, 70°	Case 3: Optimized angles
Total annual energy produced [kWh]	3463062.77	2830477.79	3955381.39

Table 2 provides a detailed comparison of the energy production values for each analyzed case. A significant variation can be observed among the three scenarios. In the first case, the system generates 3,463,062.77 kWh annually, while in the second case, the energy production drops to 2,830,477.79 kWh. The third case, representing the optimal configuration, achieves the highest energy output of 3,955,381.39 kWh per year. These differences emphasize the impact of system orientation and optimization on overall performance.
Table 3 provides a summary of all the data obtained and calculated using MATLAB, including the total investment costs and the payback period for each analyzed case.

Table 3. Economic calculation

	Case 1: (30°, 70°)	Case 2: (70°, 70°)	Case 3: Optimized angles
The total power produced by the photovoltaic panels [kW]	3000	3000	3000
Total annual energy produced [kWh]	3463062.77	2830477.79	3955381.39
Total Cost [€]	3455000	3455000	3455000
Amount obtained for injection into the network	346300	283000	395500
Investment recovery:	10 years	12 years	9 years

In the optimized case, the investment payback period was the shortest compared to the other two scenarios, emphasizing the effectiveness of optimizing system parameters. This outcome highlights the importance of carefully selecting the tilt and azimuth angles to maximize energy production and financial returns. Additionally, integrating a hydrogen production system further enhances profitability by converting excess solar energy into green hydrogen, creating additional revenue streams and increasing energy flexibility. A shorter payback period makes the project more attractive to investors, ensuring a faster return on investment and greater long-term sustainability [10].

6. CONCLUSIONS

Optimizing the tilt and azimuth angles significantly enhances the photovoltaic system's performance by maximizing energy capture. The optimized configuration achieved the highest annual energy output, demonstrating the importance of site-specific adjustments for improved efficiency.
The financial analysis revealed that the optimized case resulted in the shortest investment payback period, making the project more economically attractive. Faster returns on investment highlight the benefits of proper system design in ensuring long-term profitability and sustainability. Additionally, integrating a hydrogen production system enhances economic viability by utilizing surplus solar energy to generate green hydrogen, creating new revenue streams and increasing energy resilience.
Optimized configurations significantly improved energy production, while non-optimized setups led to lower outputs and longer payback periods, highlighting the importance of accurate simulations for maximizing performance.
The optimized system enhances sustainability by maximizing solar energy use and reducing dependence on conventional power, supporting clean energy goals.

ABSTRACT
In search of sustainable solutions to the worldwide energy crisis, PEM fuel cells (PEMFCs) are attracting attention as an environmentally friendly energy production system. Within the scope of this study, an alternative microwave-assisted polyol method has been developed by modifying the polyol method for the synthesis of Ru/C and PtRu/C catalysts. This method allowed catalyst synthesis at high temperatures and pressures, without being constrained by the boiling point of the mixture typically used in polyol synthesis. Catalysts were synthesized at 200 °C. Characterization studies were carried out using XRD and SEM-EDS. The anode activity of the catalyst at different temperatures (60, 70 and 80 °C) was determined in a single-cell test system. PtRu/C catalyst synthesized at high temperatures demonstrated anode side activity of 171.2 mW/cm^2 @ 70 °C, which was comparable to commercial Pt/C.

Keywords: Fuel cell, PEM, Polyol, Microwave heating, PtRu

1. INTRODUCTION

The worldwide energy crisis has become increasingly important in recent years due to the demand for energy and the limitations of current energy production methods. The energy demand is primarily met by fossil fuels, such as coal, oil, and natural gas. However, concerns regarding the sustainability of these energy production methods have emerged due to the limited nature of these resources, their rapid depletion, and their negative environmental impacts. As a result, the focus is shifting towards renewable energy sources. Among renewable energy sources, hydrogen has emerged as a critical component. As the most abundant element in the universe, hydrogen is a clean and versatile energy carrier [1], [2]. Hydrogen can be produced using different methods and when produced using renewable energy sources, it is classified as a zero-emission fuel.

With respect to the utilization of hydrogen, there is an ever-increasing focus on fuel cells. In its most fundamental form, a fuel cell is an electrochemical system that directly converts the chemical energy of a fuel into electrical energy. Among the various types of fuel cells, PEM fuel cells are distinct in their capacity to directly utilize hydrogen, resulting in the production of water and heat as by-products through electrochemical reactions within the cell. The primary factor hindering the commercialization of these PEMFC is the high cost of the catalyst. Platinum (Pt) metal is the most commonly used electrocatalyst in PEMFC due to its stability and activity [3]. The main challenge of catalyst development lies in improving the cost-effectiveness of platinum. To address this challenge, various approaches have been adopted to enhance the utilization of Pt by addition of metals like Ru. One of these approaches involves reducing the particle size of the active metal and enhancing its dispersion on the support material.

Microwave-assisted polyol synthesis is an important method due to its simplicity and efficiency in controlling the synthesis of metal nanoparticles. This approach involves the reduction of metal ions to form colloids. The main advantages of this method is enhanced reaction kinetics, the formation of particles with uniform size distribution, the generation of new phases, and a significant reduction in energy consumption.

In this study, an alternative method that has already been developed for the synthesis of Pt/C [1] was adapted for synthesis of Ru/C and PtRu/C catalysts under pressure by microwave assisted polyol method. This study aims to fill the knowledge and method gap between synthesis at atmospheric pressure and synthesis under supercritical conditions. In this context, the synthesis of the catalysts was carried out under pressure, at a temperature of 200 °C, which is above the boiling point of the polyol mixture. The catalysts were characterized by X-Ray Diffraction (XRD) and Scanning Electron Microscopy-Energy Dispersive X-Ray Spectroscopy (SEM-EDS). Fuel cell tests were performed in a single-cell test station to determine the activity of the PtRu/C catalyst.

2. MATERIALS AND METHODS

Dihydrogen hexachloroplatinate(IV) hexahydrate (ACS, Premion™), Ruthenium(III) chloride trihydrate (Sigma-Aldrich) ethylene glycol (Sigma-Aldrich), sodium hydroxide (VWR Chemicals), hydrochloric acid, sulfuric acid, and isopropyl alcohol from Riedel-de Haën were used as received. Vulcan carbon (Cabot) was used as the carbon support and 20 wt% Nafion™ solution (Ion Power) was used in Membrane Electrode Assembly (MEA) preparation.

The Ru/C catalysts were synthesized by using the modified polyol method described in a previous study [1]. In summary, a Teflon reactor (HPR-1000/10S) and the Milestone Start S system was utilized. The reaction temperature was 200 °C, and the reaction was carried out for 35 minutes. To further improve the previously developed method, the synthesis of the PtRu/C catalyst was carried out in a single step, in which the synthesized metal nanoparticles are directly deposited on the carbon support.

For the characterization of the catalysts, XRD analysis was carried out using Rigaku XRD MiniFlex 600 (5°/min scanning

speed, step size of 0.02°, in the range of 5°<2θ<85°) and SEM-EDS analysis were carried out using Zeiss Supra 50 VP where prior to imaging, the samples were subjected to Au-Pd coating to ensure electron conductivity. Catalyst ink for the MEA was made by ultrasonically mixing calculated amounts of catalyst, Nafion solution, deionized water, and isopropyl alcohol for 1 hour. After that, the ink was spray coated onto the carbon paper via a spray gun. Cathode electrode was prepared by the same methodology, where the commercial 20% Pt/C was used as the catalyst. MEA was manufactured by hot pressing the electrodes and membrane at 130 °C, under 400 psi pressure for 3 minutes. To condition the cell (5 cm^2 active area) and stabilize its performance, the cell voltage was kept constant at 0.5 V and power is drawn from the cell with an electronic load until the change in power stabilized. The activity tests were carried out at 100% relative humidity at different cell temperatures of 60, 70, and 80 °C, using hydrogen feed rate of 0.25 L/min and dry air feed rate of 1.0 L/min.

3. RESULTS AND DISCUSSION

The crystal structure of Vulcan carbon support and the Pt and Ru metals in the catalysts are determined by XRD analysis, as illustrated in Figure 1.

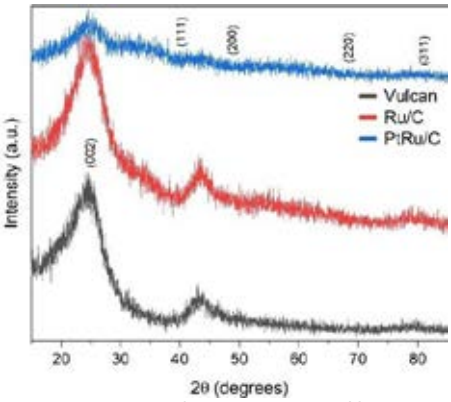

Fig. 1. XRD patterns of the Vulcan, Ru/C, and PtRu/C

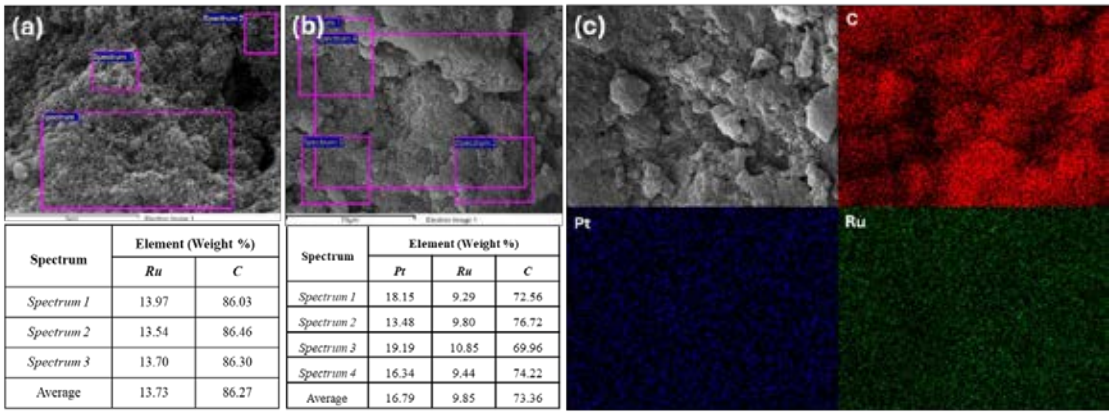
The peak observed in the range of 15°<2θ<30° corresponds to the hexagonal structure of Vulcan carbon [4]. The Ru peak at about 43° corresponds to the (101) plane [5]. The diffraction peaks attributed to RuO_2 at 28.1° and 40.1° were not observed due to the extremely small size of the Ru [6]. In the diffraction patterns of all Ru/C catalysts, extremely broad peaks are observed [7], indicating that the crystallinity of Ru/C catalysts is very low. The absence of diffraction peaks at approximately 35° (101) and 55° (211) further confirms the amorphous structure. During the formation and growth of Ru nanoparticles, it has been reported that this process occurs selectively on the carbon support, with carbon support acting as the core center for the growth of Ru nanoparticles. The method used in this study successfully synthesizes Ru catalysts with small particle sizes and homogeneous distribution. For the PtRu/C catalyst, the barely visible peaks at approximately 46.5°, and 69.5° in the diffraction patterns represent diffractions of Pt-Ru alloy. The absence of diffractions from monometallic Pt, Ru, or RuO_2 compounds may serve as evidence that the metals in the catalyst PtRu/C mostly in the form of Pt-Ru alloy [8]. The mean crystallite size of Pt and Ru nanoparticles is expected to be less than 1.5 nanometers. However, due to the extreme peak broadening precise calculations were not possible.
The results obtained from the SEM-EDS analysis of the Ru/C and PtRu/C catalysts are presented in Figure 2.



Spectrum	Element (Weight %)	
	Ru	*C*
Spectrum 1	13.97	86.03
Spectrum 2	13.54	86.46
Spectrum 3	13.70	86.30
Average	13.73	86.27

Spectrum	Element (Weight %)		
	Pt	*Ru*	*C*
Spectrum 1	18.15	9.29	72.56
Spectrum 2	13.48	9.80	76.72
Spectrum 3	19.19	10.85	69.96
Spectrum 4	16.34	9.44	74.22
Average	16.79	9.85	73.36

Fig. 2. SEM image and respective elemental composition for (a)Ru/C, (b)PtRu/C, and (c)EDS mapping of PtRu/C

As illustrated in Fig. 2(a), the characteristic structure of the carbon support remains unchanged during catalyst synthesis. Analysis of the SEM image shows that there is no Ru clustering, indicating that Ru metal is distributed homogeneously on the carbon support. The results obtained from different EDS regions are similar, further supporting that Ru metal is homogeneously distributed on the carbon support.
In Fig. 2(b), the weight percentages of Pt, Ru, C on the surface of the catalyst varies. On average, Pt's weight percentage is 16.8%, and Ru's weight percentage is 9.85%. Furthermore, the Pt:Ru ratio is close to the ratio of atomic 1:1, and this ratio is reported to be a suitable ratio for bimetallic catalysts [4], [9].
Upon examination of the EDS maps provided in Fig. 2(c), it can be seen that the PtRu/C catalyst has homogenous Pt and Ru distribution on the surface. This result shows that the method presented in this study is suitable for synthesizing bimetallic catalysts, as high temperature and pressure conditions used in this work enhance the catalyst synthesis. The polarization curves of the PtRu/C catalyst at temperatures of 60, 70, and 80 °C are given in Figure 3. The hydrogen and air feed rates were 0.25 L/min and 1.00 L/min, respectively.

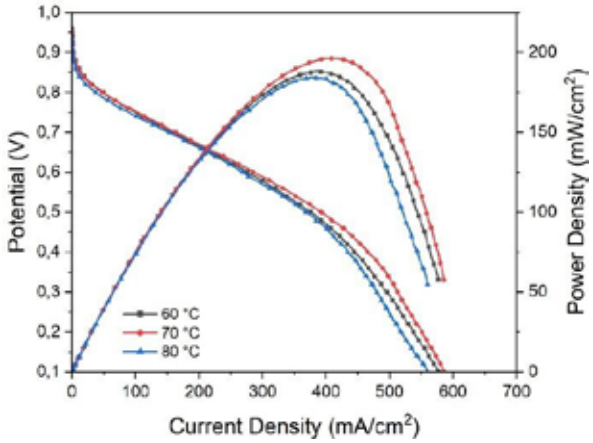


Fig. 3. The polarization curves of the PtRu/C catalyst at different temperatures

For the PtRu/C bimetallic catalyst, the highest cell performance was obtained at 70 °C. The performance loss at 80°C indicates that the degradation of membrane takes place at high temperatures [10]. The highest power density value was obtained at 70 °C cell temperature, while the decrease in power density at 80 °C is attributable to the reduction in proton conductivity of the Nafion membrane [3]. Activation polarization, ohmic losses, and mass transfer losses are discernible in the current density curves at all temperatures. At high current densities, mostly the mass transfer losses contribute to the cell performance degradation. But, at low and medium current densities, the performance decline is attributed to activation losses and ohmic losses.The temperature effect becomes more pronounced as the current density increases. This can be attributed to that the activation energy required for electrochemical reactions at low currents being lower than the energy required at high current [11].

4. CONCLUSIONS

In this study, Ru/C and PtRu/C catalysts were synthesized under high-temperature and pressure conditions by microwave-assisted polyol method. To address the knowledge gap in literature, the polyol method was modified. XRD analysis showed that synthesized PtRu/C catalyst had ultra-small crystallite sizes (<1.5 nm). SEM-EDS analysis showed that no metal clustering was present on the surface of the catalysts and Pt and Ru metal were distributed homogeneously over the carbon support. The activity of the PtRu/C catalyst was investigated in a single-cell test system and the highest activity of (171.2 mW/cm^2) was obtained at 70 °C. The loss of performance at 80 °C was attributed due to the degradation of the Nafion membrane. Addition of Ru also positively influenced the cost of the catalyst. The metal nanoparticles and catalysts that are synthesized in this work have the potential to be used in many different areas.

Abstract
The climate crisis necessitates inclusive, climate-resilient solutions, with renewable energy and hydrogen gas as key components. This study aimed to produce electrodes for PV-supported electrolyzer systems using 3D printing technology, ensuring scalable, repeatable, and cost-effective production. Electrodes with enhanced electrical conductivity and electrocatalytic efficiency were developed via FDM-based filament production. For this purpose, NiMo@Ag additive made using green chemistry methods was combined with commercial polymer resins that contain graphene and polylactic acid (PLA). The mixture was extruded to create filaments that can be used in 3D printers. Electrode geometry in honeycomb form was constructed with the aid of the software application. The cathode was connected to the PV panel on our university campus, enabling the production of "green hydrogen". The characterization of catalyst (NiMo@Ag) was achieved by XRD, FESEM-EDX and TEM. The electrochemical behaviour was investigated by LSV and EIS.
Keywords: Green Hydrogen, Fused Deposition Modeling (FDM), Electrolysis Systems, Sustainable Manufacturing.

I. INTRODUCTION

The use of sustainable energy sources is very important in combating climate change; however, the intermittency of solar and wind energy presents a significant drawback. Hydrogen gas serves as a solution to this issue by acting as an energy carrier, with green hydrogen production via water electrolysis from renewable sources emerging as a key focus. While there are deficiencies in industrial-scale, cost-effective, and high-performance electrocatalyst production in Türkiye, 3D printing technology offers scalability and reproducibility advantages in electrode manufacturing [1,2]. In this study, NiMo@Ag was prepared via green chemistry method. The active compound in the extract used for electrocatalyst modification is curcumin, a polyphenol with strong chelating properties. It binds to metal ions (Mo^{5+} and Ni^{2+}) through various functional groups:

(a) Complexation with Mo^{5+}:

- Two curcumin molecules can form complexes with Mo^{5+} through keto-enol tautomers:
  $$\text{Curcumin-enol} + Mo^{5+} \rightleftharpoons [\text{Curcumin-Mo(V)}]^{2+} + H^+ \quad (1)$$
- Alternatively, a single curcumin molecule can bind to Mo^{5+} via bidentate coordination through a phenolic oxygen and a β-diketone carbonyl group:
  $$\text{Curcumin} + Mo^{5+} \rightleftharpoons [\text{Curcumin-O,O′-Mo(V)}]^{1+} + H^+ \quad (2)$$

(b) Complexation with Ni^{2+}:

- One or two curcumin molecules can coordinate with Ni^{2+} through their phenolic oxygen atoms:
  $$\text{Curcumin} + Ni^{2+} \rightleftharpoons [\text{Curcumin-O-Ni(II)}]^{+} + H^+ \quad (3)$$
  $$2\ \text{Curcumin} + Ni^{2+} \rightleftharpoons [\text{Curcumin-O,O′-Ni(II)}] + 2H^+ \quad (4)$$

The extract contains various reducing agents, such as phenolic compounds, that donate electrons to the metal-curcumin complexes:

$$[\text{Curcumin-Mo(V)}]^{2+} + e^- \rightarrow [\text{Curcumin-Mo(IV)}] + H^+ \quad (5)$$
$$[\text{Curcumin-Ni(II)}]^{+/2+} + e^- \rightarrow [\text{Curcumin-Ni(I)}]^{0/1+} + H^+ \quad (6)$$
$$Mo^{4+} + Ag \rightarrow MoO_x@Ag \quad (7)$$
$$Ni^{1+/0} + Ag \rightarrow NiO_x@Ag \quad (8)$$

Further addition of metal ions and their reaction with the extract promotes the growth of a core-shell structure:

$$Mo^{4+} + [\text{Curcumin-Mo(IV)}] \rightarrow Mo@MoO_x@Ag \quad (9)$$
$$Ni^{1+/0} + [\text{Curcumin-Ni(I)}]^{0/1+} \rightarrow Ni@NiO_x@Ag \quad (10)$$

Curcumin stabilizes the core-shell structure through chemisorption onto the newly formed metal oxide surface.

In summary, the complexation of curcumin with metal ions enhances their solubility and prepares them for reduction. The reduction of these ions by the reducing agents in the extract forms nucleation centers for nanoparticle growth.

After the sythnesis of NiMo@Ag characterization was achieved and then PLA- NiMo@Ag was produced via FDM method, the prepared electrocatalyst was tested in 1 M KOH solution for HER.

2. MATERIALS AND METHODS

Ammonium molybdate (0.5 mmol, analytical grade) was dissolved in 20 mL of deionized water using an ultrasonic bath operating at 40 kHz and 100 W for 15 minutes at room temperature. Separately, a solution of nickel nitrate hexahydrate (0.5 mmol) was prepared in 20 mL of deionized water and added dropwise to the ammonium molybdate solution at a controlled rate of 1 drop per second, under continuous magnetic stirring at 500 rpm for 30 minutes. Subsequently, 10 mL of the prepared Curcuma longa (C. longa) ethanol extract (5.72 mg/mL) was introduced into the mixture dropwise over 10 minutes while maintaining stirring at 400 rpm, followed by an additional 30 minutes of stirring to ensure uniform incorporation. Ag suspension (0.5 mmol) was prepared by dispersing Ag in 20 mL of ethanol using an ultrasonic bath (40 kHz, 120 W) at 60 °C for 15 minutes. This suspension was then added dropwise to the reaction mixture while stirring continuously at 500 rpm. The mixture was stirred at 400 rpm for a further 10 minutes to ensure homogeneity. The reaction mixture was then transferred to a 50 mL Teflon-lined autoclave, sealed, and subjected to hydrothermal treatment at 121 °C for 1.5 hours under autogenous pressure (~1.5 bar), ensuring uniform heating throughout. After cooling the autoclave to room temperature, the product was collected by centrifugation at 5000 rpm for 10 minutes using a bench-top centrifuge. The resulting precipitate was thoroughly washed three times with 20 mL each of ethanol and deionized water to remove any residual impurities. Finally, the purified product was dried in a vacuum oven at 60 °C for 24 hours to obtain the MoNi@Ag nanoparticles. X-ray diffraction (XRD) analysis was performed on Pan Analytical Philips. The surface morphology, and elemental compositions of the nanocatalyst were examined using SEM and energy dispersive X-ray (EDX) spectroscopy on a Czech FEI SEM-type instrument at an accelerating voltage of 25 kV. The HR-TEM analysis (Thermoscientific, Talos F200i) was used to characterize the size, morphology, aggregation, and crystallization of the nanoparticles. As the first step in producing filaments with NiMo@Ag particles, a conductive PLA/NiMo@Ag polymer matrix (Protopasta) was fabricated using mechanical mixing and melt blending. Specifically, 1.5% NiMo@Ag was incorporated into PLA via mechanical mixing, followed by extrusion in a twin-screw extruder and pelletization to obtain PLA/NiMo@Ag nanocomposite granules. These granules were subsequently processed through a single-screw extruder and a winding mechanism to produce nanocomposite filaments with a standard 1.75 mm diameter. During extrusion, the barrel temperatures of the twin-screw and single-screw extruders were set to 160°C, 160°C, and 170°C for the three heating zones from the nozzle to the hopper. Then the obtained flament was used during the 3D printing procedure via 3D printer (Raise3D Pro3). The obtained form was 1*1*0.1 cm honeycomb shaped electrode. Electrochemical measurements were performed using a CHI 660B electrochemical analyzer at room temperature. A conventional three-electrode electrochemical cell was employed. The LSV was obtained at 100 mV s^{-1} scan rate. The EIS was performed at - 1.5 V, in the frequency range with 100 kHz and 10^{-2} Hz with the 5 mV amplitude. The energy harvesting experimental setup consisted of an 80 W photovoltaic (PV) panel installed on the roof of Adana Alparslan Türkeş Science and Technology University building to evaluate Adana's hydrogen production potential throughout 2024. The system was integrated with an HMI interface and a PLC control unit, enabling real-time monitoring and control of the setup. Data from solar radiation, wind speed, and temperature sensors were collected and processed through the PLC system. This comprehensive monitoring system ensured accurate data acquisition under varying environmental conditions. The aim was to analyze the energy generation performance of the PV panel and identify the most suitable periods for maximizing hydrogen production. This advanced setup provides a robust framework for evaluating renewable energy potential in real-world applications.

3. RESULTS AND DISCUSSION

In Fig. 1, diffraction peaks were detected at angles of 9.3599°, 12.4303°, 13.8173°, 14.9532°, 17.0897°, 19.1665°, 22.0755°, 24.0724°, 24.9882°, 25.8552°, 26.5454°, 27.1364°, 28.2495°, 30.6494°, 32.2314°, 33.1564°, 38.2176°, 40.1133°, 42.5428°, 44.9120°, 47.5648°, 54.3999°, 61.9902°, 64.5393°, 74.4323°, and 77.5770° in the XRD pattern. Notably, the strong peak at 27.1364° (d = 3.28614 Å, 100% relative intensity) matches the JCPDS card 00-038-0449, indicating the presence of a Ni-Mo alloy phase in the sample. This phase suggests an intermetallic structure formed by the strong interaction between Ni and Mo atoms. Additionally, the peaks at 38.2176° (d = 2.35499 Å, 41.12% relative intensity), 64.5393° (d = 1.44396 Å, 14.14% relative intensity), and 77.5770° (d = 1.22963 Å, 6.50% relative intensity) match the JCPDS cards 01-087-0718 and 00-038-0449, demonstrating that the Ni-Mo intermetallic phase is stabilized by Ag coating. Examination of the peak widths (FWHM) reveals that the narrow band at 14.9532° (0.0984°) indicates high crystallinity of the material, while the broad band at 28.2495° (0.7085°) suggests that some crystal regions may be in the nanometer scale. In conclusion, the detected peaks and their matching with JCPDS cards confirm the successful synthesis of the Ni-Mo intermetallic phase and its stabilization through Ag coating. These findings verify that the NiMo@Ag nanocomposite has achieved the intended structure and ensured phase stability. The morphology of the nanoparticles is formed by the aggregation of spherical structures exhibiting size diversity. Most nanoparticles are characterized by a lighter-colored shell surrounding a darker core. This structure indicates that the core consists of a NiMo alloy, while the shell is composed of silver, which can be attributed to either Ag(OH) or Ag_2O. The FESEM-EDX results further corroborated this finding.

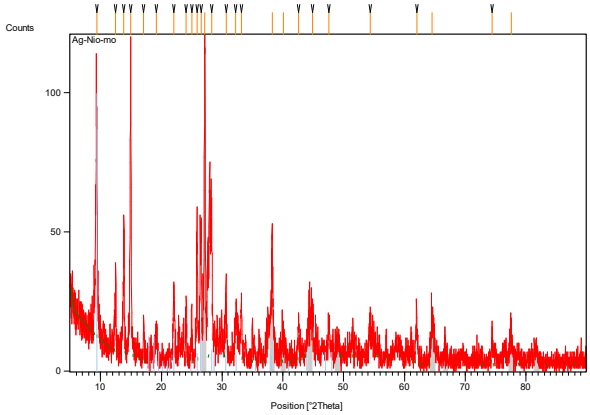

Fig. 1. The XRD of MoNi@Ag

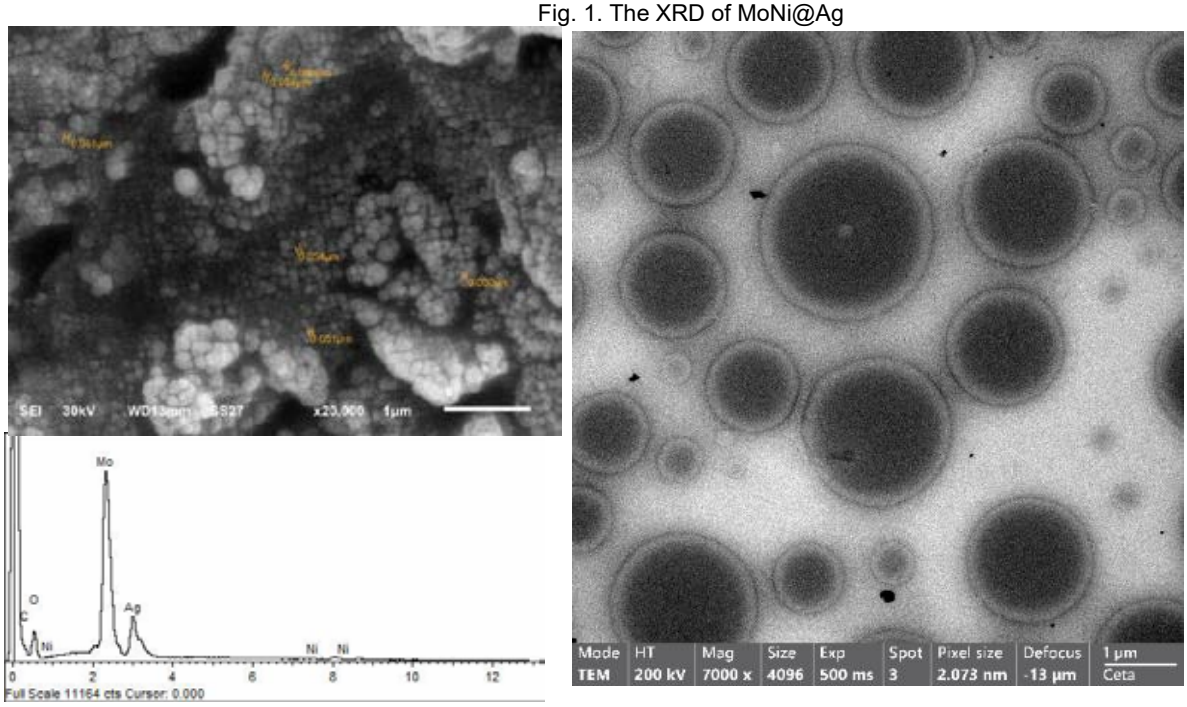

Fig. 2. FESEM (a)-EDX (b) and TEM (c) analysis of MoNi@Ag

The LSV curve presented in Fig. 3a demonstrated the enhanced HER activity of the 3D printed PLA-MoNi@Ag electrode in KOH electrolyte compared to the bare 3D electrode. The significantly lower onset potential and higher current density of the 3D PLA-MoNi@Ag electrode indicated its higher catalytic efficiency for HER vs bare electrode. This can be attributed to the synergistic effect of MoNi and Ag, which enhances electron transfer kinetics and provides more active sites for HER. The corresponding Nyquist plot (Fig. 3b) further supported this observation, revealing a lower charge transfer resistance for PLA-MoNi@Ag, suggesting faster charge transfer and improved electrocatalytic performance. This study also evaluated the monthly maximum power output performance of an 80 W photovoltaic (PV) panel using solar radiation and temperature data from Adana for the year 2024. The findings indicate that the power generation capacity of the panel is directly influenced by solar radiation levels, with temperature also playing a significant role in overall efficiency.

Table 1. Monthly maximum power output values for the 80 W PV panel in Adana during 2024

Month	Max Power Output (W)	Radiation (W/m^2)	Temperature (°C)
August	71.3	950.6	35.0
September	71.3	950.8	32.3
October	63.9	852.5	26.5
November	55.8	744.7	19.8
December	46.7	623.1	15.0

In August, the maximum power output of 71.3 W was observed at a solar radiation level of 950.6 W/m² and a temperature of 35.0°C, representing the highest performance recorded throughout the year. Similarly, in September, the panel achieved the same maximum power output of 71.3 W with slightly higher radiation (950.8 W/m²) and a lower temperature of 32.3°C, highlighting the continued high solar potential during late summer. In October, the maximum power output decreased to 63.9 W at a radiation level of 852.5 W/m² and a temperature of 26.5°C, reflecting the seasonal decline in solar radiation. November showed a further reduction, with a maximum output of 55.8 W at 744.7 W/m² radiation and 19.8°C temperature. Finally, in December, the lowest maximum power output of 46.7 W was recorded at a radiation level of 623.1 W/m² and a temperature of 15.0°C, corresponding to the reduced solar intensity during winter.

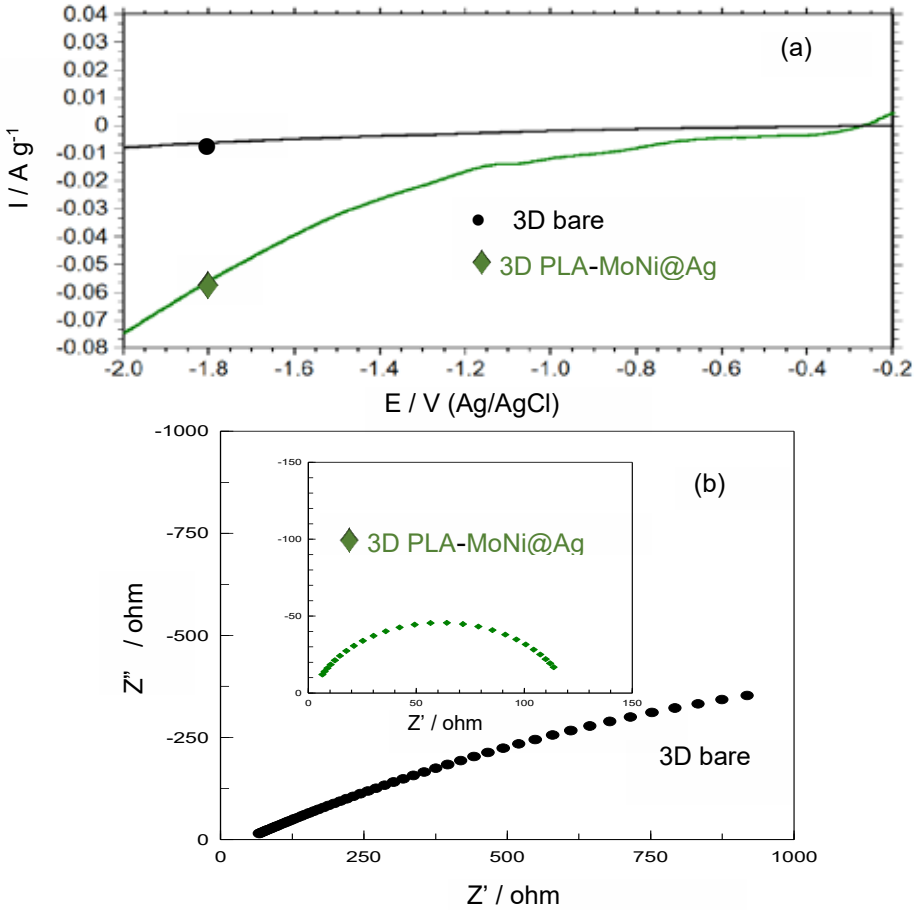

Fig. 3. The LSV curves (a) and Nyquist plots (b) of electrodes in 1M KOH

4. CONCLUSIONS

The structural, morphological and electrochemical analyses confirmed the formation of the MoNi@Ag structure. FESEM-EDX and TEM analyses further corroborated this core-shell configuration, demonstrating the uniform encapsulation. Electrochemical characterization revealed high HER catalytic activity of the 3D PLA-MoNi@Ag, as evidenced by its lower onset potential, higher current density, and reduced charge transfer resistance compared to the bare electrode. It can be attributed to the synergistic effect of MoNi and Ag, which enhances electron transfer kinetics and increases the density of active sites. PV results demonstrated that the power generation capacity of panels is primarily driven by solar radiation levels, while temperature has a secondary effect. Higher temperatures may reduce efficiency, but the impact is less significant during periods of high solar radiation, such as summer months. Conversely, the reduced solar radiation in winter months significantly limits power output. Therefore, in regions like Adana, which receive high solar radiation, PV panels operate more efficiently during summer and early autumn, while seasonal variations significantly affect their performance.

ABSTRACT
Increasing energy demand and environmental concerns cause efficient and clean transportation solutions. Therefore, hydrogen fuel cell electric vehicles (FCEVs) emerge as an effective alternative to reduce dependence on fossil fuels. This study presents a new simulation tool named Performance Analysis and Driving Simulation Program (PADSIP) to determine performance results and powertrain simulations of the FCEVs and compare them for wheeled and tracked vehicle configurations. The vehicle dynamics and powertrain component models are designed in the Matlab-Simulink environment and simulated using the Worldwide Harmonized Light Vehicles Test Cycle (WLTC). The main results indicate that the tracked vehicle provides better traction on rough terrains, but it causes higher energy and hydrogen consumption compared to the wheeled vehicle. Finally, it can be seen that PADSIP enables simulation and optimization of the FCEVs in their design and development process with its user-friendly interface.
Keywords: fuel cell vehicle, powertrain simulation, wheeled vehicle, tracked vehicle

1. INTRODUCTION

The transportation sector is undergoing a significant transformation toward alternative energy sources to address environmental concerns and reduce dependence on fossil fuels. Among these alternatives, hydrogen fuel cell electric vehicles have gained considerable attention due to their high energy efficiency, zero greenhouse gas emissions, and fast refueling capabilities [1]. FCEVs offer a sustainable solution for a wide range of applications, from urban mobility to heavy-duty operations. However, their performance and energy management depend heavily on the drivetrain configuration. Wheeled and tracked systems provide unique advantages tailored to specific operational needs. While wheeled vehicles are widely used for on-road transportation due to their efficiency and maneuverability, tracked vehicles perform better in off-road and rugged terrains because of their superior traction and stability [2]. Understanding the differences in energy consumption and dynamic behavior between these systems is critical for optimizing their design and application.

Research on FCEV energy management and performance optimization has predominantly focused on wheeled configurations. However, studies comparing wheeled and tracked FCEVs within the same simulation environment remain limited, as existing research often focuses on one configuration, overlooking the unique challenges and opportunities of the other. Additionally, there is a lack of studies integrating user-friendly interfaces to facilitate parameter adjustments and configuration selection, which are essential for practical applications. This study aims to address these gaps by directly comparing the energy consumption, dynamic performance, and operational efficiency of both configurations under the same conditions of wheeled and tracked vehicles using a new proposed simulation tool named PADSIP. The primary objective is to develop a comprehensive simulation model to evaluate and optimize energy management strategies for these systems. By analyzing their dynamic behavior and energy consumption, this research not only distinguishes itself from existing literature but also provides a practical tool for engineers and researchers to enhance FCEV designs. The findings are expected to contribute significantly to the advancement of FCEV technology, offering valuable insights for improving energy efficiency and performance across various applications.

2. MODELING AND SIMULATION

In this study, two separate heavy-duty vehicle models (wheeled and tracked FCEVs) were developed in the Matlab-Simulink environment to compare their performance and optimize energy management strategies (Fig. 1). Both models include essential subsystems, such as vehicle dynamics, powertrain components, battery, fuel cell, and control strategies, while also considering design-specific dynamics and resistance forces. The system icludes an electric motor for traction, a battery for energy storage, and a fuel cell as a complementary power source. Both the battery and the fuel cell supply power to the electric motor, which also operates as a generator during regenerative braking, recovering energy to recharge the battery. The simulation uses the Worldwide Harmonized Light Vehicles Test Cycle (WLTC) Class 1 speed and acceleration profiles, following global standards to evaluate performance and energy efficiency. This section details the structure of the models, their mathematical foundations, the simulation methodology, and the parameter management system integrated with a user-friendly Graphical User Interface (GUI).

2.1. Vehicle models

The power required for traction in heavy-duty FCEVs (wheeled or tracked) is determined by calculating resistance forces

acting on the wheels or tracks, using a 1,022-second driving cycle (Fig. 3), that incorporates low-to-medium speeds, with a maximum vehicle speed of 64.44 km/h. For wheeled vehicles, key resistances include rolling resistance (F_R, [N]), Eq. (1), aerodynamic drag resistance (F_L, [N]), Eq. (2), and acceleration resistance (F_a, [N]), Eq. (3), while tracked vehicles include for internal resistance (R_{in}, [N]), Eq. (4), and movement resistance (R_c, [N]), Eq. (5). These forces are computed using longitudinal motion equations and suitable parameters for heavy-duty vehicles to simulate energy consumption under dynamic conditions. The methodology integrates empirical coefficients and soil mechanics models, e.g., sinkage depth (z_0, [m]), track width (b, [m]), to ensure accurate power demand predictions for both vehicle types [3].

The rolling resistance is calculated using the vehicle mass (m, [kg]), gravitational acceleration (g, [m/s^2]), and rolling resistance coefficient (f_r, [-]), while the aerodynamic drag force is determined by considering air density (ρ, [kg/m^3]), vehicle frontal area (A, [m^2]), aerodynamic drag coefficient (C_W, [-]), and vehicle speed (V, [m/s]). The acceleration resistance is computed using the rotational inertia factor (λ, [-]), vehicle mass and vehicle acceleration (a, [m/s^2]). Additionally, while b represents the track width [m], n [-], k_c [kN/m$^{(n+1)}$] and k_ϕ [kN/m$^{(n+1)}$] are variables that depend on the type of terrain [3].

$$F_R = m \,.\, g \,.\, f_r \tag{1}$$

$$F_L = \frac{1}{2} \,.\, \rho \,.\, A \,.\, C_W \,.\, V^2 \tag{2}$$

$$F_a = \lambda \,.\, m \,.\, a \tag{3}$$

$$R_{in} = m \,.\, g \,(222 + 3 \,.\, V) \tag{4}$$

$$R_c = 2 \,.\, b \left(\frac{k_c}{b} + k_\phi\right)\left(\frac{{z_0}^{n+1}}{n+1}\right) \tag{5}$$

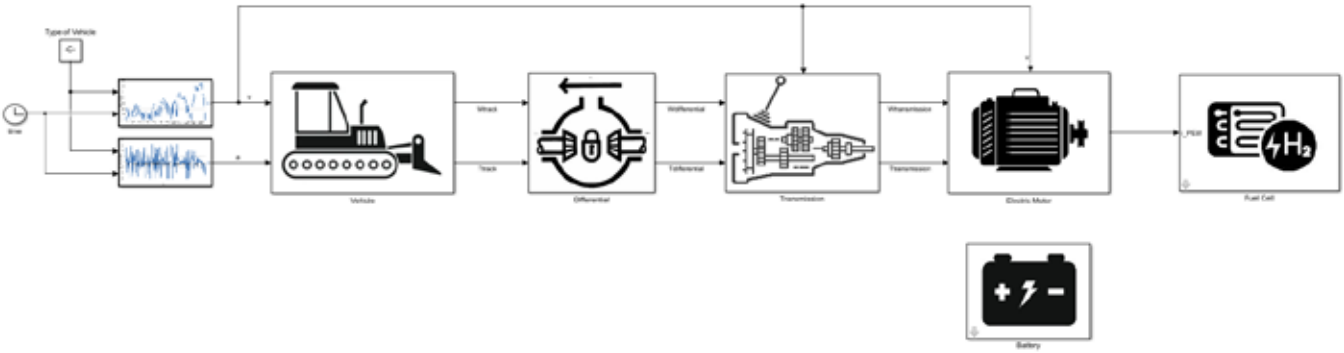

Fig. 1. Matlab/Simulink model for fuel cell electric tracked vehicle

2.2. Mathematical modeling of powertrain systems with energy conversion and storage

The power output of the electric motor (P_{EM}, [W]) can be calculated by dividing the total time-dependent resistance forces by the product of drivetrain efficiency (η_d, [-]) and transmission efficiency (η_t, [-]), then multiplying by the vehicle speed. For wheeled vehicles in Eq. (6), the power depends on the rolling resistance force, aerodynamic drag force and acceleration force:

$${P_{EM}}^w = \frac{(F_R + F_L + F_a)}{\eta_d \cdot \eta_t} \,.\, V \tag{6}$$

For tracked vehicles in Eq. (7), additional resistances are included: internal resistance and movement resistance, alongside F_L and (F_a) [1].

$${P_{EM}}^t = \frac{(R_{in} + R_c + F_L + F_a)}{\eta_d \cdot \eta_t} \,.\, V \tag{7}$$

The battery model estimates the state of charge (SOC, [%]) of the battery in FCEVs during simulation. The battery is represented as an energy source using the R_{int} model, which simplifies internal resistance and open-circuit voltage dynamics. The SOC, calculated based on the battery current (I_B, [A]) and battery capacity [A.h] for both wheeled and tracked vehicles, is formulated in Eq. (8). Here, $SOC(t)$ represents the instantaneous state of charge, while SOC_i represents the initial state of charge. The model integrates these parameters to simulate energy storage behavior under

varying operational demands [4].

$$SOC(t) = SOC_i - \frac{1}{Q_B}\int_0^t I_B \,.\, dt \tag{8}$$

The fuel cell model dynamically estimates the voltage output (V_{cell}, [V]), hydrogen consumption rate [g/s], and power output (P_{cell}, [kW]) in fuel cell electric vehicles. The cell voltage is derived from the Nernst potential (E_{Nernst}, [V]) and calculated for voltage losses: activation loss ($\eta_{activation}$, [V]) due to electrode reaction kinetics, ohmic loss (η_{ohmic}, [V]), from electrolyte and component resistance, and concentration loss ($\eta_{concentration}$, [V]) caused by mass transport limitations, as shown in Eq. (9). Hydrogen consumption depends on electrochemical reactions and current demand. The motor's power requirement, converted to current (I_{motor}, [A]), is fed into the fuel cell model per the energy management strategy, ensuring accurate dynamic response modeling under varying conditions [5].

$$V_{cell} = E_{Nernst} - \eta_{activation} - \eta_{ohmic} - \eta_{concentration} \tag{9}$$

2.3. Tracked and wheeled fuel cell vehicle simulator - PADSIP

A GUI designed for performance analysis and driving cycle simulations of tracked and wheeled FCEVs is illustrated in Fig. 2. Users can input parameters such as vehicle type, vehicle dynamic properties, battery configurations, powertrain, electric motor and fuel cell parameters, and energy management system limits to initiate simulations. Critical parameters such as terrain properties (e.g., moisture content [%], specific weight [kN/m^3], etc.) for tracked vehicles was particularly considered. Defined data via the "Confirm Parameters" option is processed through the "Run" command to generate results including vehicle performance, energy consumption, and system efficiency. This GUI provides a user-friendly interface for academic and industrial modeling studies, enabling detailed analysis of fuel cell vehicle dynamics under diverse operational and environmental conditions.

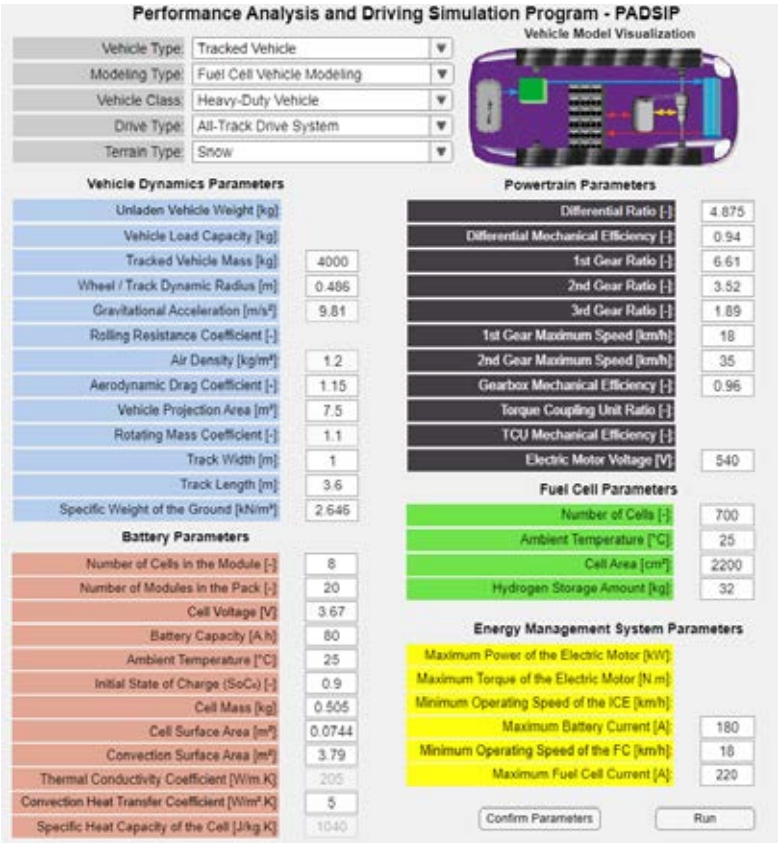

Fig. 2. Input parameters for performance analysis and driving simulation

3. RESULTS AND DISCUSSION

In the simulation study conducted under the WLTC Class 1 driving cycle, the performance of tracked and wheeled heavy-duty FCEVs was compared (Fig. 3). Although both vehicle types shared identical acceleration and speed profiles, the tracked vehicle exhibited 115-120% higher electric motor output power due to elevated terrain interaction resistances (e.g., internal and movement resistances). Additionally, the dominance of motion resistance over acceleration resistance in tracked systems significantly limited negative torque generation during regenerative braking, reducing energy recovery

efficiency. Both vehicle configurations utilized a battery system capable of delivering up to 180 A, which effectively met motor power requirements at *SOC* below 90%. As a result, their *SOC* levels and battery power profiles remained almost close. However, the tracked vehicle's higher energy demand was offset by its fuel cell, which operated at significantly higher power levels. This resulted in hydrogen consumption increasing by roughly 11 times compared to the other configuration.

It can be clearly stated that tracked vehicles demonstrate superior performance in challenging terrain conditions (e.g., rough paths, steep slopes, etc.), whereas they exhibit weaker range performance compared to wheeled vehicles, particularly when hydrogen consumption is considered [6]. To further explore this comparison and achieve more comprehensive results, future studies should integrate factors such as drive cycles, battery capacities, road condition parameters, and steering dynamics into simulation models.

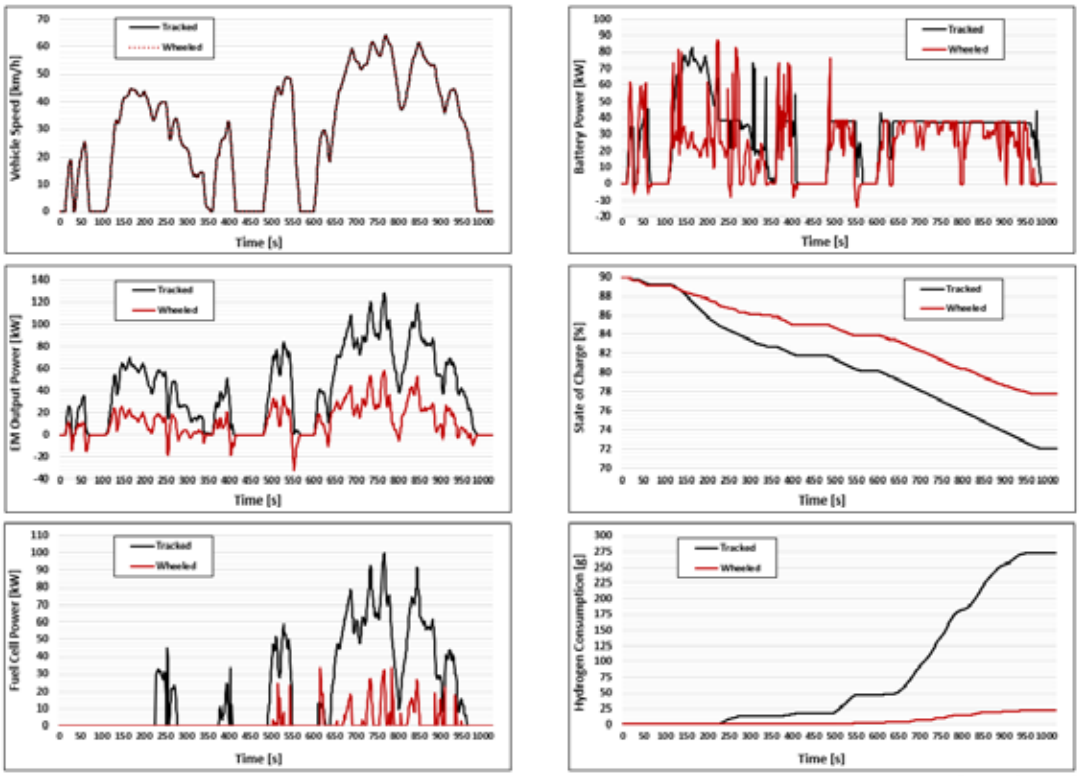

Fig. 3. Comparative analysis of speed, battery power, electric motor output power, state of charge, fuel cell power, and hydrogen consumption over time

4. CONCLUSIONS

This study has pointed the significant differences between wheeled and tracked hydrogen fuel cell electric vehicles in terms of energy consumption, performance, and hydrogen efficiency under the same operating conditions. Tracked vehicles demonstrated better performance in challenging and rough terrain conditions but faced considerably higher energy demand, particularly in terms of hydrogen consumption. The developed simulation tool, PADSIP, has proven to be an effective and reliable resource, enabling users to easily explore and optimize various configurations for detailed performance analyses. Future studies should aim to further enhance simulation models and expand their applicability to real-world conditions by incorporating different driving cycles, extended environmental parameters, and steering dynamics.

ABSTRACT

Methane decomposition is a promising pathway for hydrogen production that avoids CO_2 emissions while yielding valuable carbon nanomaterials. This study examines the catalytic performance of carbon supported nickel (Ni) activated catalyst with and without promoter in a microwave-assisted system. Two different carbon materials, namely mesoporous carbon (MC) and silicon carbide (SiC) were used as a support and palladium (Pd) is selected as a promoter. Different characterization techniques, including Raman spectroscopy, SEM/EDS, and TEM, revealed that Pd addition significantly improves the structural and catalytic properties of Ni-based catalysts. Pd enhances nickel dispersion, reduces particle agglomeration, and facilitates the formation of uniform carbon nanostructures. Activity tests demonstrated that while 40Ni@SiC achieved the highest methane conversion (80%) among SiC-supported catalysts, and 10Ni@MC exhibited the highest initial activity (89%) with rapid deactivation, Pd-modified catalysts like 50Ni1Pd@MC stood out for their exceptional stability, maintaining high activity for over 400 minutes. This underscores Pd's critical role in enhancing catalyst durability and enabling precise control over carbon morphology. By integrating Pd-promoted catalysts with microwave-assisted technology, this approach provides an efficient and sustainable method for methane decomposition, advancing clean hydrogen production and the synthesis of high-value carbon nanomaterials.

Keywords: Methane decomposition, microwave reactor, palladium, carbon nanomaterials.

1. INTRODUCTION

Fossil fuels play a critical role in meeting global energy demands but pose significant challenges, such as greenhouse gas emissions and resource depletion. These issues have driven the search for cleaner, sustainable alternatives, with hydrogen emerging as a particularly promising energy carrier. Hydrogen boasts high energy density, generates three times more energy than conventional fuels, and is efficiently utilized in fuel cells for heat and electricity production [1,2]. One innovative approach to clean hydrogen production is the catalytic decomposition of methane, a process that not only avoids greenhouse gas emissions but also produces valuable carbon nanomaterials. While catalysts like nickel (Ni), cobalt (Co), and iron (Fe) have been widely studied, Ni is preferred for its superior activity at moderate temperatures (500–700°C) [3]. However, methane decomposition faces challenges such as high reaction temperatures (above 750°C) and catalyst deactivation due to carbon deposition and metal sintering. To overcome these hurdles, microwave reactor technology has emerged as a game-changer, enabling rapid and volumetric heating, enhancing reaction rates, catalyst stability, and product selectivity. Studies have shown that microwave systems achieve superior conversion rates at lower temperatures compared to conventional heating, making them a sustainable and efficient alternative [4].However, application of MW technology on methane decomposition reaction is limited and it is still to open research. Palladium (Pd) has garnered significant attention as an effective promoter in catalytic systems, particularly for methane decomposition. Incorporating Pd into Ni-based catalysts significantly enhances both catalytic activity and stability. [5,6]. The integration of Pd into catalyst design, combined with the advantages of microwave-assisted technology, represents a significant breakthrough in methane decomposition. These advancements address the limitations of conventional systems, paving the way for efficient, sustainable hydrogen production while enabling the simultaneous synthesis of high-value carbon nanomaterials. The study conducted a detailed analysis of mesoporous carbon (MC) and silicon carbide (SiC)-supported nickel-based catalysts, highlighting the transformative effect of palladium (Pd) on their structural and physical properties and showing the effects of microwave on the catalysts acitivity.

2. EXPERIMENTAL

2.1. Catalyst Preparation

Mesoporous carbon and silicon carbide supported catalysts were prepared using the impregnation method, with improvements to ensure homogeneous metal distribution and minimize agglomeration, especially for high metal loadings (up to 50 wt%). Mesoporous carbon (99.95% purity, Sigma Aldrich) and silicon carbide (99.9% purity, Nanografi) were used as supports. Nickel(II) nitrate hexahydrate ($Ni(NO_3)_2 \cdot 6H_2O$, 97% purity, Sigma Aldrich) was used for nickel loading, while palladium(II) nitrate hydrate ($Pd(NO_3)_2 \cdot H_2O$, Sigma Aldrich) served as the promoter. The catalysts were labeled as XMP@S, where X represents the metal loading percentage (10–50%), M is the metal type (Ni), P is the promoter (Pd),

and S is the support material. Samples were calcined at 700°C for 5 hours under a nitrogen flow (10°C/min heating rate) and reduced at 400°C for 3 hours under a hydrogen flow.

2.2. Catalyst Characterization

The physical and structural properties of the synthesized catalysts were characterized using various techniques, such as Inductively Coupled Plasma (ICP) analysis, Nitrogen physisorption, X-ray diffraction (XRD), Scanning electron microscopy (SEM) and energy-dispersive spectroscopy (EDS), Raman spectroscopy, Transmission electron microscopy (TEM).

2.3. Catalytic Activity Studies

The catalytic activities of the synthesized catalysts were evaluated under continuous flow conditions using a microwave generator provided by SAIREM. The system operates at a frequency of 2.45 GHz with a maximum power capacity of 2 kW. Temperature control during reactions was achieved by adjusting the power level of the microwave generator, and temperature measurements were conducted using an infrared pyrometer (Raytek M13).

3. RESULTS AND DISCUSSION

3.1. Characterization of synthesized catalysts

X-ray diffraction analyses confirmed successful reduction, showing distinct peaks for amorphous carbon and metallic nickel phases in MC-supported catalysts (10%–50% metal loadings) and metallic nickel alongside SiC structures in SiC-supported catalysts. Notably, SiC-supported catalysts exhibited larger crystal sizes compared to their MC counterparts. SEM and EDS provided further insights into surface morphology and elemental distribution. While the 50Ni@SiC catalyst displayed nickel agglomeration at high metal loadings despite good dispersion, the 50Ni@MC catalyst suffered from significant agglomeration and uneven particle distribution. The addition of Pd (50Ni1Pd@MC) substantially improved these characteristics, achieving greater particle homogeneity, reducing agglomeration, and enhancing nickel dispersion. These findings underscore the pivotal role of Pd in tailoring catalyst structure and morphology. By improving nickel dispersion and reducing agglomeration, Pd enhances the performance potential of nickel-based catalysts, demonstrating its critical importance in the design of advanced catalytic systems for methane decomposition and other applications.

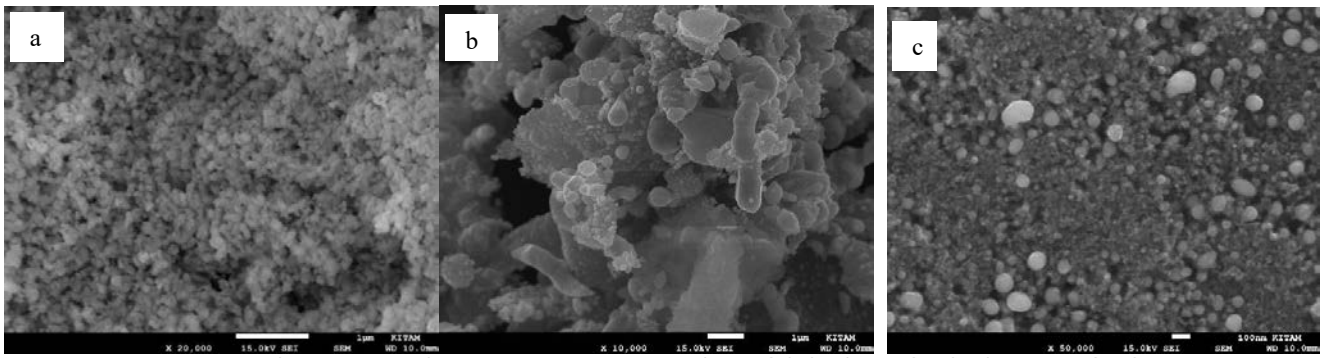

Fig.1. SEM images of the synthesized catalyst a)50Ni@SiC, b)50Ni@MC, c)50Ni1Pd@MC

3.2. Catalytic Activity Results

The catalytic activity of synthesized catalysts was evaluated in a microwave-heated reactor under methane flow at 500°C. Among the Ni@SiC catalysts, 50Ni@SiC achieved the higher activity and stability than the lowest Ni loaded 10Ni@SiC catalyst (Fig.2a), whereas, for Ni@MC catalysts, the 10Ni@MC catalyst exhibited the highest initial activity (89%) but suffered from rapid deactivation (Fig.2b). Higher metal loadings resulted in more prolonged, albeit less active, catalytic behavior due to changes in crystal size and surface area. The addition of Pd as a promoter significantly improved catalyst stability and activity. Pd-modified catalysts such as 50Ni1Pd@MC, 30Ni1Pd@MC, and 50Ni15Pd@MC exhibited enhanced durability, with 50Ni15Pd@MC maintaining high activity for 400 minutes under reaction conditions (Fig.2c). Pd facilitated better nickel dispersion, reduced agglomeration, and enhanced methane conversion efficiency. The addition of Pd as a promoter significantly enhanced catalyst performance and stability. These results highlight the critical role of Pd in enhancing the stability and efficiency of nickel-based catalysts, emphasizing its importance in optimizing catalyst design for effective methane conversion in microwave-assisted systems.

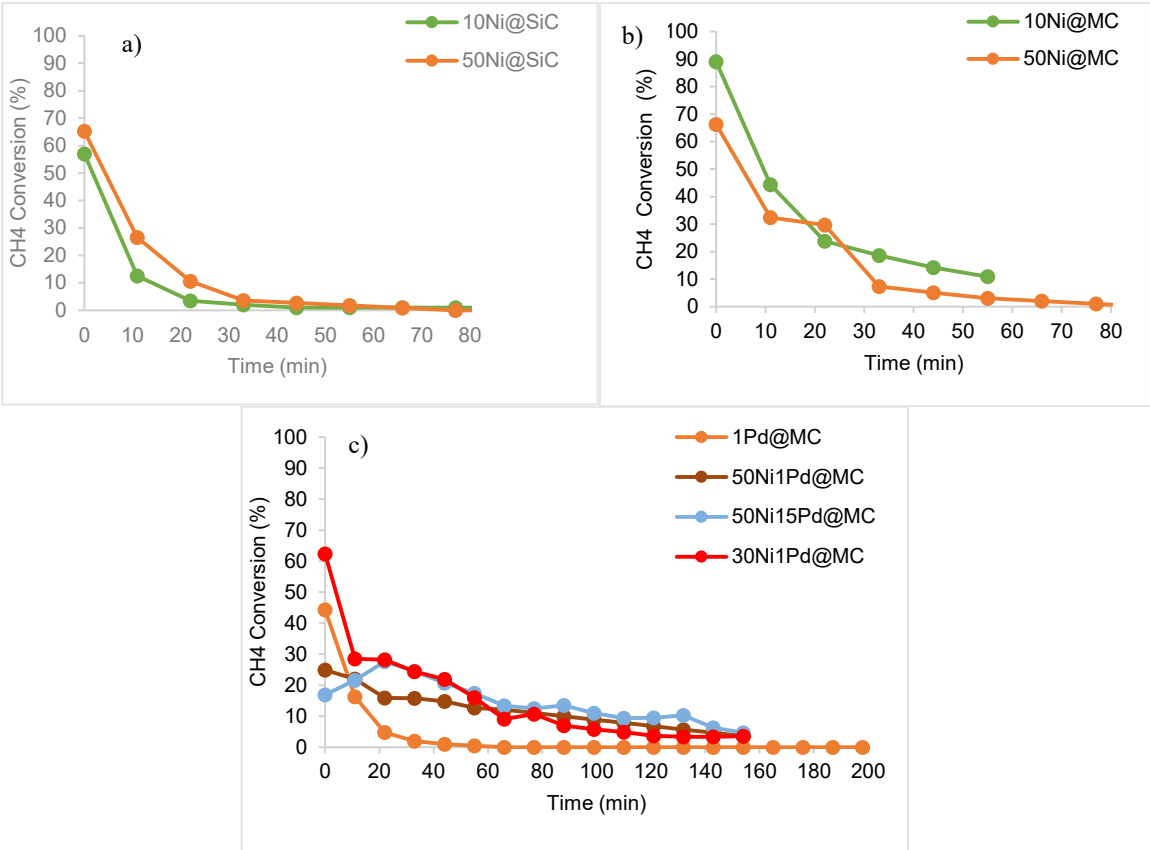

Fig.2. Catalytic activity results of microwave heated system a) MC support, b) SiC support, c) Palladium promoted catalysts

3.3 Characterization of post-reaction catalysts

The post-reaction properties of nickel (Ni) and palladium (Pd) catalysts were analyzed using Raman spectroscopy, SEM/EDS, and TEM, highlighting the significant impact of Pd incorporation. Raman spectroscopy revealed differences in graphitization and defect density among the catalysts, while SEM/EDS demonstrated that carbon morphology—ranging from filamentary to bamboo-shaped and nanotube-like structures—was influenced by metal loading, reaction conditions, and catalyst composition (Fig.3). Notably, the addition of Pd promoted the formation of uniform carbon structures and significantly enhanced catalytic stability. TEM analysis further confirmed the presence of carbon nanostructures on Pd-modified catalysts, showing that filament dimensions were closely linked to Ni particle sizes. These results underscore the critical role of Pd in improving carbon uniformity, stabilizing the catalyst, and optimizing catalytic performance, offering valuable insights into the structural evolution of catalysts for advanced methane decomposition applications.

4. CONCLUSIONS

This study focuses on the synthesis and performance evaluation of mesoporous carbon (MC) and silicon carbide (SiC)-supported nickel (Ni) and palladium (Pd) catalysts for methane decomposition in microwave-assisted systems, with a particular emphasis on the pivotal role of Pd. Catalytic activity results revealed that Pd addition significantly enhanced both activity and stability. Pd-promoted catalysts, such as 50Ni1Pd@MC, sustained higher activity over extended reaction durations compared to non-promoted counterparts. Among the catalysts, 40Ni@SiC achieved the highest methane conversion (80%) within the Ni@SiC group, though its stability declined rapidly over time. For MC-supported catalysts, 10Ni@MC exhibited the highest initial activity (89%) but experienced rapid deactivation. In contrast, Pd-modified catalysts demonstrated superior performance, with 50Ni1Pd@MC retaining activity for up to 400 minutes under reaction conditions. Pd's ability to promote the growth of uniform carbon nanostructures, mitigate carbon agglomeration, and prevent sintering greatly enhanced catalytic efficiency. These findings highlight Pd's critical role in driving sustainable hydrogen production while simultaneously enabling the efficient synthesis of valuable carbon nanomaterials in energy-efficient catalytic systems.

ABSTRACT

This study performed a comprehensive technical, economic, and environmental evaluation of a hybrid green hydrogen production plant integrating photovoltaic (PV) panels and wind turbines. The analysis focused on comparing various hybrid configurations both with one another. The optimization of the hybrid systems was conducted using Simulink and the Response Surface Methodology (RSM), aiming to determine the most cost-effective configuration for achieving an optimal levelized cost of hydrogen (LCOH). The findings revealed that the optimal hybrid system configuration consists of a 1 MW PV, 2,82 of WT and 1 MW electrolyzer system. This configuration demonstrated the optimal energy cost, with an LCOH of 4,99 $/kgH2. Sensitivity analyses were also carried out to evaluate the influence of critical parameters, interest rates, and system efficiency. These analyses provided valuable insights into the robustness and adaptability of the system under varying conditions, highlighting the potential for further optimization and scalability in real-world applications.

Keywords: Levelised cost of hydrogen, optimization, response surface methodology, optimization

1. INTRODUCTION

The integration of hybrid renewable energy systems with hydrogen production represents a significant advancement in the pursuit of sustainable energy solutions. This approach enhances the reliability and efficiency of energy systems while addressing the intermittency challenges associated with renewable energy sources such as solar and wind. By coupling hydrogen production with hybrid systems, it is possible to create a versatile energy storage solution that can buffer against fluctuations in energy supply and demand, thereby facilitating a more stable energy grid [1].

One of the primary advantages of integrating hydrogen production into hybrid renewable systems is the ability to utilize excess energy generated during peak production times. For instance, when solar or wind resources are abundant, the surplus energy can be directed towards electrolysis to produce hydrogen. This hydrogen can then be stored and used later when energy demand exceeds supply, effectively acting as a long-term energy storage solution [2],[3]. Such integration maximizes the utilization of renewable resources and mitigates issues of energy waste that can occur when production exceeds immediate consumption needs [4].

Moreover, the hybridization of renewable energy systems with hydrogen production can significantly enhance the economic viability of these systems. Recent advancements in electrolyzer and fuel cell technologies have reduced costs and improved efficiencies, making hydrogen production more competitive with traditional energy sources [5],[6]. For example, studies have shown that hybrid systems combining solar, wind, and hydrogen production can achieve lower levelized costs of energy and hydrogen compared to systems relying solely on conventional energy sources [7],[8].

The operational flexibility offered by hybrid renewable systems with hydrogen production is another critical advantage. These systems can be designed to operate in various configurations, allowing for tailored solutions that meet specific energy demands and resource availability [9]. For instance, in off-grid applications, hybrid systems can provide continuous power supply to remote locations by integrating hydrogen storage with battery systems, thereby ensuring reliability even in the absence of direct renewable energy generation [10].

Recent studies emphasize that one of the most critical cost determinants in green hydrogen production is the cost of renewable energy. For instance, it has been observed that the production cost of green hydrogen varies significantly depending on the type of renewable energy source utilized. The integration of high-capacity renewable energy sources, such as wind and solar power, facilitates the efficient operation of electrolyzers, thereby substantially reducing the levelized cost of hydrogen [11],[12].

A comprehensive review of the literature on hybrid renewable energy systems integrated into hydrogen production plants reveals that optimization studies are often conducted using oversimplified methodologies and basic formulas. Such approaches may limit the depth of analysis and the potential for accurately capturing the complexities of these systems. Additionally, research focusing specifically on hybrid configurations involving PV and wind energy systems is relatively scarce, highlighting a gap in the existing body of knowledge.

In this study, a detailed and comprehensive approach was adopted to address these limitations. A hybrid system comprising PV panels, wind turbines, and an electrolyzer was modeled extensively within the Simulink environment. The

model incorporated technical, economic, and operational parameters to ensure a realistic representation of the system. System sizing and configuration optimization were performed using the Response Surface Methodology (RSM), a technique less frequently employed in the literature but capable of capturing complex interactions between system variables and delivering robust optimization results.
Furthermore, sensitivity analyses were conducted to evaluate the effects of various critical variables, such as efficiency, capacity factors, economic parameters, and operational conditions, on the system's performance. These analyses provided valuable insights into the resilience and adaptability of the hybrid system under different scenarios. By integrating detailed modeling with advanced optimization techniques, this study offers a significant contribution to literature and demonstrates a novel approach to designing and optimizing hybrid renewable energy systems for hydrogen production.

2. MATERIALS AND METHODS

In this study, a comprehensive mathematical modeling of a off-grid system comprising PV panels, wind turbines, a PEM electrolyzer, and a compressor was developed and implemented in the Matlab-Simulink environment, as illustrated in Figure 1. Unlike most models in literature, which often rely on simplified equations, our approach employs detailed mathematical models to enhance accuracy and reliability. An economic model was integrated with the mathematical framework to calculate the Levelized Cost of Hydrogen, and based on system variables, an optimization model was developed using Response Surface Methodology to determine the most suitable system size. Finally, a sensitivity analysis was conducted to examine the influence of key variables on the system's performance and economic viability.

2.1. Mathematical Modelling

The electrical characteristics of the PV module and the equivalent circuit of a PV cell with a single diode, on which the mathematical model is based, are presented in Figure 2.

Spesifications	Value	Unit
Open Circuit Voltage (Voc)	32.8	V
Short Circuit Current (Isc)	8.1	A
Number of Cells	54	Adet
Module Area	1.222	m²
Maximum Power Current (Imp)	7.7	A
Maximum Power Voltage (Vmp)	26	V

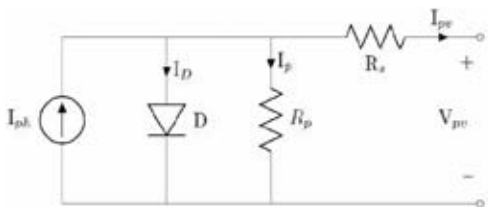

Fig. 2. Spesifications and single-diode model of the modelled PV

All the equations for pv modelling are given below:

Photon Current

$$I_{ph} = [I_{sc} + K_i(T - T_n)]x\left(\frac{G}{Gn}\right)$$

Reverse Sat. Cur.

$$I_{rs} = \frac{I_{sc}}{e^{\left(\frac{qV_{oc}}{nN_sKT}\right)} - 1}$$

Saturation Cur.

$$I_0 = I_{rs}\left[\frac{T}{Tn}\right]^3 e^{\left[\frac{qE_{go}\left(\frac{1}{T_n}-\frac{1}{T}\right)}{nK}\right]}$$

I shunt

$$I_{sh} = \frac{V + IR_s}{R_{sh}}$$

I output

$$I = I_{ph} - I_0\left[e^{\frac{q(V+IR_s)}{nKNT}} - 1\right] - I_{sh}$$

The specifications of the turbine used in the study are presented in Table 2.

Table 1. Spesifications of the modelled WT

Manufacturer	LEITWIND AG / SPA (Italy)	**Number of Blades**	3
Model	LTW77	**Maximum Rotor Speed**	18 U/min
Cut-in Wind Speed	3 m/s	**Hub Height**	80 m
Cut-out Wind Speed	25 m/s	**Power Output**	1000 kW
Rotor Area	4.608 m²	**Blade Pitch Angle (β)**	0
Rotor Diameter	76,6 m		

All the equations for wind turbine modelling are given below:

Electrical Output

$$P_m = \frac{1}{2} Cp(\lambda_i)\rho A V^3$$

Performance Coefficent

$$Cp = C_1 e^{(C_2\lambda_i)} + C_3 e^{(C_4\lambda_i)}$$

Speed Rate

$$\frac{1}{\lambda_i} = \frac{1}{\lambda + 0.08\beta} - \frac{0.035}{1+\beta^3}$$

Speed Constant

$$\lambda = \frac{w_r R}{V}$$

Figure 3 illustrates the equivalent circuit structure of a single PEM electrolyzer cell. This circuit model enables the analysis of current-voltage relationships among the components representing the internal dynamics of the PEM electrolyzer [13].

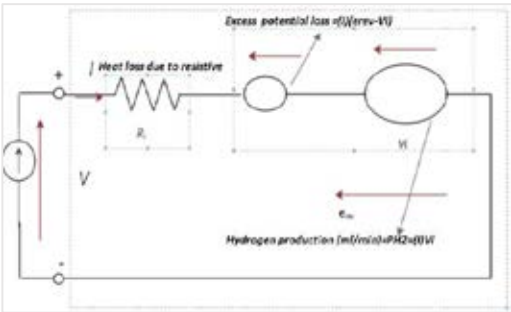

Fig. 3. The modelled PEM electrolyzer model

All the equations for PEM electrolyzer modelling are given below:

Current-Voltage

$$V(T,P) = E_{rev}(T,P) - E_{rev}(T,P)e^{\frac{5I}{0.02}} + I.R_i(T,P)$$

Reversible Voltage

$$E_{rev}(T,P) = E_{rev_0} + \frac{R(273+T)}{2F} ln\left(\frac{P}{P_0}\right)$$

H2 Rate

$$v_H = \frac{60000 v_m I}{2F}$$

$$V(T,P) = \begin{bmatrix} 0 & V \le E_{rev}(T,P) \\ \frac{1}{R_i(T,P)}V - E_{rev}(T,P) & V \ge E_{rev}(T,P) \end{bmatrix}$$

İdeal Voltage

$$V_i = \frac{\Delta G}{2F}$$

Molar volume

$$v_m = \frac{R(273+T)}{P}$$

Electrolyzer resistant

$$R_i(T,P) = R_{i_0} + k ln\left(\frac{P}{P_0}\right) + dR_T(T - T_0)$$

$$\Delta G = 285.84 - 163.2(273+T)$$

The specifications of the electrolyzer used in the study are presented in Table 3.

Table 2. Spesifications of the modelled WT

Property	Value	**Property**	Value
Nominal Current Density	1-2 A cm⁻²	**Voltage Efficiency (LHV)**	50 - 68 %
Voltage Range	1.4-2.5 V	**Size**	1 MW
Cell Pressure	<30 bar	**Electrode Area**	1500 cm²

The equations used for calculating the LCOH are provided below:

Annualized Cost

$$ACS(\$) = \sum_{i=1}^{n} N_i \times [(CAPEX_i + RC_i \times F_i(rdr, L_i, y_i)) \times CRF(rdr, R) + OPEX_i]$$

Capital Recovery Cost

$$CRF = \frac{r_{dr}\,(1+r_{dr})^R}{(1+r_{dr})^R - 1}$$

LCOH

$$\mathrm{LCoH}\left(\frac{\$}{\mathrm{kg}}\right) = \frac{\mathrm{ACS}}{\mathrm{AP}_{\mathrm{H_2}}}$$

NPV

$$F = \sum_{n=1}^{Q_i} \frac{1}{[1+ir]^{L_i \times n}}$$

3. RESULTS AND DISCUSSION

The Response Surface Methodology (RSM) was utilized to analyze the interactions among 5 parameters: PV and wind turbine sizes, electrolyzer temperature, pressure, and current density, in relation to the cost of hydrogen production. A Box-Behnken design was employed, and the lower and upper limits of the parameters are provided in Table 3.

Table 3. Design parameters of the Response surface methodology

	Pv Size (MW)	WT Size (MW)	Pressure (Bar)	Temperature (^{0}C)	Current Density (A/cm2)
Lower Limit	1	1	5	50	1000
Upper Limit	5	5	30	80	3500

The Pareto chart given in Figure 4 highlights that current density (E) is the most influential factor affecting the LCOH, with a standardized effect value far exceeding those of other parameters. Additionally, interaction terms involving current density (EE) and wind turbine size (BB) also demonstrate significant impacts. This underlines the critical role of optimizing these variables to achieve cost reductions.

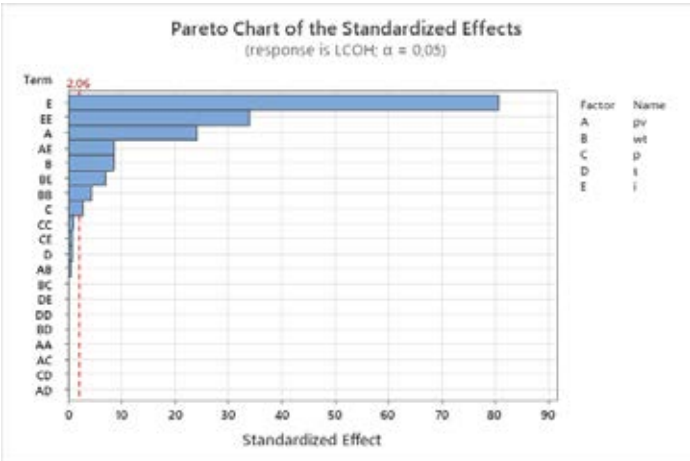

Fig. 4. Pareto Analysis of Factor Effects on LCOH

The regression analysis further emphasizes the importance of specific parameters. Among the linear terms, PV size, wind turbine size, and current density are statistically significant (P-value < 0.05), with current density having the most pronounced effect. Quadratic terms also reveal that the square of current density is highly significant, indicating a nonlinear relationship with LCOH. Furthermore, interaction terms such as those between PV size and current density, and wind turbine size and current density, are shown to be statistically meaningful.

The regression equation for LCOH is:

LCOH = 19.60 + 1.792 * PV + 0.510 * WT - 0.0516 * P + 0.0040 * T - 0.010191 * I + 0.0019 * PV² + 0.0952 * WT² + 0.000503 * P² - 0.000047 * T² + 0.000002 * I² - 0.0197 * PV * WT + 0.00019 * PV * P + 0.00002 * PV * T - 0.000437 * PV * I + 0.00090 * WT * P + 0.00046 * WT * T - 0.000354 * WT * I + 0.000008 * P * T + 0.000007 * P * I - 0.000001 * T * I

Where, PV and WT are the size of pv and WT, T is temperature, P is pressure, and I is current density of electrolyzer.

The optimization results indicate that the minimum LCOH achieved is 4.99, with optimal parameter settings of PV size at 1 MW, wind turbine size at 2.82 MW, pressure at 26.46 bar, temperature at 80°C, and current density at 3070.71 A/cm². The model shows a high desirability of 1.00, confirming the optimal solution's reliability. The predicted LCOH has a standard error of 0.269, with a 95% confidence interval of (4.44; 5.54) and a 95% prediction interval of (4.23; 5.75), demonstrating strong model accuracy and prediction capability.
Using the optimized parameters obtained from the design process, the LCOH was calculated in Simulink for varying discount rates. Figure 5. illustrates the relationship between the discount rate and LCOH. As the discount rate increases from 4% to 12%, the LCOH shows a consistent upward trend, starting at \$3.87/kgH_2 at a 4% discount rate and rising to \$6.82/kgH_2 at a 12% discount rate.

Fig. 5. The LCOH variation with changing discount rate

With advancements in technology, the costs of renewable energy components are continuously decreasing. In line with this trend, an analysis was conducted in Simulink to evaluate the impact of reduced initial expenditures on the LCOH. The results show that as the initial expenditure rate decreases from 1 to 0.8, the LCOH significantly drops from \$5.22/kgH_2 to \$4.18/kgH_2. This highlights the direct correlation between technological advancements, reduced costs, and the economic feasibility of hydrogen production systems.

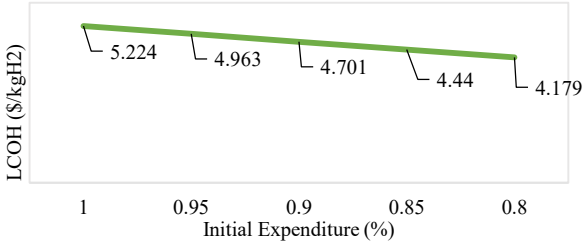

Fig. 6. The LCOH variation with changing initial expenditure

4. CONCLUSIONS

The size optimization was performed using the RSM for a system comprising PV and WT units, as well as an electrolyzer. The optimization considered key parameters such as PV and WT capacities, electrolyzer pressure, temperature, and current density. The results indicate that the optimal configuration includes a 1 MW PV, 2.88 MW WT, an electrolyzer pressure of 26.46 bar, a temperature of 80°C, and a current density of 3070.71 A/cm², achieving an LCOH of \$4.99. The analysis was conducted using Simulink, which allowed for a detailed and dynamic modeling approach.
Unlike many studies in the literature that rely on simplified formulas, our approach incorporated detailed and comprehensive equations to enhance the accuracy of the results. Furthermore, sensitivity analyses were conducted to evaluate the impact of various parameters on system performance.
For future work, integrating biogas into the system to develop a triple-hybrid configuration could be a promising direction. Additionally, optimizing the production of other power-to-X gases, such as e-methane and e-methanol, could further expand the scope and applications of such systems.

ABSTRACT
This study integrates Geographic Information System (GIS), Analytical Hierarchy Process (AHP), and the TOPSIS method within the Multicriteria Decision-Making (MCDM) framework to assess the potential for green hydrogen production in the Southern Marmara region of Turkey. By evaluating technical, economic, and environmental criteria across 12 sub-criteria, suitable sites for solar and wind-based green hydrogen production were identified. Results reveal that 44636 ha of the study area, particularly in western and northern Balıkesir, is highly suitable for constructing solar-wind powered green hydrogen plants. These identified locations hold significant potential for fostering the green hydrogen industry in the region. Furthermore, the applied methodology can be adapted for assessing green hydrogen production potential in other regions, contributing to national and global green hydrogen roadmaps. This approach underscores the importance of combining advanced spatial analysis with decision-making techniques to support sustainable energy strategies.
Keywords: Hydrogen, Site selection, TOPSIS, AHP

1. INTRODUCTION

The selection of optimal locations for renewable energy projects, particularly in wind and solar energy, plays a crucial role in advancing sustainable energy systems. Multi-Criteria Decision Making (MCDM) methods are widely utilized for site selection, allowing experts to evaluate and balance various conflicting factors while prioritizing alternatives across multiple dimensions. Among these, AHP is particularly notable for its ability to decompose complex problems into a hierarchical structure, facilitating the evaluation of criteria and sub-criteria through systematic pairwise comparisons. [1],[2]. This approach has been particularly effective in renewable energy site selection, as demonstrated by research on wind energy projects [3],[4]. AHP's strength lies in determining the relative importance of various criteria, which is critical for prioritizing locations based on their suitability for energy production. However, AHP has limitations, such as the potential for inconsistency in pairwise comparisons and subjective biases in weight assignments [5].

TOPSIS, in contrast, mitigates some of these challenges by ranking alternatives based on their geometric proximity to an ideal solution—defined as the most favorable outcome across all criteria. This method not only offers a clear range of options but also enhances decision-making by incorporating relative proximity to the ideal scenario [6]. One advantage of TOPSIS over AHP is its ability to handle a larger number of criteria without requiring extensive pairwise comparisons, making it suitable for complex scenarios involving numerous factors such as environmental impact, cost-effectiveness, and social acceptability [7].

On the other hand, site selection for hydrogen production facilities involves additional challenges due to the complexity of factors involved. While AHP and TOPSIS are commonly used, many studies rely on a narrow set of criteria, potentially neglecting key environmental, social, and economic considerations critical to the sustainability of hydrogen production sites [8]. This limitation can lead to suboptimal decisions that fail to align with broader sustainability goals or community needs. Furthermore, inadequate integration of geographical and spatial data in MCDM analyses remains a significant gap. Geographic Information Systems (GIS) are essential for improving site selection methodologies, yet many studies continue to use conventional AHP and TOPSIS approaches without fully leveraging GIS capabilities. As a result, geographical factors such as proximity to renewable energy sources, infrastructure availability, and environmental constraints are often underrepresented in the analysis [9]. Combining GIS with MCDM techniques like AHP and TOPSIS can provide a more comprehensive understanding of site suitability and enhance decision-making outcomes.

Building on these considerations, Messaoudi et al. (2019) integrated AHP with GIS for selecting sites for wind-powered hydrogen refueling stations, showcasing the potential of combining spatial analysis with MCDM methods. Despite these advancements, the application of such methods specifically for green hydrogen production remains limited. Future research should focus on refining these methodologies to incorporate broader sustainability metrics, stakeholder engagement, and geographic analysis for identifying optimal locations for hydrogen facilities [10]. Additionally, studies such as Jozaghi et al. (2018) demonstrate the effectiveness of MCDM techniques in site selection for dams, emphasizing the potential for analogous applications in hydrogen production. However, criteria unique to hydrogen, including renewable energy accessibility, infrastructure readiness, and environmental considerations, warrant further investigation

to address existing gaps and strengthen site selection frameworks in this emerging field [11].

A significant body of literature has examined the costs associated with PV-wind-driven hydrogen production, both under current conditions and in future projections. These studies often focus on regions with optimal meteorological conditions, such as high solar radiation or wind potential, to showcase the feasibility of hydrogen production. By addressing the existing gaps in the literature, this study aims to serve as a valuable resource for policymakers involved in planning and decision-making processes regarding green hydrogen production facilities in Turkey. Given the global emphasis on reducing dependence on hydrocarbons, our research highlights the potential of blending hydrogen with natural gas pipelines as a promising strategy. Turkey's strategic geographical location, acting as a critical bridge between energy-producing and energy-consuming regions, further strengthens its role as a prospective energy hub. Capitalizing on its abundant renewable energy resources for hydrogen production and integrating this hydrogen into natural gas networks could provide substantial benefits. This transition holds considerable importance not only for Turkey but also for Europe's broader efforts toward a sustainable and renewable energy future. In this context, Balıkesir was selected as the focus area for this study due to the ongoing development of a hydrogen production facility project in the region. By exploring this potential, our research aims to contribute significantly to the strategic planning of green hydrogen infrastructure and its integration into existing energy systems.

2. MATERIALS AND METHODS

In this study, the criteria weights were first determined using the Analytical Hierarchy Process (AHP) method. Subsequently, the criteria were rated and evaluated within ArcMap, and unsuitable locations were excluded from the analysis. Based on these evaluations, a Weighted Overlay Analysis was conducted to identify suitable areas along with their respective suitability levels. The coordinate data, originally in point format, were then converted to polygons. Polygons larger than 10 hectares were selected and exported to Excel for further processing. A TOPSIS analysis was then applied to these polygons to identify the most suitable ones. Finally, the selected polygons were re-mapped in ArcMap and visualized on Google Earth to provide a comprehensive spatial representation.

2.1. Multi-Criteria Analysis

The Multi-Criteria Analysis (MCA) was conducted using the first AHP, which is widely applied to assign weights to various criteria.
The AHP methodology follows these steps:

The decision problem is defined, and the goal is clearly identified. A hierarchical structure is created, encompassing the goal, criteria, and sub-criteria. Saaty's 9-point scale [12] is performed for comparison matrix. A pairwise comparison matrix is constructed using Saaty's scale (Eq. 1),

$$A(n_i x n_j) = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} \end{bmatrix} \quad (1)$$

The pairwise comparison matrix is normalized using Eq. 2:

$$N_{ij} = \frac{a_{ij}}{\sum_{i=1}^{n} a_{ij}} \quad (2)$$

where i,j=1,2,…,n, The row averages of the normalized matrix form the priority vector.

Consistency is checked by multiplying the pairwise comparison matrix with the priority vector to obtain the weighted sum matrix. Each element of the weighted sum matrix is divided by its corresponding priority vector to calculate consistency values. The average of these values provides λi. The Consistency Index (CI) is calculated using Eq. 3, and the Consistency Ratio (CR) is determined using Eq. 4. A CR value below 0.1 indicates acceptable consistency.

$$Concistency\ Index\ (CI) = \frac{\lambda_{max} - n}{n - 1} \quad (3)$$

$$Concistency\ Ratio\ (CR) = \frac{CI}{RI} \quad (4)$$

Table 1. Random inconsistency index (RI) values

n	1	2	3	4	5	6	7	8	9	10
RI	0	0	0.58	0.9	1.12	1.24	1.32	1.41	1.45	1.49

TOPSIS Methodology:
The goal, alternatives, and criteria are defined. A decision matrix is constructed, where the features of alternatives based on the criteria are represented.

Alternatives	Features
a1	y11 y12 ... y1k
a2	y21 y22 ... y2k
a3	yn1 yn2 ... ynk

The normalized decision matrix is calculated using Equation (5):

$$\boldsymbol{Z_{ij}} = \frac{\boldsymbol{y_{ij}}}{\sqrt{\sum_{i=1}^{n} \boldsymbol{y_{ij}^2}}} \quad \boldsymbol{i = 1, \dots, n; j = 1, \dots, k} \tag{5}$$

The weighted normalized decision matrix is determined using Equation (6), where wij represents the weight of the jth criterion

$$\boldsymbol{X_{ij}} = \boldsymbol{w_{ij}\ x\ Z_{ij}} \quad \text{i=1, …, n;j=1, …, k} \tag{6}$$

The maximum and minimum values for each column are identified:

$$\begin{aligned} \mathbf{A}^* &= \{\mathbf{x_1^*}, \mathbf{x_2^*}, \dots, \mathbf{x_k^*}\} \ (\textbf{max values}) \\ \mathbf{A}^- &= \{\mathbf{x_1^-}, \mathbf{x_2^-}, \dots, \mathbf{x_k^-}\} \ (\textbf{min values}) \end{aligned} \tag{7}$$

The distance from the positive ideal solution (PIS) is calculated using Equation (8):

$$\boldsymbol{S_i^*} = \sqrt{\sum_{i=1}^{k} \left(\boldsymbol{x_{ij} - x_j^*}\right)^2} \quad \boldsymbol{i = 1, \dots, n} \tag{8}$$

The distance from the negative ideal solution (NIS) is calculated using Equation (9):

$$\boldsymbol{S_i^-} = \sqrt{\sum_{j=1}^{k} \left(\boldsymbol{x_{ij} - x_j^-}\right)^2} \quad \boldsymbol{i = 1, \dots, n} \tag{9}$$

The relative closeness to the ideal solution is determined using Equation (10):

$$\boldsymbol{C_i^*} = \frac{\boldsymbol{S_i^-}}{\boldsymbol{S_i^- + S_i^*}} \quad \boldsymbol{0 \le C_i^* \le 1,\ \ i = 1, \dots, n} \tag{10}$$

Alternatives are ranked based on C_i^* values, where the alternative closest to the ideal solution has the highest priority.

3. RESULTS AND DISCUSSION

Figure 3 illustrates the maps generated for each criterion using Euclidean Distance in ArcMap. These maps facilitate the identification of spatial patterns and relationships within the analyzed data, enabling more informed and data-driven decision-making processes.

The land suitability map in Fig. 2. identifies the most optimal location for establishing a solar-wind-based hydrogen production plant within the Balıkesir region. The total suitable area is calculated to be 44636 hectares. This map was created using ArcMap's Weighted Overlay Analysis, which integrates criteria weighted through the AHP. The map is color-coded based on the degree of suitability, providing a visual representation of varying levels of appropriateness across the region. It is observed that the western and northern parts of Balıkesir exhibit higher suitability, making these areas particularly favorable for the proposed plant's development.

The TOPSIS analysis was utilized alongside the AHP-based weighted criteria to identify the most suitable site for a wind-solar-based hydrogen production plant in the Balıkesir region. TOPSIS enabled the ranking of potential sites by calculating the relative closeness of each site to the ideal solution.

The analysis revealed that Site X emerged as the most suitable location, achieving the highest TOPSIS score of 0.867115. This site demonstrated the closest proximity to the ideal solution, indicating its superior alignment with the weighted 12 criteria. Additionally, the analysis identified the top 25 most suitable locations, as presented in Figure 3, providing a comprehensive ranking for site selection. This highlights the effectiveness of the integrated AHP-TOPSIS approach in systematically evaluating site suitability for the proposed hydrogen production plant.

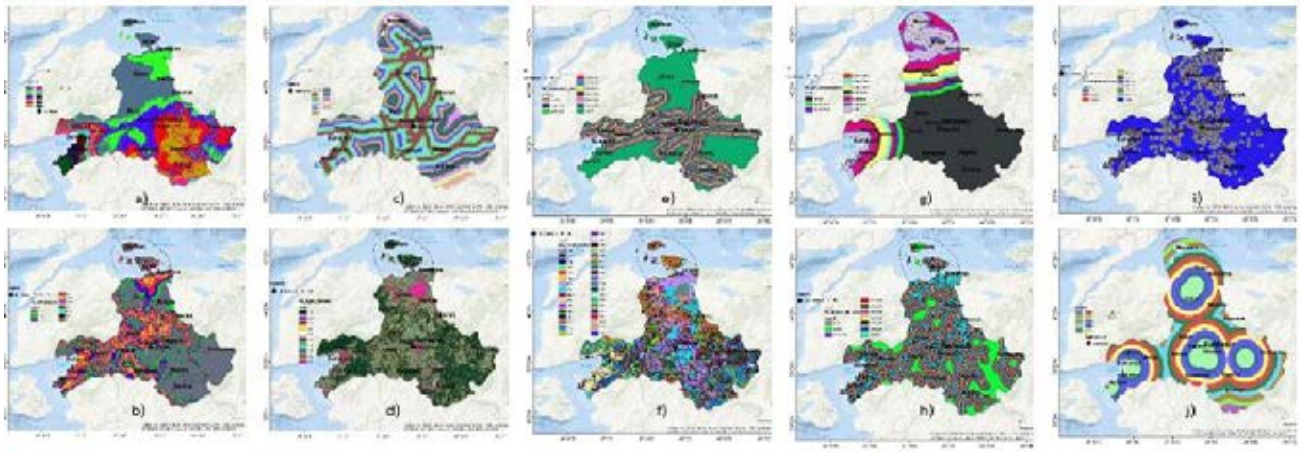

Fig. 1. Euclidean distance analyses of selection criteria for Balıkesir in ArcMap: The criteria include a) solar radiation, b) wind potential, c) distance to electrical power lines, d) slope, e) distance to fault lines, f) land use, g) distance to the sea, h) distance to rivers, i) distance to settlements, and j) distance to industrial zones

Fig. 2. Weighted overlay analysis for site selection in Balıkesir using AHP

Fig. 3. Top 25 most suitable locations identified through TOPSIS analysis

To further illustrate the findings, the top 25 most suitable locations identified through the analysis were visualized using Google Earth (Figure 4). This graphical representation provides a geospatial perspective, enabling a clear understanding of the spatial distribution of the most optimal sites across the Balıkesir region.

Fig. 4. Visualization of the top 25 most suitable locations using Google Earth.

4. CONCLUSIONS

This study utilized an integrated approach combining AHP and TOPSIS methods to determine the most suitable location for the installation of a solar-wind-powered hydrogen production plant. The AHP method was employed to calculate the criteria weights, while TOPSIS facilitated the ranking of alternatives based on their alignment with these weighted criteria. The results can support the adoption of sustainable energy in Turkey, by guiding stakeholders, investors, and policymakers in making informed decisions on solar-wind-based hydrogen plant construction.

Site selection is a critical step in renewable energy projects, as it significantly influences their feasibility and efficiency. By addressing this stage systematically, this study provides a foundation for future research, including detailed optimization, energy performance assessments, and comprehensive economic analyses. These subsequent steps will further enhance the decision-making process, ensuring both technical and economic viability for hydrogen production initiatives.

ABSTRACT
This study presents a novel dual-layered control strategy for a 1 kW micro-mobility vehicle powered by a proton exchange membrane fuel cell (PEMFC) and ultracapacitor hybrid system. The proposed approach consists of two main components: motor drive control, which regulates the speed and operation of the electric motor, and an energy management system utilizing a DC/DC converter to optimize power flow between the fuel cell, ultracapacitor, and load. This hybrid configuration leverages the complementary characteristics of PEMFCs and ultracapacitors, enabling efficient handling of transient and steady-state power demands. Simulation results demonstrate the effectiveness of the control strategy, achieving rapid dynamic response, improved energy efficiency, and enhanced system stability. The ultracapacitor supplies transient power demands, while the PEMFC handles steady-state operation, minimizing fuel cell degradation and extending its operational lifespan. This approach shows significant potential for sustainable and efficient micro-mobility solutions, paving the way for future advancements in hybrid energy systems.

Keywords: Hydrogen energy, Micro-mobility applications, Proton Exchange Membrane Fuel Cell (PEMFC), Ultracapacitor hybrid systems, Energy management strategies.

1. INTRODUCTION

The increasing need for sustainable and efficient transportation solutions has driven significant advancements in the field of electric mobility [1]. Among the alternatives to conventional internal combustion engines, proton exchange membrane fuel cells (PEMFCs) have emerged as a promising power source due to their high efficiency, environmental benefits, and zero-emission characteristics [2]. However, the inherent limitations of PEMFCs, such as their slow dynamic response and inability to handle transient power demands, necessitate the integration of complementary energy storage systems. Ultracapacitors, with their rapid charge-discharge capabilities and high power density, present an ideal solution for balancing these limitations in hybrid systems.

Hybridization of PEMFCs with ultracapacitors has gained significant attention in recent years due to its potential to address the limitations of standalone fuel cell systems. PEMFCs, while offering high energy density and zero emissions, are inherently limited by their slow dynamic response and challenges in meeting transient power demands. Ultracapacitors, on the other hand, are characterized by their high power density, rapid charge-discharge capabilities, and excellent cycle life, making them an ideal complement to fuel cells in hybrid configurations [3].

Various hybridization topologies have been explored in the literature, including fully active, semi-active, and passive configurations, each differing in the number and role of DC/DC converters. Fully active systems, as discussed in studies [4,5], provide maximum control over power distribution but come at the cost of increased system complexity, weight, and energy losses. Semi-active configurations, which reduce the number of converters, have been shown to improve efficiency while maintaining some degree of control over energy management. Passive configurations, where ultracapacitors and fuel cells are directly connected, leverage the inherent characteristics of each component to achieve a natural power split. For instance, ultracapacitors handle transient loads, while fuel cells provide steady-state power. Studies such as [6] and [7] demonstrate the feasibility of this approach in automotive applications, emphasizing its ability to reduce fuel cell stack size, minimize hydrogen consumption, and enhance overall system efficiency.

Recent advancements in control strategies have also been pivotal in optimizing the performance of PEMFC/ultracapacitor hybrid systems. Model predictive control techniques have been employed to minimize fuel cell degradation and hydrogen consumption, as highlighted in [8]. Additionally, adaptive droop control methods have been proposed for dynamic power distribution, ensuring stable operation under varying load conditions. While significant progress has been made, challenges remain in ensuring robust control, optimizing component sizing, and improving the overall energy efficiency of these systems. Future research is likely to focus on the integration of machine learning-based energy management strategies and the development of lightweight and cost-effective hybrid configurations tailored for specific applications, such as micro-mobility and unmanned vehicles.

In light of these considerations, this study proposes a dual-layered control strategy for a 1 kW micro-mobility vehicle powered by a PEMFC and ultracapacitor hybrid system. The control framework is divided into two key components: the motor drive control, which ensures precise operation and speed regulation, and the energy management system, which utilizes a DC/DC converter to optimize power distribution between the fuel cell, ultracapacitor, and the load. This paper

focuses on the design, implementation, and evaluation of this novel control strategy, highlighting its potential to improve the performance of small-scale electric mobility solutions.

2. PEMFC-ULTRACAPACITOR HYBRIDIZATION MODEL

Fig.1 illustrates the hybrid power system architecture integrating a PEMFC and an ultracapacitor to drive an electric motor [9]. The hydrogen tank supplies fuel to the PEMFC, which generates electrical energy. This power is then conditioned by Converter-I before being supplied to the inverter, which drives the electric motor. In parallel, the ultracapacitor, managed through DC/DC converter-II, provides transient power support to enhance system dynamics and efficiency [10]. This dual energy source approach ensures stable power delivery while optimizing energy efficiency and component longevity. The detailed electrical characteristics and specifications of the PEMFC and ultracapacitor are provided in Table 1.

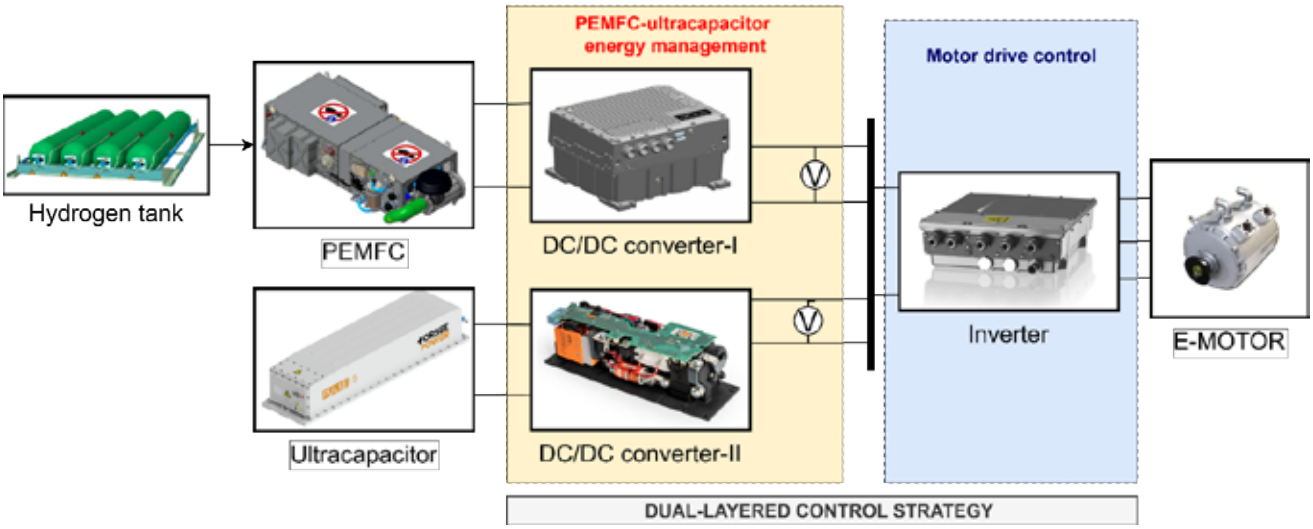

Fig. 1. PEMFC-Ultracapacitor Hybridization Model

Table 1. Parameters in Fuel cell-ultracapacitor system model [9,10]

PEMCF Parameters	Value	Ultracapacitor Parameters	Value
Rated power (kW)	1	Rate discharge capacitance (F)	1.25 F
Operating Temperature (℃)	55	C tolerance (%)	-10 to +20
Nerst voltage of one cell (V)	1.115	Operating Temperature (℃)	-40 to +70
Number of Cells	42	Nominal voltage (V)	50
Nominal stack efficiency (%)	*46*	Nominal current (A)	5
Nominal air flow rate (lpm)	*2400*	Maximum voltage (V)	56
Nominal fuel flow rate (lpm)	*12.2*	Maximum peak current (A)	15
Fuel supply pressure (bar)	*1.5*	Equivalent series resistance	mΩ at 1000Hz
Air supply pressure (bar)	*1*		
Nominal composition (H2) (%)	*99.95*	-	-
Nominal composition (O2) (%)	*21*	-	-

3. DUAL-LAYERED CONTROL STRATEGY APPROACH

The control strategy is implemented in two main parts: the motor drive, which governs the operation and speed of the electric motor, and the fuel cell-ultracapacitor energy management system, which utilizes a DC/DC converter to efficiently regulate the power flow between the fuel cell, ultracapacitor, and the load. This dual-layered approach ensures optimal performance, balancing dynamic response and energy efficiency.

(i) Fuel cell-ultracapacitor energy management: In systems integrating a fuel cell and ultracapacitor, DC/DC control plays a critical role in managing the power flow between energy sources, ensuring seamless operation by balancing the slow dynamic response of the fuel cell with the rapid energy delivery capability of the ultracapacitor. The hybrid topology presented in Fig. 1 integrates a proton exchange membrane fuel cell (PEMFC) and an ultracapacitor through a DC/DC converter to manage power flow efficiently. This configuration balances the slow dynamic response of the PEMFC with the rapid transient power delivery capability of the ultracapacitor. As observed in Fig. 2, the fuel cell provides a stable base power, ensuring continuous energy supply, while the ultracapacitor effectively handles transient loads by supplying or absorbing power instantaneously. The fuel cell further supports the system by compensating for medium-term variations in power demand. The numerical results demonstrate that the system

efficiently distributes power, with the ultracapacitor initially supplying up to 1000 W and then stabilizing, while the fuel cell fluctuates between 300 W and 800 W, adapting dynamically to system needs. This coordination reduces fuel cell stress, minimizes voltage fluctuations, and enhances overall efficiency. The ability to maintain DC bus voltage stability within ±2V despite varying loads further validates the robustness of the control strategy. These findings confirm that the proposed hybrid system effectively improves energy efficiency, extends fuel cell lifespan, and ensures reliable power delivery for micro-mobility applications.

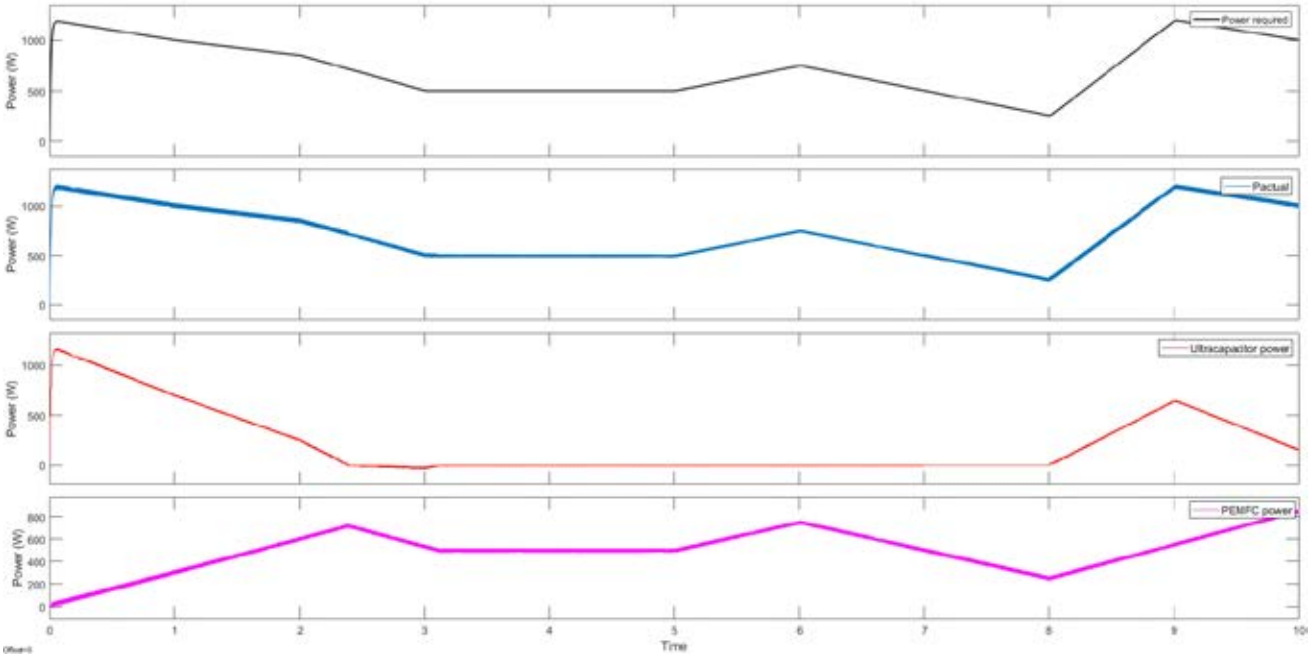

Fig. 2. Power distribution in a PEMFC-Ultracapacitor hybrid system

(ii) Motor drive control: The analyzed system incorporates a PEMFC connected to an electric motor through an inverter (Fig.3). The inverter operates using a hysteresis-based switching technique, which dynamically regulates the direct-axis current to manage the active power supplied to the motor. This control strategy enables efficient and reliable power transfer from the PEMFC to the electric motor, ensuring smooth operation across varying load conditions.

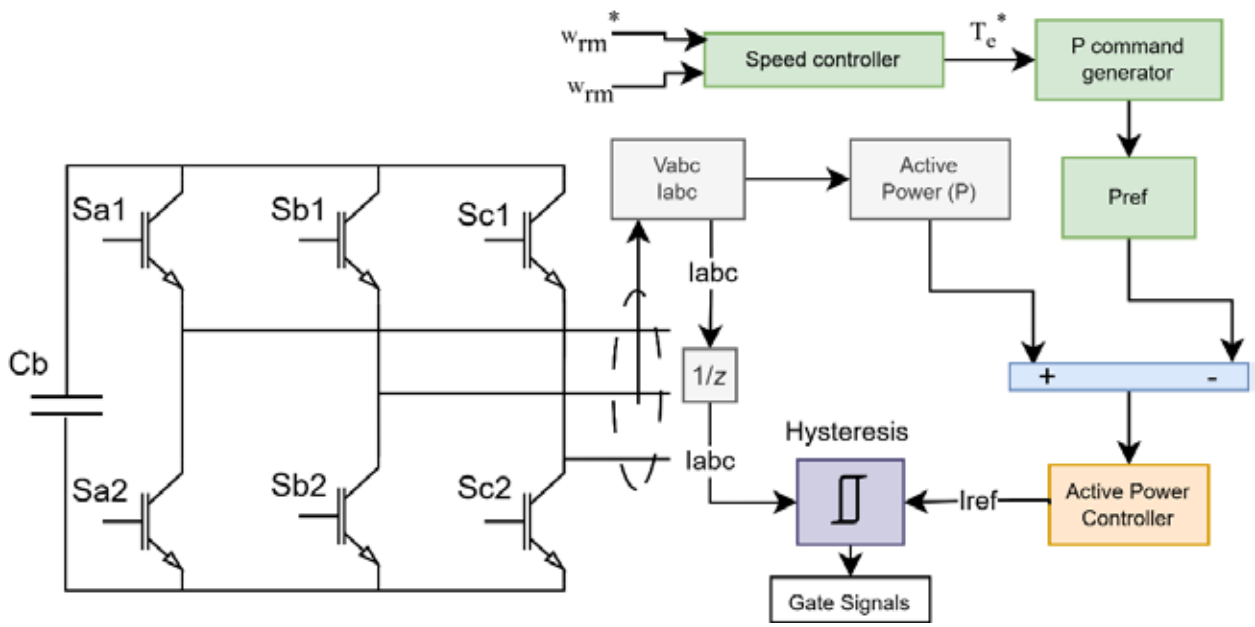

Fig. 3. Active power-based control strategy

As illustrated in Fig. 4, the motor's active power demand initially started at 1 p.u. and was successfully reached within

0.1 seconds, demonstrating the system's rapid response and effective control strategy. At 1 second, the demand sharply increased to 1.2 p.u. representing a significant load change. Despite this abrupt increase, the system smoothly transitioned to meet the higher demand, as shown by the red curve (Pactual) which tracks the reference power (pref) with minimal delay. This seamless adaptation highlights the critical role of the supercapacitor, which provides instantaneous power support during transient conditions. The supercapacitor compensates for the PEMFC's inherently slower dynamic response, ensuring uninterrupted power delivery and stability during load changes. The control strategy, implemented through the inverter, efficiently managed the power flow by adjusting the direct-axis current to match the new load while maintaining system efficiency and stability. This configuration demonstrates the synergy between the PEMFC, inverter, and supercapacitor, showcasing their ability to work together for reliable, energy-efficient, and fast power delivery in electric motor drive systems under varying load conditions.

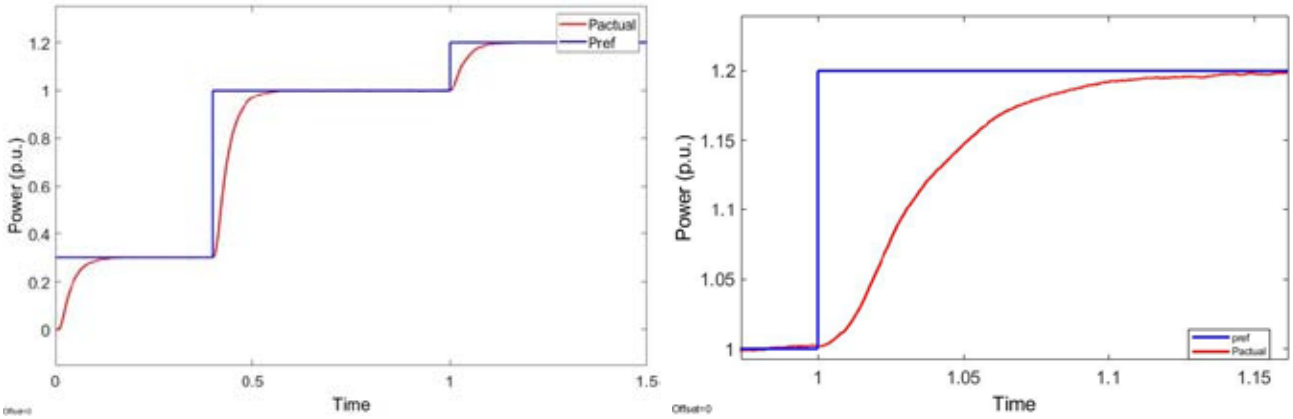

Fig. 4. Dynamic interaction between motor power demand and ultracapacitor support

4. CONCLUSIONS

This study demonstrates a dual-layered control strategy for a 1 kW micro-mobility vehicle powered by a PEMFC-ultracapacitor hybrid system. The proposed approach effectively balances power distribution, ensuring that the ultracapacitor handles transient demands, while the PEMFC provides steady-state power, improving efficiency and system stability. The dual-layered approach integrates motor drive control for precise speed regulation and an energy management system that optimizes power distribution between the PEMFC and ultracapacitor, ensuring efficient, stable, and responsive operation in dynamic load conditions. Simulation results confirm the robustness of the control strategy, maintaining DC bus voltage stability and enabling fast dynamic response to load variations. The findings highlight the feasibility of PEMFC-ultracapacitor integration for micro-mobility applications, offering a reliable and energy-efficient solution. Future work will focus on optimizing energy management and real-world validation.

ABSTRACT
This study compares from a thermodynamic perspective different bio-oil steam reforming technologies: conventional steam reforming, autothermal reforming, and sorption-enhanced steam reforming. The effect of temperature, pressure, and steam-to-carbon ratio was evaluated on the energy requirements and hydrogen yield using Aspen Plus® V12.1. Conventional steam reforming achieves high hydrogen production but demands significant external energy due to its endothermic nature. Autothermal reforming integrates endothermic steam reforming with exothermic partial oxidation, enabling thermal neutrality and lowering energy requirements at the expense of reducing the hydrogen yield. Conversely, sorption-enhanced steam reforming by using sorbents for in-situ CO_2 capture, shifts the equilibrium toward hydrogen production, achieving purities above 98 mol%. Additionally, the exothermic CO_2 capture reactions reduce energy consumption or even generate excess energy that can serve as a heat source. Across all configurations, sorption-enhanced steam reforming achieves superior hydrogen production efficiency and lower energy demands, making it a promising option for sustainable hydrogen generation from bio-oil. The composition of bio-oil shows minimal impact on hydrogen yield, indicating broad applicability to different bio-oils.

Keywords: thermodynamic analysis, hydrogen, steam reforming, sorbents, autothermal

1. INTRODUCTION
Energy, being fundamental for society can transition from fossil fuels – which dominate energy generation and drive climate change [1] – to other renewable options like biomass-to-energy processes [2]. Biomass can be converted into bio-oil with higher energy density through thermochemical processes. This bio-oil can be further revalorized to produce renewable hydrogen via steam reforming, although this process is highly energy-intensive and susceptible to catalyst-deactivating side reactions that produce coke [3]. To address these challenges, advanced reforming techniques such as autothermal reforming where oxygen is added to balance energy needs, and sorption-enhanced reforming where CO_2 is captured – improving both energy and hydrogen efficiency – have been developed [4,5]. In this regard, thermodynamics studies can provide valuable insights for evaluating different process strategies to optimize hydrogen production assessing the theoretical feasibility of different steam reforming technologies. These results can also provide preliminary findings and recommendations for future research on this topic. Sugarcane with global production exceeding 1.5 billion tonnes annually, generates large quantities of fibrous residues named sugarcane bagasse [6]. In this study, a thermodynamic analysis was carried out using Aspen Plus® V12.1 to assess various reforming scenarios for bio-oil produced from sugarcane bagasse torrefaction. The bio-oil composition used in the analysis was based on data reported by Chang et al [7]. Additionally, this work examines how variations in bio-oil compositions – obtained from torrefaction or pyrolysis of different biomass feedstocks – affect hydrogen production in reforming processes.

Based on the above, the main goal of this research is to provide a thermodynamic comparison of three different bio-oil reforming technologies: conventional steam reforming (SR), autothermal reforming (ATR), and sorption-enhanced steam reforming (SESR). For that purpose, the influence of the operating conditions – pressure, temperature, and the steam-to-carbon ratio – on the reaction performance to maximize hydrogen production while minimizing coke formation was analyzed. Next, the energy requirements of conventional steam reforming were assessed, focusing on the minimum oxygen required to achieve neutral-thermal conditions in autothermal reforming. Then, the performance of autothermal reforming was compared to that of conventional reforming under the same conditions. Lastly, the sorption-enhanced steam reforming configuration which uses CO_2-selective sorbents was evaluated as an alternative to autothermal reforming. In this process, the CO_2 is captured not only by providing heat – due to the exothermic nature of the adsorption reaction – for driving forward the endothermic steam reforming reactions but also by shifting the water-gas shift reaction toward hydrogen production.

2. MATERIALS AND METHODS
Simulations were carried out using Aspen Plus V12.1® software, utilizing a non-stoichiometric approach that focuses on

minimizing Gibbs free energy through the RGIBBS block. To calculate the equilibrium composition at the reactor outlet the Peng-Robinson thermodynamic model was used. The general simulation flowsheet is illustrated in Fig. 1. It includes four separate feed streams: “BIO-OIL” for bio-oil on a dry basis, “WATER” for water to provide the steam required for the reaction, “O2” for oxygen to support the autothermal reaction, and “SORBENT” for calcium oxide (CaO), which acts as a CO_2-selective sorbent in the sorption-enhanced steam reforming process. A sensitivity analysis was conducted at different temperatures (400–800 ºC), pressures (1–20 bar), steam-to-carbon molar ratios (S/C = 0.5–5), oxygen-to-carbon molar ratios (O_2/C = 0–0.4), and sorbent-to-carbon molar ratios (CaO/C = 0–4).

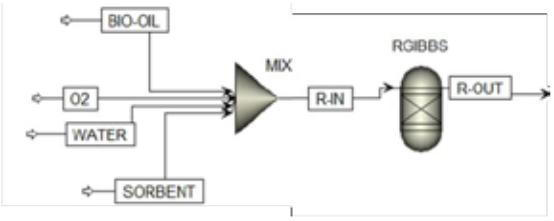

Fig. 1. Steam reforming flowsheet.

Reaction performance was evaluated based on product yields, calculated as the ratio of the molar flow rate of each component at the reactor outlet to the maximum molar flow rate of hydrogen (for hydrogen yields) or the molar flow rate of carbon in the bio-oil feed (for carbon co-product yields). It was assumed complete conversion, as the molar flow rate of oxygenated hydrocarbons in the outlet stream was almost zero. The bio-oil used in this work ($C_{1.00}H_{1.91}O_{0.85}$ is a blend of oxygenated hydrocarbons derived from the torrefaction of sugarcane bagasse. Table 1 provides a summary of its composition in molar fractions on a dry basis.

Table 1. Bio-oil composition on a dry basis [7]

Compound	Mole fraction on a dry basis (%)
Acetic acid	73.48
Acetol	1.41
Propionic acid	12.27
Methanol	4.79
Furfural	4.18
Furfuryl alcohol	2.34
Phenol	0.42
Guaiacol	0.38
Eugenol	0.56
Vanillin	0.17

3. RESULTS AND DISCUSSION

3.1. Conventional steam reforming

Figure 2 shows the effect of pressure, temperature, and S/C ratios on hydrogen yields. Despite industrial processes generally working at pressures of 15–30 bar to optimize reaction rates, efficiency, and process stability; hydrogen yield decreases as pressure increases due to Le Chatelier’s principle, which shifts the equilibrium away from hydrogen production. In contrast, hydrogen yield improves with temperature due to the endothermic nature of bio-oil steam reforming reactions, which are more favorable at higher temperatures. For lower S/C ratios (0.5-1), hydrogen yields gradually increase with temperature regardless of pressure, as the steam is below the stoichiometric level required for bio-oil reforming. In contrast, higher S/C ratios (2-5) achieve the highest yields (78-91%) within the 600-700ºC range. Further increase in temperature decreases the hydrogen yield given that the reverse water-gas shift reaction is favored thus consuming some of the hydrogen produced. While higher S/C ratios improve hydrogen yields, they also require larger equipment and more energy for steam generation. Therefore, an optimal balance between yield, cost, and energy efficiency is essential. The outlet stream contains other gaseous products alongside hydrogen, including CO, CO_2, and CH_4. Although CO and CO_2 do not directly interfere with hydrogen production, CH_4 does thus, to maximize the hydrogen production during bio-oil steam reforming effective control of these species and the reactions they participate in is essential. The obtained results demonstrate that atmospheric pressure is better for increasing hydrogen yield, as it favors reactions that produce fewer gaseous moles. A temperature range of 500–700 ºC enhances the reaction performance, but temperatures above 700ºC may lead not only to a decrease in hydrogen production but also to CO formation.

Maintaining an S/C ratio above the stoichiometric value helps reduce secondary products like CO, CH_4, and coke, particularly for ratios over 2. However, higher ratios require more energy to produce steam. Based on these factors, atmospheric pressure, temperatures between 500-700ºC, and an S/C ratio of 2 and 3 will be used in further analyses.

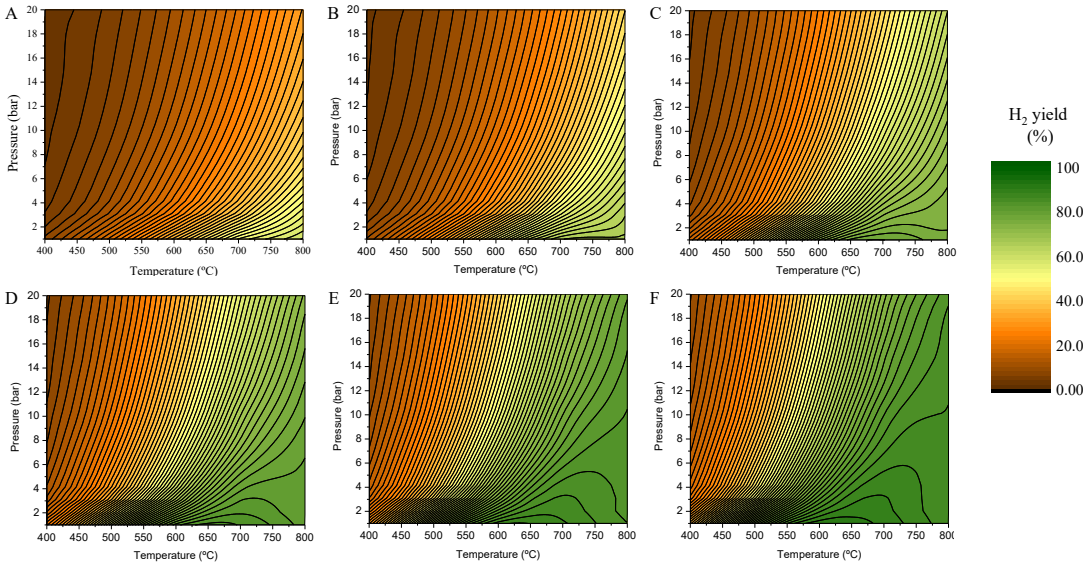

Fig. 2. Effect of pressure and temperature on H_2 yield for varying S/C molar ratios: (A) 0.5, (B) 1, (C) 2, (D) 3, (E) 4, and (F) 5.

3.2. Autothermal steam reforming

Conventional steam reforming requires significant energy due to its endothermic reactions, but co-feeding oxygen can overcome this by promoting exothermic partial oxidation reactions. These reactions release heat, which can meet some or all of the energy demand for steam reforming, leading to thermal neutrality. This approach also helps control the reaction environment, reducing undesirable byproducts like coke and carbon monoxide. The amount of oxygen needed for thermal neutrality depends on the temperature and S/C ratio. Higher temperatures and S/C ratios require more oxygen to balance the energy demand, as higher steam levels increase thermal energy needs. This strategy improves the energy efficiency of hydrogen production but, under thermal neutral conditions, hydrogen yields were significantly lower compared to conventional steam reforming, especially at higher temperatures due to its consumption in the oxidation reactions. CO yields were also lower than in steam reforming due to the partial oxidation reactions that convert CO to CO_2. Similarly, methane yields were decreased because the combined partial oxidation and reforming reactions reduce methane concentrations by converting it to hydrogen and CO_2.

3.2. Sorption-enhanced steam reforming

Autothermal steam reforming offers advantages like improved energy efficiency and reduced CO and CH_4 production but results in lower hydrogen yields compared to traditional methods, posing a challenge for hydrogen-centric applications. To address this, sorption-enhanced steam reforming has gained attention. This process uses CO_2 sorbents like CaO to capture CO_2 in situ, shifting the thermodynamic equilibrium towards hydrogen production. The presence of CaO in the feed stream, significantly improves hydrogen yield, especially at lower temperatures, stabilizing at CaO/Cfeed ratios above 1. This technology minimizes byproduct formation and produces higher-purity hydrogen compared to conventional steam reforming. Optimizing the CaO/C_{feed} ratio, temperature, and S/C ratio improves hydrogen yield, energy efficiency, and carbon capture while reducing emissions. Excess heat from the process can lower operating costs by serving other uses like electricity generation.

Table 2 displays the ideal conditions for the reforming technologies studied – SR, ATR, and SESR – using S/C molar ratios of 2 and 3. It also includes the energy needed to drive the reactions under these conditions. This information is crucial for assessing the trade-off between energy use and hydrogen yield/purity, providing a solid foundation for optimizing the reforming process. These parameters provide valuable insights for optimizing hydrogen production while considering the reactor's energy efficiency, opening the way for future economic and environmental analyses. Finally, the effect of the bio-oil composition was evaluated on the hydrogen yield. Higher H content enhances hydrogen production, while higher O content can create byproducts that reduce efficiency. Using an S/C ratio of 2, hydrogen yields ranging from 81-95% were obtained following the same trend for 5 different bio-oil compositions obtained from: sugarcane bagasse, maple, oak, spruce wood, and maize stalk; in agreement with other results reported in the literature.

Given no significant changes were obtained, the insights of this study are broadly applicable to various bio-oil compositions, independent of the biomass source.

Table 2. Maximum hydrogen yield and energy requirements for different reforming technologies under atmospheric pressure

Reactor configuration	S/C	Temperature (ºC)	O_2/C	CaO/C	Y H_2 (%)	H_2 molar fraction (on a dry basis)	Energy requirements (kJ/kg_{feed})
SR	2	700	-	-	78.0	0.622	5762.55
ATR	2	600	0.28	-	58.2	0.551	-
SESR	2	550	-	1	95.8	0.987	-1102.58
SR	3	650	-	-	84.5	0.641	6037.58
ATR	3	600	0.32	-	60.6	0.561	-
SESR	3	550	-	1	99.1	0.996	-468.78

4. CONCLUSIONS

This study evaluates traditional, autothermal and sorption-enhanced steam reforming of bio-oil, with an emphasis on hydrogen production, energy efficiency and byproduct generation. While conventional steam reforming allows high hydrogen yields, particularly at raised temperatures, its endothermic characteristics make this process energy-intensive. Autothermal steam reforming balances energy needs through exothermic partial oxidation, reducing energy demand but lowering hydrogen yield by about 25% compared to traditional methods. Conversely, sorption-enhanced steam reforming reached better results than the other technologies by capturing CO_2 in situ with CaO to shift equilibrium toward hydrogen production. This configuration achieves hydrogen yields exceeding 95% of the theoretical maximum, reduces CO_2 emissions, minimizes byproducts, and improves energy efficiency by leveraging exothermic CO_2 capture reactions. This study also shows that hydrogen yields vary slightly with the H and O balance in bio-oil composition, making the findings applicable across a wide range of bio-oils. These findings offer key insights for optimizing reforming processes in industrial settings, incorporating renewable energy and investigating advanced materials to enhance CO_2 capture and catalyst efficiency.

ABSTRACT
In this study, agglomerated catalysts were synthesized by combining powdered Ni catalysts supported on mesostructured ceria with different clays (kaolinite, sepiolite, attapulgite and bentonite) to get suitable extrudates for large-scale use in the oxidative steam reforming of acetic acid. Extrudates prepared with bentonite and attapulgite and then calcined at a heating rate of 1 ºC/min showed higher mechanical strength. Despite having slightly lower mechanical resistance, better catalytic results in terms of acetic acid conversion and hydrogen yield were achieved over Ni/m-CeO_2 using attapulgite as a binder. External and internal resistance to mass transfer were evaluated for shaped catalysts, disregarding the presence of reactant concentration gradients neither around the catalyst particle's external surface nor through the particle porosity, in this sense, there are no limitations for internal diffusion since the calculated Weisz-Prater modulus was below 1.
Finally, the reusability of the Ni/m-CeO_2-A extrudates was assessed to have information about its suitability for industrial-scale reformers. Thus, its catalytic performance was tested over multiple cycles. Reactions were performed for 6 hours at 550 ºC at a high space velocity to ensure fast deactivation (WHSV of 41.8 h^{-1}). Between cycles, the catalyst was regenerated in situ by introducing an air stream to remove coke deposits, followed by a hydrogen stream to reduce the active phase again before the next cycle. The results revealed good stability, maintaining complete conversion and just 10% lower hydrogen yield compared to the first run after six reaction cycles.

Keywords: extrusion, nickel, mesoporous ceria, hydrogen, regeneration

1. INTRODUCTION
As the global population grows and energy demand rises, greenhouse gas emissions from fossil fuels continue to increase, highlighting the need for alternative energy sources [1]. In this context, hydrogen is receiving attention as an interesting option to replace fossil fuels. It is primarily produced from methane reforming, but researchers are increasingly focused on its production from renewable sources to avoid fossil fuel use [2]. Acetic acid is emerging as a promising alternative renewable feedstock for hydrogen production, with its market projected to grow significantly, reaching $319.6 million by 2030 [3]. Unlike other hydrogen production sources like methanol or ethanol, acetic acid is non-flammable and non-toxic, making it safer and more convenient to store and transport [4]. Moreover, it can be produced through fermentative processes using different sources including carbohydrates, as well as agricultural and forestry lignocellulose, shells, and microalgae.
To obtain hydrogen from acetic acid, steam reforming is widely reported [5]. Steam reforming is constrained by some limitations including high operating temperatures and coke formation. To address these challenges, including oxygen in the feed stream resulting in oxidative reforming has emerged. This configuration decreases the energy requirements given the exothermicity of the partial oxidation reactions and reduces coke formation [6]. In this regard, catalyst formulation plays a crucial role in maximizing hydrogen production while limiting activity loss. As an active phase, noble metal catalysts are commonly used for reforming purposes, however, their high cost has driven interest toward transition metals, such as nickel or cobalt since they have demonstrated excellent performance on the cleavage of C-C and C-H bonds [7]. As catalyst support, cerium oxide (CeO_2) has gained widespread use in oxidative reforming reactions due to its high oxygen mobility which reduces coke deposition on the catalyst apart from being active in the water-gas shift reaction. Most of the catalysts reported in the literature are prepared in powder resulting in high-pressure drops in large-scale reactors hindering their implementation in the industry. For this reason, it is necessary to prepare pelletized catalysts by adding different binders to improve mechanical strength, water, and an organic additive, such as methylcellulose to get plasticity in the paste during the extrusion process [8].
Based on the above, this work investigates the effect of the inorganic binder – bentonite, attapulgite, kaolinite, and sepiolite – in the mechanical strength and the physicochemical properties of extrudates obtained in Ni/m-CeO_2 agglomeration. Additionally, to study the possibility of overcoming catalyst deactivation by coke deposition, regeneration cycles between two catalytic tests were performed.

2. MATERIALS AND METHODS
The synthesis of the mesostructured CeO_2 was carried out by nanocasting using SBA-15 as a template as described elsewhere [9]. The incorporation of Ni as the active phase was done through the wet impregnation method to get a 7 wt.% of Ni loading. Extruded materials were synthesized by mixing 70 wt.% of powder catalyst with 30 wt.% of clay

(bentonite, attapulgite, sepiolite, or kaolinite). Additionally, methylcellulose was added as a plasticizer to enhance the viscosity of the paste formed as a result of adding deionized water. To facilitate the extrusion the paste was left overnight in a humid atmosphere. The pellets were obtained using a circular homemade extruder and subjected to calcination, first to select which clays have the highest mechanical resistance a heating rate of 0.1 ºC/min up to 110 ºC and then 0.5 ºC/min up to 650 ºC was used according to previous work [8]. Then, with the selected clays, the influence of the calcination ramp on the mechanical strength was evaluated. The synthesized pellets were characterized and those samples with high mechanical strength were tested in the oxidative steam reforming of acetic acid under regeneration cycles, which were done by initially introducing a stream of air to eliminate the coke formed with a ramp of 10 ºC/min up to 600 ºC and, subsequently, a stream of H_2 was added to reduce the active phase for another hour.

3. RESULTS AND DISCUSSION

3.1. Catalysts characterization

Using commercial ceria, the mechanical resistance of pellets synthesized with different clays was evaluated as summarized in Table 1. It can be discerned that the samples prepared using attapulgite and bentonite showed the highest mechanical resistance using a calcination rate of 0.1 ºC/min up to 110 ºC and then 0.5 ºC/min up to 650 ºC.

To prepare extrudates with high resistance, both clays were selected to evaluate the influence of the heating rate during calcination, as can be seen in Table 1. The highest mechanical resistance was achieved for both samples with a calcination ramp of 1ºC/min, being the mechanical resistance 11.8 N and 13.1 for the pellets prepared with attapulgite and bentonite, respectively. Consequently, this ramp was selected to evaluate the catalytic activity in the oxidative steam reforming of acetic acid.

Table 1. Mechanical resistance of pellets prepared with 4 different clays using commercial CeO_2.

Clay	Calcination rate (ºC/min)	Mechanical resistance (N)
Kaolinite	0.1ºC/min up to 110ºC, 0.5ºC/min up to 650ºC	2.4
Sepiolite	0.1ºC/min up to 110ºC, 0.5ºC/min up to 650ºC	4.1
Attapulgite	0.1ºC/min up to 110ºC, 0.5ºC/min up to 650ºC	8.1
	0.5ºC/min up to 650ºC	8.9
	1ºC/min up to 650ºC	11.8
	2.5ºC/min up to 650ºC	7.9
	5ºC/min up to 650ºC	5.8
Bentonite	0.1ºC/min up to 110ºC, 0.5ºC/min up to 650ºC	11.1
	0.5ºC/min up to 650ºC	12.8
	1ºC/min up to 650ºC	13.1
	2.5ºC/min up to 650ºC	10.2
	5ºC/min up to 650ºC	9.1

Once selected the clays and the heating rate; new pellets were prepared with powder Ni catalysts supported on mesostructured ceria synthesized by nanocasting. Samples were named as Ni/mCeO_2-X where X indicates the clay used (A for attapulgite and B for bentonite). The mechanical strength, BET surface area, pore volume, and Ni content estimated from ICP analysis are shown in Table 2. As a consequence of the mixing of the catalyst and the clay during pellet preparation, both samples have Ni content of around 5 wt.%. It is noteworthy that the mechanical resistance of the extruded catalysts is lower than that achieved with commercial ceria, ascribed to the higher porosity of the mesostructured ceria compared to the non-porous commercial ceria. Additionally, textural properties revealed higher BET surface area and pore volume for Ni/mCeO_2-A because of higher values of these parameters in attapulgite than in bentonite.

Table 2. Characterization of the catalysts.

Clay	Mechanical resistance (N)	S_{BET} (m^2/g)	V_p (cm^3/g)	Ni (wt. %)
Ni/mCeO_2-A	5.5	80.8	0.253	5.2
Ni/mCeO_2-B	7.6	59.3	0.179	5.4

3.2. Catalytic tests

The selected materials – Ni/mCeO_2-A and Ni/mCeO_2-B – were tested in the oxidative steam reforming of acetic acid. The catalytic results in terms of acetic acid conversion and hydrogen yield, are presented in Table 4. From these results, it is possible to observe that the conversion and the hydrogen yield are significantly lower with Ni/mCeO_2-B, being the

hydrogen yield three times lower than that achieved with Ni/mCeO_2-A. This difference can be attributed to the lower BET surface area obtained when using bentonite, which may limit the active phase dispersion thus resulting in a lower number of active sites necessary to catalyze the reaction effectively.

Table 4. Conversion in the oxidative steam reforming of acetic acid and hydrogen yield using Ni/mCeO_2-A and Ni/mCeO_2-B catalysts with time-on-stream (T=550 ºC; WHSV = 21.4 h^{-1}; steam/C/O_2 molar ratio =2/1/0,0375, P= 1 atm).

Time on stream (h)	Ni/mCeO_2-A		Ni/mCeO_2-B	
	Acetic acid conversion (%)	Yield to H_2 (%)	Acetic acid conversion (%)	Yield to H_2 (%)
1 h	79.9	37.0	82.9	12.3
2 h	55.7	34.8	58.1	11.8
3 h	51.2	33.4	32.5	11.3
4 h	51.1	32.3	25.6	12.6
5 h	49.3	31.5	25.0	13.2

Given that Ni/mCeO_2-A reached better catalytic performance, this sample was selected to evaluate the influence of diffusion resistance to mass transfer. To study external concentration gradients new tests were carried out keeping a WHSV of 21.4 h^{-1} but varying the amount of catalyst and the feed flow rate, whose results are summarized in Table 5. It is evident that as the flow rate increases, the conversion and the hydrogen yield values also rise, reaching a maximum at a liquid feed flow rate of 0.094 ml/min. This is a consequence of higher turbulence within the reactor which improves the mass transfer coefficient thus decreasing the acetic acid concentration gradient around the external catalyst particle surface. Beyond this flow rate, no significant changes are detected in either hydrogen yield or conversion, suggesting that external mass transfer limitations are negligible under these conditions. Moreover, the internal diffusion was evaluated following the Weisz-Prater criterion.

$$C_{WP}=\frac{(-r_A)\cdot\rho_c\cdot R^2}{D_e\cdot C_{AA}} \quad (1)$$

Where $(-r_A)$ refers to the reaction rate, ρ_c is the catalyst density, R is the catalyst radius, D_e is the effective diffusivity of gas and C_{AA} is the concentration of gas. If C_{WP} <1 there is no internal diffusion. In this case C_{WP} =$9\cdot10^{-2}$, so it was confirmed no internal diffusion.

Table 5. Experimental conditions used to analyze the external diffusion effect.

$m_{catalyst}$ (g)	Q_{feed} (ml/min)	Gas flow (ml/min)	Acetic acid conversion (%)	Yield to H_2 (%)
0.32	0.057	45	72.6	35.4
0.43	0.075	60	79.9	37.0
0.48	0.084	65	82.6	43.6
0.54	0.094	75	99.4	61.3
0.64	0.113	90	99.9	60.3

To evaluate the reusability of the catalyst, reaction-regeneration cycles were performed with Ni/m-CeO_2-A. For that purpose, 6-hour reaction tests were conducted at a WHSV=41.8 h^{-1} to ensure significant catalyst deactivation, enabling a more detailed analysis of the regeneration process. During regeneration, an air stream was added with a ramp rate of 10 ºC/min up to 600 ºC to eliminate the coke formed over the catalyst and subsequently, a hydrogen stream was passed during an hour through the catalytic bed to reduce again the active phase. The obtained results are displayed in Fig. 1. In all the cycles it is possible to observe both a conversion and hydrogen yield drop with time, ascribed to the formation of carbonaceous species which are deactivating the catalysts. After successive regeneration cycles, the activity is completely recovered given that the conversion follows a stationary trend. In contrast, hydrogen yield increases after each cycle but the value during the first hour slightly decreases until reaching values near 40% in the 6th cycle, around 10% lower than the value obtained during the first cycle. This fact suggests that although the conversion is being recovered, the selectivity towards hydrogen is affected during the catalyst regeneration increasing the formation of other compounds like CH_4.

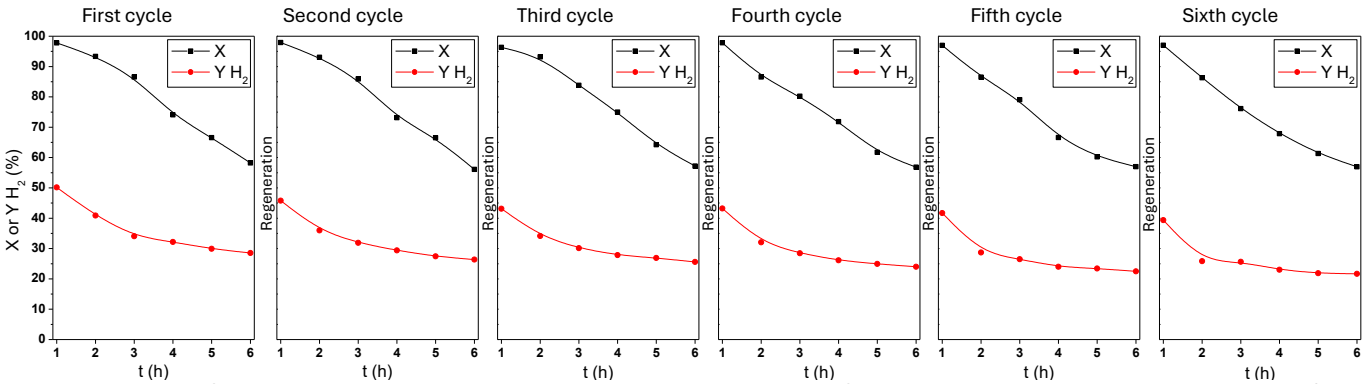

Fig. 1. Evolution of the acetic acid conversion and hydrogen yield in oxidative reforming reaction-regeneration cycles using Ni/m-CeO_2-A. Reaction conditions (T=550 ºC; WHSV = 41.8 h^{-1}; steam/C/O_2 molar ratio =2/1/0.0375, P= 1 atm)

4. CONCLUSIONS

This study focused on the influence of clay type during the agglomeration of Ni-based catalysts supported over mesostructured ceria in the oxidative steam reforming of acetic acid. Among the clays tested, attapulgite and bentonite demonstrated superior mechanical resistance in the prepared extrudates, maximizing their resistance when a calcination rate of 1 ºC/min was used. Despite attapulgite exhibiting slightly lower mechanical resistance compared to bentonite, it reached better catalytic performance in terms of acetic acid conversion and hydrogen yield.

To assess mass transfer limitations, both external and internal resistances were evaluated for shaped catalysts. In this context, the calculated Weisz-Prater modulus remained below 1, indicating that internal diffusion constraints were not significant, and the point at which the external diffusion limitations disappeared was experimentally determined.

The reusability of the Ni/mCeO_2-A extrudates was further analyzed to assess their industrial feasibility. Therefore, the catalytic performance was tested over multiple reaction cycles at 550 ºC using a WHSV of 41.8 h^{-1} to ensure rapid deactivation. Between cycles, the regeneration process involved in situ coke removal followed by reduction of the active phase. The results showed good stability, with full recovery conversion and only a 10% drop in hydrogen yield after six reaction cycles compared to the first run. These findings underscore that Ni/mCeO_2-A extrudates are suitable catalysts for the oxidative steam reforming of acetic acid, with promising application for future industrial-scale up.

ABSTRACT
This study presents the development and simulation of an AI-optimized photovoltaic (PV)-battery-electrolyzer system for green hydrogen production. A MATLAB Simulink model was created to evaluate system performance over a one-day period, focusing on energy management and hydrogen generation under varying solar irradiance conditions. The AI-based optimization strategy dynamically adjusted power distribution to maximize efficiency while ensuring stable operation. The results demonstrated that the PV system reached a peak power of 250 kW, with the electrolyzer consuming up to 200 kW, effectively utilizing solar energy. The battery played a stabilizing role, discharging ~500 kW to support the electrolyzer when solar generation declined, while its charge decreased from 100% to ~95%. Hydrogen production reached ~25 kg, with a nearly constant specific energy consumption of ~65 kWh/kg H_2, confirming the system's efficiency and reliability. These findings highlight the potential of AI-driven optimization in enhancing renewable-powered hydrogen production, providing insights for future large-scale applications.

Keywords: Green hydrogen production, Proton Exchange Membrane (PEM) Electrolyzer, AI-based optimization, Renewable energy integration, Hydrogen production efficiency

1. INTRODUCTION
Hydrogen has emerged as a key energy carrier in the transition to sustainable energy systems, particularly when integrated with renewable energy sources. In recent years, photovoltaic (PV)-battery-electrolyzer systems have gained significant attention due to their potential to enhance energy flexibility and facilitate green hydrogen production [1]. The combination of solar energy, energy storage, and water electrolysis offers a promising pathway to utilize intermittent renewable power efficiently. However, optimizing hydrogen production under varying solar irradiance conditions remains a critical challenge. To address this, standardized performance evaluation methods and optimization strategies are essential to ensure reliable and cost-effective hydrogen generation [2]. Furthermore, analyzing production trends under different irradiance levels will contribute to the development of more efficient system designs and operational strategies. Several studies have explored PV- and wind-based hydrogen production systems, focusing on their design, operation, and performance evaluation [2]. In this context, a comprehensive system model was developed to assess the efficiency of green hydrogen production by integrating a proton exchange membrane (PEM) electrolyzer with a vertical axis wind turbine (VAWT), utilizing MATLAB, Simulink, and Simscape for system optimization under varying operational conditions [3].To further enhance the integration of renewable energy sources, Tatar et al. proposed a multi-period Mixed-Integer Linear Programming (MILP) model for the optimal design and operation of microgrids. Their model accounts for the uncertainties of renewable energy sources while incorporating green hydrogen and synthetic methanation technologies [4]. Similarly, Hüner et al. developed a mathematical model for a photovoltaic (PV)-assisted PEM water electrolyzer system, evaluating the effects of operating temperature and membrane thickness on hydrogen generation efficiency [5]. In addition to system performance optimization, Criollo et al. introduced a simulation model to enhance the technical and economic aspects of green hydrogen production by integrating PV and energy storage technologies. Their study demonstrated that replacing high-fidelity electrolyzer models with reduced-order models could significantly improve computational efficiency while maintaining accuracy [6]. Building on these approaches, a techno-economic assessment was conducted to evaluate off-grid PV-based hydrogen production, optimizing electrolyzer sizing and analyzing production efficiency under varying solar irradiance conditions [7]. These studies highlight the importance of transient electrolyzer behavior, battery degradation, and grid stability in integrated hydrogen production systems. However, a systematic approach to standardizing the comparison of different renewable hydrogen production configurations is still lacking. This research aims to contribute to the field by establishing a PV-battery-electrolyzer system, evaluating its hydrogen production performance under varying irradiance conditions, and proposing optimal strategies for maximizing hydrogen yield.
In this study, a MATLAB Simulink model was developed to simulate an AI-based optimization strategy for a photovoltaic (PV) system integrated with a battery and an electrolyzer for green hydrogen production. The model represents a DC islanded microgrid that optimally manages power distribution to the electrolyzer using a solar array and an energy storage system. The simulation evaluates hydrogen production over a one-day period, incorporating electrical, thermal liquid, and thermal gas domains.

2. GREEN HYDROGEN PRODUCTION SYSTEM

In this study, a MATLAB Simulink model was developed to simulate and optimize a photovoltaic (PV)-battery-electrolyzer system for green hydrogen production (Fig. 1). The system operates as a DC islanded microgrid, where energy from a solar array and an energy storage unit is utilized to power a proton exchange membrane (PEM) electrolyzer. The AI-based optimization strategy dynamically adjusts energy distribution to maximize hydrogen production efficiency while considering real-time solar irradiance and battery state of charge. The model includes electrical, thermal liquid, and thermal gas domains to provide a comprehensive evaluation of the system's performance.

Key system parameters were defined to ensure an accurate simulation. The PV system operates with a maximum power output (Pw_max) that is dynamically regulated by a maximum power point tracking (MPPT) controller. The electrolyzer consists of 100 cells with an efficiency range between 55% and 90%, a membrane thickness of 2 cm, and a resistance of 0.25 Ohm. The hydrogen storage tank has a volume of 100 cm³ and operates at a temperature of 273.15 K. The energy storage unit consists of a battery with a nominal capacity of 50,000 As, an internal resistance of 0.2 Ohm, and a nominal voltage of 240V. The battery is managed by a DC-DC converter, which ensures efficient power distribution with an efficiency of up to 99%. Control parameters, such as the sampling time (Ts = 10s), were carefully selected to enhance the model's responsiveness and accuracy in optimizing hydrogen production.

3. RESULTS

The simulation results demonstrate the power distribution and utilization of the AI-optimized PV-battery-electrolyzer system over a one-day period. As observed in the upper plot, the PV system follows a typical solar generation curve, with peak power production occurring around midday. The electrolyzer's power consumption closely follows the PV output, indicating efficient energy utilization for hydrogen production. The energy storage system plays a stabilizing role by compensating for energy fluctuations, charging during peak solar hours, and discharging when PV generation declines. The simulation results show that the PV system reaches a peak power of approximately 250 kW around midday, while the electrolyzer operates at a maximum consumption of 200 kW, efficiently utilizing solar energy for hydrogen production (Fig. 2). The energy storage system absorbs excess power early in the day, reaching a charge of ~500 kW, and later discharges ~-500 kW to support the electrolyzer when solar generation declines. Over the one-day period, the electrolyzer maintains a stable hydrogen production rate, demonstrating the effectiveness of AI-based energy management in balancing power flow and ensuring optimal system performance.

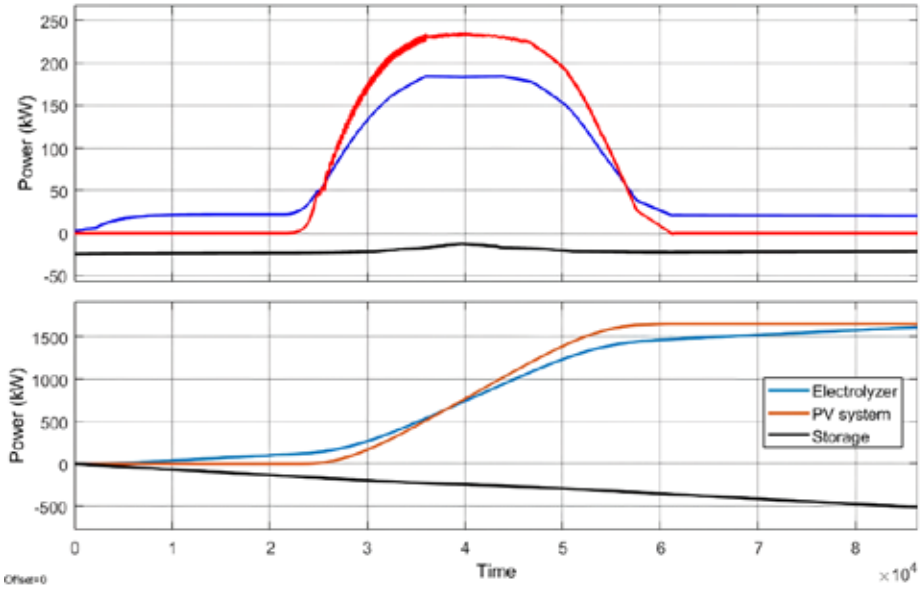

Fig. 2. Utilization in the AI-optimized PV-Battery-Electrolyzer System over a one-day period

The simulation results, as shown in Fig. 3, illustrate the system's performance over a one-day period. The electrolyzer reaches a peak current of ~750 A, following the PV system's peak generation, while the energy storage system provides a steady current of ~100 A throughout the day. Hydrogen production gradually increases, reaching ~25 kg by the end of the day. The battery charge declines from 100% to ~95%, indicating its role in stabilizing the power supply. The specific energy consumption remains nearly constant at ~65 kWh/kg H_2, demonstrating the efficiency and stability of the AI-based energy management strategy.

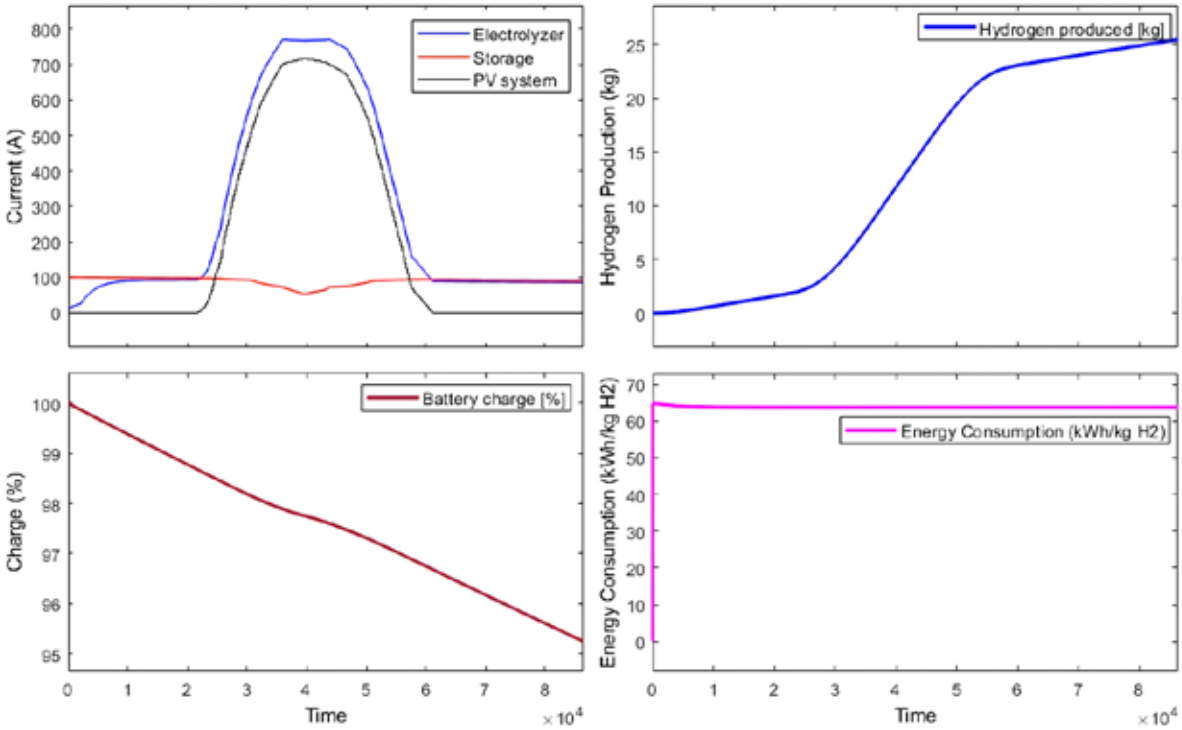

Fig. 3. System performance over a one-day period

4. CONCLUSIONS

This study successfully developed and simulated an AI-optimized PV-battery-electrolyzer system for green hydrogen production. The results demonstrate that the integration of an AI-based energy management strategy enables efficient power distribution, ensuring optimal hydrogen generation under varying solar irradiance conditions. The system's

performance over a one-day period showed that the PV system reached a peak power of 250 kW, while the electrolyzer operated at a maximum consumption of 200 kW, effectively utilizing available solar energy. The battery storage system played a critical role in stabilizing power flow, with its charge decreasing from 100% to ~95% while supporting the electrolyzer during periods of low solar generation. Additionally, hydrogen production steadily increased throughout the day, reaching ~25 kg, while the specific energy consumption remained nearly constant at ~65 kWh/kg H_2, highlighting the efficiency and stability of the proposed system. These findings confirm that AI-driven optimization can enhance the reliability and economic feasibility of renewable-powered hydrogen production. Future work could explore the integration of predictive forecasting models to further improve system efficiency and scalability for larger energy applications.

ABSTRACT
Anion Exchange Membrane (AEM) electrolysers (AEMWEs) have gained attention as a promising technology for green hydrogen production, primarily due to their potential to reduce material costs and their ability to operate efficiently in low-concentration alkaline environments. Unlike Proton Exchange Membrane (PEM) electrolysers (PEMWEs), which rely on expensive precious metals as catalyst raw materials, AEMWEs do not require precious metals for the electrodes, offering a more cost-effective solution and greater scalability for industrial large-scale applications. To fully understand the behavior of AEMWEs and optimize their operation, it is essential to develop dynamic models that capture both steady-state and transient characteristics. In this context, this study extends previously developed steady-state AEMWE model to a dynamic one to examine the impact of lye solution (KOH solution) circulation rate and temperature on the start-up dynamics. The findings indicate that a higher circulation rate and higher inlet temperature speed up thermal equilibrium. Additionally, a higher lye circulation rate minimizes the temperature difference between the stack's inlet and outlet.

Keywords: Anion exchange membrane, dynamic modeling, electrolyser, hydrogen, thermal model.

1. INTRODUCTION

AEMWEs are emerging as promising technology for high purity hydrogen production due to their potential for lower material costs and the ability to operate in low-concentration alkaline environments. Unlike PEMWEs, AEMWEs do not require precious metals for electrodes, which can reduce material costs and enhance scalability for large-scale applications. While PEMWEs are widely used in industry, AEMWEs have started to appear as an increasingly prominent alternative, particularly in the context of lower installation cost. The development of dynamic models and transient analysis of AEMWEs will help us to understand their dynamic behavior and contribute to the broader adoption of these electrolysers.

Several studies have proposed steady-state models for AEM electrolysers to understand their static performance characteristics, such as voltage-current relationships and gas production rates [1-5]. However, accurate dynamic modeling is essential for optimizing their operation, as transient behaviors during start-up, load changes, and thermal effects play a key role in the performance and energy efficiency. Dynamic models are necessary to investigate the temporal changes in temperature and voltage, which impact the overall efficiency and lifespan of the electrolyser system. Therefore, this study extends a previously developed steady-state model [1] to a dynamic one to better understand the dynamics of the AEMWE. The model is implemented in MATLAB/Simulink environment and is used to investigate the effect of lye solution circulation rate and temperature on the start-up behavior of a kW scale AEMWE.

2. MODELING

AEMWEs involve electrochemical reactions as well as heat transfer and mass transport processes. In this study, a dynamic model is developed by extending a previously established steady-state model [1]. The steady-state model developed in the previous work focused on the electrochemical behavior of the AEM electrolyser and its steady-state performance characteristics. It utilized a simplified approach based on electrochemical kinetics to describe the current-voltage relationship, considering the overpotentials at both the anode and cathode. The model incorporated Faraday's law to estimate the hydrogen and oxygen gas production rates based on the applied current.

The core of the present study is the unsteady-state energy balance. The thermal model includes key parameters such as internal heat generation within the cells and heat losses to the surroundings. The energy balance equation accounts for these thermal effects, ensuring that both the electrochemical performance and the temperature evolution of the stack are modeled dynamically. Heat generation is linked to the current density, while heat dissipation is modeled through convective heat transfer mechanisms. Additionally, the model considers the influence of solution circulation on the thermal dynamics, as it impacts the rate of heat transfer and temperature uniformity across the stack. This extension to the steady-state model allows for a more accurate simulation of the AEM electrolyser's behavior, particularly under transient conditions such as during start-up or load changes, where thermal effects are significant for system stability and performance.

The thermal model of the system requires thermal inertia of the system, i.e. the thermal capacity of the AEMWE stack. In this work, lumped thermal capacity assumption is considered so that stack temperature is homogeneous and volume

average of the specific heat of stack components are used to calculate lumped thermal capacitance, C_t, of the stack [6-10].

$$C_t = \sum_j \rho_j V_j c_j \quad (1)$$

where; c_j, ρ_j, and V_j and are the specific heat, density and volume, respectively, of each of the electrolyzer parts denoted by j. Due to the limited availability of the stack component dimensions and material information and by considering the significant contribution of the thermal capacitance of the bipolar plates and end plates, the thermal capacitance of the stack is estimated using bipolar plate and end plate information.

The stack energy balance can be written as follows

$$C_t \frac{dT}{dt} = W - Q + \sum_j^{inlet} \dot{m}_j h_j - \sum_j^{outlet} \dot{m}_j h_j \quad (2)$$

where; T is the stack temperature, W electrical work, i.e. power supplied to stack, Q is the heat loss to the surroundings, $\dot{m}_j$ is the mass flow rate of species j and h_j is the enthalpy of the species j. Heat transfer from AEMWE stack to the environment is calculated by

$$Q = h_t A (T - T_a) \quad (3)$$

where; h_t is the total heat transfer coefficient, which is approximated as 19 W/(m^2.K) [11], A is the external surface area of the stack, and T_a is the ambient temperature.

3. RESULTS AND DISCUSSION

In this study, a 46-cell AEMWE stack with a 50 cm^2 active area was considered as a case study. The AEMWE stack has nominal power of 5 kW at a current density of 1 A/cm^2 and the estimated thermal capacitance is 4.6 kJ/K. AEMWE stack cell parameters are used as given in previous study [1]. The developed model was initially used to analyze the AEMWE stack temperature response for various inlet temperature profiles. Constant inlet temperature and ramp input temperature profiles are applied, and the stack temperature response is recorded for different lye flow rates. Fig. 1 shows the stack temperature response for a constant inlet temperature at four different lye flow rates at 1 A/cm^2 current density. According to the results, as the lye flow rate increases, the stack temperature reaches the steady-state temperature more quickly. Additionally, the inlet and outlet lye solution temperature difference decreased to approximately 11°C. It has been determined that to maintain a temperature difference of less than 10°C at a stack power of 5 kW, the lye flow rate must be kept above 2.5 mL/(min.cm^2). For constant inlet temperature the stack reaches thermal equilibrium within 3 minutes.

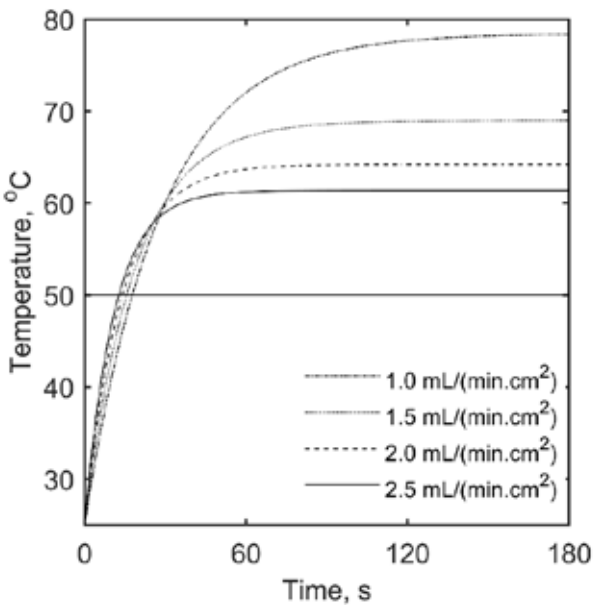

Fig. 1. Stack temperature response for a constant inlet temperature at four different lye flow rates and at 1A/cm^2

The developed model is then utilized to investigate the effect of the ramp inlet temperature profile. For this purpose, the dynamics of stack temperature is analyzed for two different rates of inlet temperature increase, with the inlet temperature rising from 25°C ambient temperature to 50°C at 1 A/cm^2. Fig. 2 illustrates the thermal behavior of the stack for different lye solution inlet temperature heating rates. The results show that as the heating rate increases, the stack temperature stabilizes more rapidly. Moreover, it has been observed that the ramp increase of the inlet temperature, compared to a constant inlet temperature, significantly prolongs the time required for the stack to reach thermal equilibrium. This suggests that a ramped inlet temperature profile can delay the startup time of AEMWE stack, which must be considered for optimal operation of AEMWE.

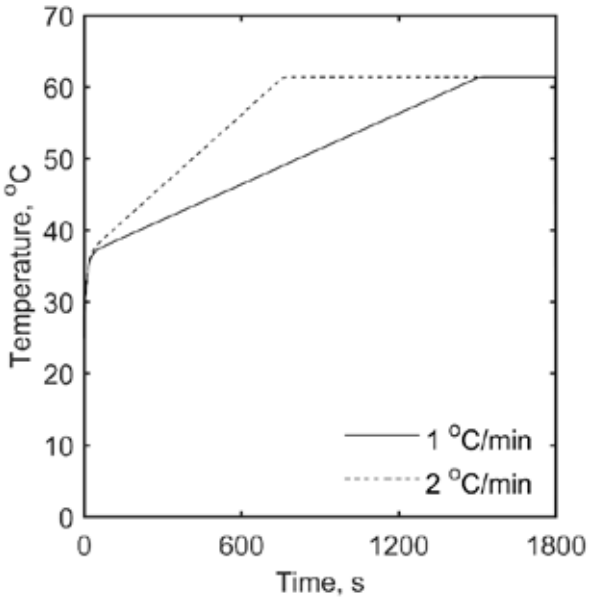

Fig. 2. Stack temperature evolution at a constant lye flow rate, 2.5 mL/(min.cm^2) for two different inlet temperature increase rates.

While the focus of this study is solely on the stack, it is important to recognize that the stack typically operates as part of a closed-loop lye circulation system in an electrolyzer system. Considering the complete electrolyzer system, it has been evaluated that using a pre-heater in the lye circulation circuit, prior to the stack, to maintain a constant inlet temperature would be more effective in shortening the stack's startup time than heating the lye solution with the heat produced by the stack and feeding it back into the stack. In the former approach, it is also recommended to consider the potential thermal stress that could be caused by the rapid stack temperature increase. Additionally, the energy consumption of the pre-heater should also be considered, as it could increase the overall energy demand of the system, potentially offsetting some of the benefits gained from reduced startup time.

4. CONCLUSIONS

In this study, a dynamic model was developed and utilized to investigate the thermal behavior and startup characteristics of a 46-cell AEMWE stack under various lye solution flow rates and inlet temperature profiles. The results demonstrated that increasing the lye solution flow rate accelerates the stack's stabilization, reducing the lye solution inlet and outlet temperature difference to approximately 11°C, with a required flow rate of 2.5 mL/(min.cm^2) to maintain this temperature difference. Additionally, the effect of different inlet temperature profiles was examined, showing that a ramped inlet temperature significantly delays the stack's startup time compared to a constant inlet temperature profile. Based on this comparison of stack thermal responses, it is suggested that the use of a pre-heater in an electrolyzer system containing an AEMWE stack would be more effective. The results obtained in this study also highlight the importance of predicting the thermal behavior of the stack in AEMWE systems using a model for optimizing the stack startup processes.

ABSTRACT
Material-based hydrogen storage systems stand out for their reliability and ease of use. Studies on ammonia borane (AB), having hydrogen storage capacity of 19.6%, have gained significant attention. Although noble metal-based catalysts (such as Pt, Ru, etc.) show the best results in AB dehydrogenation, their high cost has shifted focus toward transition metal-based alternatives. In this study, copper and cobalt, as transition metals, were supported on titanium dioxide and their performances were investigated under various parameters, including different stoichiometric ratios, AB amount, temperatures and sodium hydroxide concentrations. At 30°C, the $CuCo/TiO_2$ catalyst demonstrated a maximum catalytic activity of 218 min^{-1} and an apparent activation energy of 41.8 kJ/mol. This result represents promising performance among transition metal-based catalysts, highlighting the synergistic effect of Cu-Co compared to monometallic copper or cobalt catalysts.

Keywords: Ammonia borane, Hydrolysis, Material-based hydrogen storage, Bimetallic catalyst, Synergistic effect.

1. INTRODUCTION
The world's energy demand is increasing along with the population. Unfortunately, a significant amount of today's energy needs is still met from fossil resources. However, due to stringent regulatory frameworks and protocols aimed at reducing carbon emissions, such as the Carbon Border Adjustment Mechanism (CBAM) and The European Green Deal, countries are compelled to develop clean energy solutions. Hydrogen, with its high energy density, is notable as a promising clean and alternative energy source. The challenges of storing hydrogen in conventional gaseous and liquid forms, such as high pressure and energy costs, highlight the importance of solid hydrogen storage technologies. Among these, ammonia borane stands out as a promising material due to its stability in air and water at room temperature, low molecular weight, high hydrogen content by weight (19.6%), and non-toxicity. Compared to highly flammable and toxic compounds like $LiBH_4$ and $NaBH_4$, ammonia borane provides a safer and more efficient alternative with its superior gravimetric hydrogen storage capacity [1].
There are three ways to produce hydrogen from ammonia borane. These include (1) thermolysis, which releases 6.5% hydrogen by mass when heat is applied; (2) hydrolysis, which releases 3 moles of H_2 per 1 mole of AB at room temperature but requires appropriate catalysts because of the strong N-B bonds in ammonia borane; and (3) methanolysis, uses methanol, which is highly soluble in ammonia borane (23% at 23°C), in place of water in hydrolysis. Catalysts required for the dehydrogenation of AB can include transition metals, noble metals etc. While catalysts containing 4d and 5d metals (such as Ru, Pt, etc.) exhibit high activity, their scarcity results in high costs. In contrast, those incorporating 3d transition metals (such as Ni, Fe, Co etc.) present a cost-effective alternative with the potential for efficient hydrolysis [2].
In particular, bimetallic and trimetallic catalysts formed by combining different metals have been observed to be more active and efficient than their monometallic versions due to the synergistic effect between the elements. CuCo, CuNi, NiCo and FeNi are examples of active catalyst candidates [3]. However, it has been reported that unsupported metal alloy nanoparticles tend to agglomerate quickly while the reaction progress. Therefore, the use of support materials to prevent agglomeration by cost effectively has come to the fore. With using support materials, the active sites of the catalyst are dispersed over the support. Popular support materials include metal oxides (e.g., TiO_2, SiO_2, CeO_2, Al_2O_3), activated carbon, graphene species, and carbon nanotubes [4-5].
Copper and cobalt as a versatile non-precious metal catalyst is a good catalyst candidate with its abundant availability (i.e. low cost) and catalytic activity in the hydrolysis of amine boranes. In addition, the synergistic effect between Cu-Co has been emphasized in many studies. In this work, bimetallic, TiO_2 supported catalysts containing copper and cobalt from transition metals developed using impregnation reduction method for ammonia borane hydrolysis. The reason for the use of support material is to increase the surface area by preventing agglomeration.

2. MATERIALS AND METHODS

2.1 Materials
Reagents (analytical grade), including Copper(II)nitrate hemipentahydrate (Alfa Aesar, $Cu(NO_3)_2 \cdot 2.5H_2O$, 98%), Cobalt(II)nitrate hexahydrate (Alfa Aesar, $Co(NO_3)_2 \cdot 6H_2O$, 98%), Titanium dioxide (Alfa Aesar, TiO_2, 99,9%) and sodium

borohydride (Alfa Aesar, $NaBH_4$, 98.0%) were used in catalyst synthesis and sodium hydroxide (VWR, NaOH, 99.9%) were utilized during the hydrolysis reaction. All experiments employed high-resistivity ultrapure water (18.2 MΩ·cm⁻¹) to ensure consistency and purity. The synthesis of ammonia borane followed the procedure outlined by Ramachandran and Gagare (2007) [6].

2.2 Catalyst Synthesis

The catalysts were prepared using the impregnation-reduction process, a straightforward, useful, one-pot synthesis technique. To synthesize $Cu_{40}Co_{60}/TiO_2$ catalyst, copper (II) nitrate hemipentahydrate (2.51 mg Cu) and cobalt (II) nitrate hexahydrate (3.49 mg Co) were dissolved in 25 mL deionized water. The support material (144 mg TiO_2) was added to the solution and then stirred for 1-1.5 h to facilitate impregnation of metal ions onto the support surface. $NaBH_4$ reducing solution was then prepared in six-fold molar excess and added dropwise to the mixture to provide the amount required for complete reduction of the metal ions. Following the reduction process, the catalyst was seperated via vacuum filtration, washed thoroughly with ultrapure water, and allowed to dry overnight at 80°C in a vacuum oven.

2.3. Measurement of Catalytic Activity

The catalytic activity measurements of the bimetallic CuCo catalysts were carried out in a 4-necked jacketed reactor (20 mL) connected to a gas collection tube in a sealed manner. Temperature adjustment was provided by circulation from the reactor jacket with cryostat (Lauda RP870). Ammonia borane was dissolved in NaOH solution and injected into the reactor. The water displacement method was used to determine the volume of hydrogen generated.

2.4. Characterization

The elemental analyses and surface morphology of Cu/TiO_2, Co/TiO_2, and $Cu_{40}Co_{60}/TiO_2$ catalysts were performed using scanning electron microscopy (SEM-Philips XL30 SFEG) and energy-dispersive X-ray spectroscopy (EDS-Bruker). The crystal structures of the samples were examined using an X-ray diffractometer (XRD-Rigaku D/Max - 2200/PC) with Cu-Kα radiation at 40 kV and 40 mA. XRD patterns were recorded in the 2θ range of 5°–90° and at 3°/min scanning speed.

3. RESULTS AND DISCUSSION

In Fig. 1a – Fig. 1c SEM images of the Co/TiO_2, Cu/TiO_2 and $Cu_{40}Co_{60}/TiO_2$ catalysts are shown, respectively. According to SEM images of the catalysts, irregular structures were observed and particle diameters ranged from 1-2 µm. Analysis of the EDS results in Fig. 2 shows a peak at 2.4 keV binding energy in all spectra, corresponding to the Au coating used during sample preparation. Additionally, peaks for Copper (Cu), Cobalt (Co), Titanium (Ti), Boron (B), and Oxygen (O) were identified at their characteristic binding energies. The elemental composition analysis indicates that Cu/TiO_2 contains 5.49 wt% Cu, Co/TiO_2 contains 3.56 wt% Co and $Cu_{40}Co_{60}TiO_2$ contains 2.06% and 2.44 wt% Cu and Co, respectively. These values are consistent with the metal loading rate of the catalysts of 4 wt%. XRD analysis was performed to investigate the crystal structures of Co/TiO_2, Cu/TiO_2 and $Cu_{40}Co_{60}/TiO_2$ catalysts.

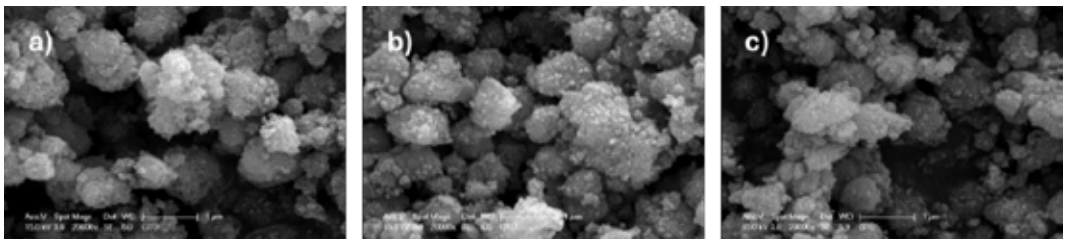

Fig. 1. The SEM images of catalysts at a scale of 1 µm, a) Co/TiO_2, b) Cu/TiO_2 and c) $Cu_{40}Co_{60}/TiO_2$

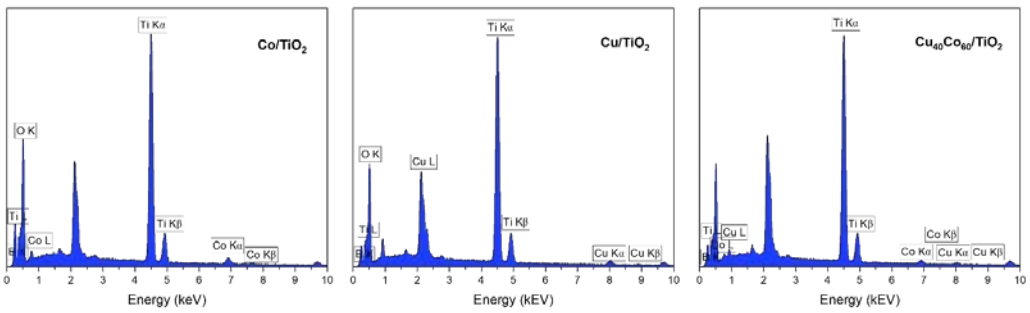

Fig. 2. EDS spectrum of Co/TiO_2, Cu/TiO_2 and $Cu_{40}Co_{60}/TiO_2$

The results of the analysis are shown in Fig.3. Peaks of TiO_2 anathase phase were sharply detected in each of the catalysts. The copper and cobalt structures were not visible in the XRD spectra as they are amorphous and only constitute a small fraction of the catalyst content (4%wt.).

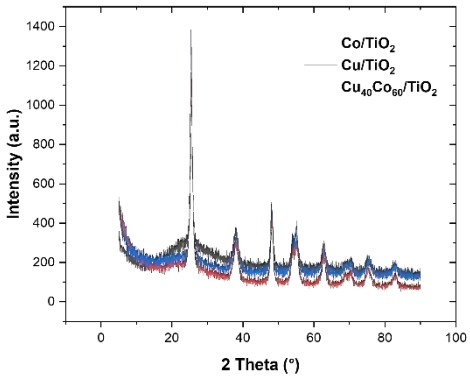

Fig. 3. XRD patterns of Co/TiO_2, Cu/TiO_2 and $Cu_{40}Co_{60}/TiO_2$

In the first part of the study, copper and cobalt catalysts were synthesized as monometallic (Cu/TiO_2 and Co/TiO_2) and bimetallic in different stoichiometric ratios ($Cu_{20}Co_{80}/TiO_2$, $Cu_{40}Co_{60}/TiO_2$, $Cu_{50}Co_{50}/TiO_2$, $Cu_{60}Co_{40}/TiO_2$ and $Cu_{80}Cu_{20}/TiO_2$). The performance test results are shown in Fig.4 a) (initial test parameters: 1mmol AB, 4%wt. Catalyst metal loading, 1 mg metal, 0.1M NaOH, 25°C).

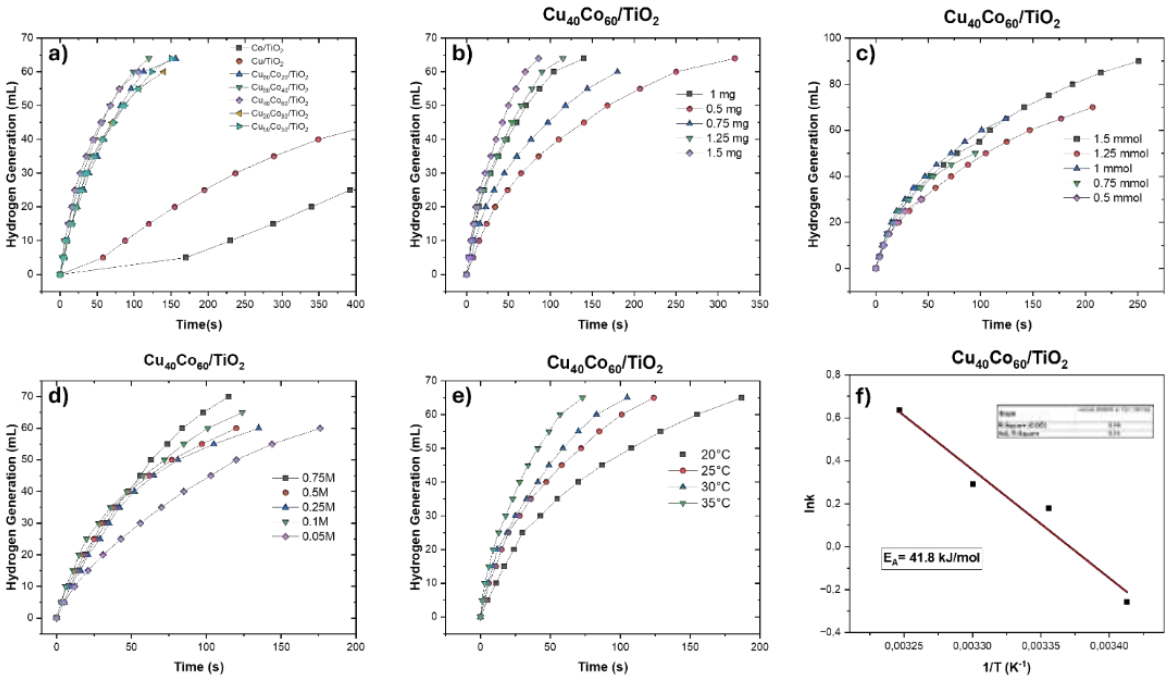

Fig. 4. Catalyst performans tests a) testing of catalysts in different stoichiometric ratios, b) The metal amount effect on $Cu_{40}Co_{60}/TiO_2$ catalyst, c) The AB mmol effect on the $Cu_{40}Co_{60}/TiO_2$ catalyst, d) The NaOH concentration effect on the $Cu_{40}Co_{60}/TiO_2$ catalyst, e) The temperature effect on the $Cu_{40}Co_{60}/TiO_2$ catalyst, f) Using Arrhenius plot for the determination of the $Cu_{40}Co_{60}/TiO_2$ catalyst

It is evident that the monometallic Cu/TiO_2 and Co/TiO_2 catalysts exhibited a lower performance than the bimetallic catalysts. $Cu_{40}Co_{60}/TiO_2$ was selected as the most active. Subsequently, as shown in Fig. 4b, tests were conducted with the $Cu_{40}Co_{60}/TiO_2$ catalyst to examine the impact of the catalyst metal amount on activity. The tests were carried out using total Cu and Co metal amounts in the range of 0.5 - 1.5 mg, with the optimum metal amount determined to be 1 mg. Further tests were conducted with varying AB fuel amounts in the range of 0.5 - 1.5 mmol AB to evaluate its impact, with the optimal AB amount determined as 1 mmol (33 mg), as shown in Fig. 4c. To examine the effect of sodium hydroxide on the reaction, experiments were performed with NaOH concentrations in the range of 0.05 - 0.75 M. The highest activity was achieved in a 0.1 M NaOH solution (Fig. 4d). Finally, tests were performed at 20°C, 25°C, 30°C, and 35°C, revealing that the reaction rate increased with rising temperature. Based on the findings from all tests, the optimum

reaction conditions for the most active catalyst, $Cu_{40}Co_{60}/TiO_2$, were determined as follows: 4 wt.% catalyst loading, 1 mg total metal content, 1 mmol AB (33 mg), 0.1 M NaOH solution, and 30°C. Under these conditions, the catalyst exhibited a turnover frequency (TOF) of 218 min^{-1} and an activation energy of 41.38 kJ/mol. Catalysts developed for ammonia borane hydrolysis are summarized in Table 1, along with their activation energies and TOF values. The $Cu_{40}Co_{60}/TiO_2$ catalyst demonstrates superior performance compared to many other catalysts reported in the literature, achieving higher catalytic activity while reducing activation energy.

Table 1. Comparison of catalyst for ammonia borane hydrolysis

	TOF (min^{-1})	**Ea (kJ/mol)**	**Ref.**
$Ni_{0.6}Cu_{0.4}O/NC$	26.20	56.8	[7]
CoCu-NC-5	8.12	34.25	[8]
$Co_{0.52}Cu_{0.48}$	3.40	33.7	[9]
$Ni_{0.19}Cu_{0.81}$	2.70	33.3	[9]
$Ni_{0.3}Co_{0.3}Cu_{0.4}/TiO_2$	10	61.4	[10]
$Co_{0.8}Cu_{0.2}/CNC$	23.37	50.79	[11]
$Cu_{40}Co_{60}/TiO_2$	218	41.8	This work

4. CONCLUSIONS

One of the safe and practical methods for hydrogen storage is ammonia borane, which has been gaining increasing importance. Particularly in scenarios requiring rapid and convenient hydrogen production, such as critical and emergency situations, ammonia borane plays a vital role. For the hydrolysis of AB, cost-effective catalysts based on non-noble transition metals are essential. This study focuses on copper and cobalt catalysts with synergistic effects, revealing that at 30°C, the $Cu_{40}Co_{60}/TiO_2$ catalyst achieves a TOF value of 218 min^{-1} and an activation energy of 41.8 kJ/mol. These values stand out in the literature for their high activity and low activation energy among non-noble metal-based catalysts.

ABSTRACT
The study deals with the synthesis and characterization of semiconductor oxides CuO and ZnO for the production of green H_2 gas by photo catalysis reaction under UV-visible light. The oxides were hydrothermally synthesised from reactive reagents with a thermally treatment at 450-500°C during 6 h for several anneals. The oxides were identified and observed by X-ray diffraction (XRD) and scanning electron microscopy (SEM) respectively. The chemical composition of oxides was determined by energy dispersive spectroscopy (EDS) analysis. The results showed that CuO and ZnO oxides as semiconductor phases were obtained successfully. The gas production by photo catalysis was carried out in a double-walled pyrex glass photo reactor, equipped with a thermostat. It is connected to a U-shaped water pressure gauge that allows the volume of gas released to be measured directly. The photo catalytic tests are carried out in various media. The oxides have shown promising results in terms of improving the catalytic activity of semiconductors in a neutral environment, showing to be effective in hydrogen gas production.

1. INTRODUCTION

The 21st century is marked by unprecedented energy challenges, where the search for renewable and sustainable energy sources has become a global priority. In the face of the climate crisis and the depletion of fossil resources, technological innovation plays a crucial role in the transition to a green economy [1-2]. Among the many emerging solutions, the production of biohydrogen stands out for its potential to provide clean and abundant energy, without greenhouse gas emissions. Hydrogen, as an energy carrier, offers considerable advantages [2]. It can be used in various applications, ranging from fuel cells for electric vehicles to energy storage systems, as well as for the production of heat and electricity [2-3].
However, the method of producing this hydrogen is crucial for its environmental impact. Traditional methods, often based on hydrocarbons, are energy-intensive and generate a significant amount of CO_2. Therefore, the production of biohydrogen, exploiting renewable sources and ecological processes, has become a particularly promising avenue of research [4-6]. Hydrogen is not a primary energy like coal, oil or natural gas; it is an energy vector that must be produced before being used. Hydrogen production represents a major advance in the search for renewable and sustainable energy. Unlike conventional hydrogen, which is often produced from fossil fuels, hydrogen is a process that is produced by electrolysis of water and uses electricity from renewable sources such as wind and solar [4-5]. Since this process does not emit CO_2, it has become an ecological and promising alternative to reducing greenhouse gas emissions. Hydrogen can also be produced from chemical reactions and photo catalysis [5-6]. Hydrogen has the potential to play an important role in the global energy transformation.
In this context, our work focuses on the synthesis and characterization of oxides CuO and ZnO as semiconductors for the production of hydrogen gas.

2. MATERIALS AND METHODS

The oxides were prepared by hydrothermal method using $Cu(NO_3)_2.3H_2O$) and $Zn(NO_3)_2.6H_2O$) nitrate salts from Merk with a purity of 99%. The mixtures are stirred at room temperature and heated to 100 °C to remove water and then to 300 °C to denitrify them. After grinding, the homogenized powder is heated in the oven at a temperature of 450 to 500°C for 6 h under several anneals to obtain the semiconductor phases of CuO and ZnO.
The H_2 production by photo catalysis was carried out in a double-walled glass reactor in neutral and basic media as reported in previously work [6]. The reactor (125 cm^3) is irradiated by tungsten lamps with a total power of 600 W. The photo activity was measured by the gas volume produced in these media solutions. All reactions are carried out at 50°C under stirring of about 300 rpm. The bubble of solutions is used with He gas in the presence or without catalysts during 15 and 30 respectively.
The oxides were identified by XRD using a Philips diffractometer type PW 1710. The morphology of the samples was observed by SEM using an equipment type XL20. The chemical composition of the oxides was determined by EDS analysis coupled in the same SEM equipment.

3. RESULTS AND DISCUSSION

3.1. Characterization of samples

The Fig.1 shows XRD patterns of prepared CuO and ZnO oxides. All XRD peaks are indexed as Muller (hkl) in the range 2θ of 5 to 120° and identified as belong to the pure phases of CuO and ZnO oxides according to the standard files JCPDS 01-080-0076 and JCPDS 01-089-7102 respectively. These results are in agreement with those of Belaissa and al.[7].
The morphology of the oxides is highlighted by SEM micrographs shown in Fig.2. One can observe irregular forms of CuO and ZnO grains with average size between 0.5 and 1 µm. These fine particles offer are necessary to diffuse into the interface of CuO and ZnO oxides to improve the photo catalysis reaction for the H_2 gas production.
The Table 1 shows the results of EDS analysis of prepared oxides, confirming the presence of the main elements Cu and Zn in their structures. The carbon element is detected by EDS because it was used on the surface of the samples to make them conductive and facilitate the analysis.

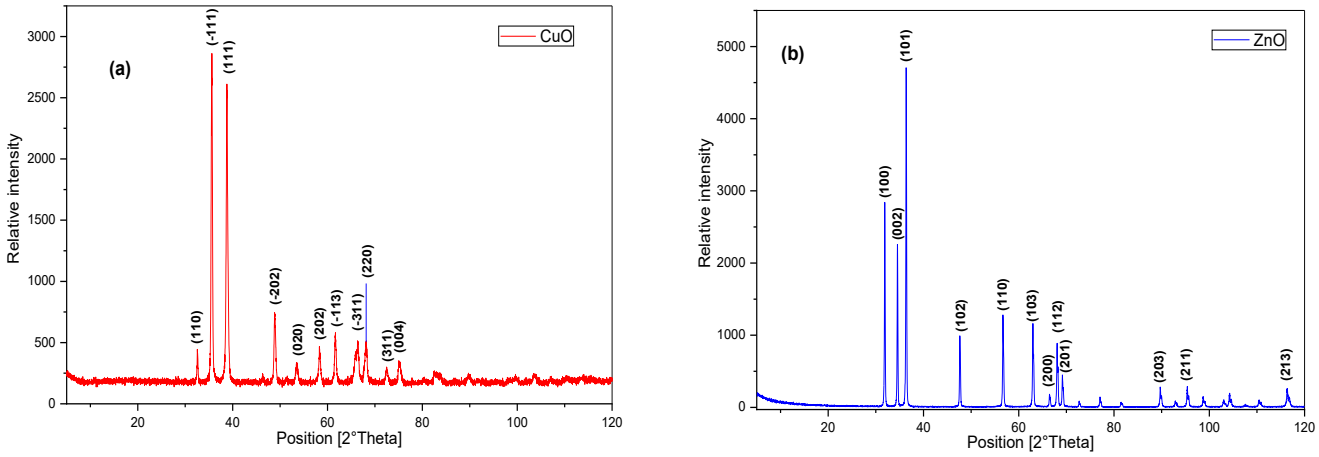

Fig.1. XRD patterns of CuO (a) and ZnO (b)

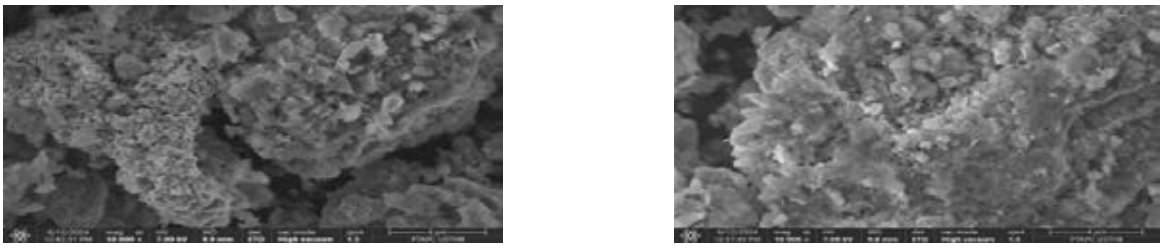

Fig.2. Micrographs by SEM of CuO (a) and ZnO (b)

Table 1. Chemical composition by EDS analysis of CuO and ZnO oxides

	C	O	Cu	Zn
CuO				
At. %	12.0	52.0	35.4	-
Wt. %	6.2	35.5	57.3	-
ZnO				
At. %	14.4	58.0	-	27.5
Wt. %	9.0	48.64	-	41.1

3.2. Hydrogen production by photo catalysis

The H_2 production by photo catalysis was carried out firstly in neutral medium using sodium sulfate Na_2SO_4 dissolved in water. We start with a blank test (nb) using a bubble of the He gas to eliminate all the gases dissolved in the solution. After closing the He, the reactor is placed under visible light in order to produce H_2 gas. One gas production has stopped, the lamps are closed and 0.1 g of CuO is introduced into the reactor. A bubble is also carried out and after the

production of H_2 is obtained in the presence of CuO oxide or semi conductor (nsc). When equilibrium is reached, the lamps are turned off again and a quantity of 0.19 g of hole sensor (Na_2SO_3) is added to the previous solution. We then measure the quantity of H_2 gas produced in the presence of the holes in the solution (nct).
Fig.3 shows the evolution in time of the mole number of hydrogen produced in this media for CuO and ZnO oxide catalyst respectively. According to the Figures, it seems that the behavior of the two catalysts is different. In the case of CuO catalyst (Fig.3(a)), the mole number of H_2 gas increases rapidly during the 5 minutes of the reaction to reach a maximum in the case of (nct) and (nsc) modes of 4 10^{-7} and 2.25 10^{-7} mole respectively. After these times, a decrease of the production of H_2 is observed until 40 min of reaction. The test of blank mode highlights a maximum of H_2 quantity of 3 10^{-7} mole reached at 10 min with a visible plateau between 6 and 12 min, indicating an equilibrium. In the other hand, Fig.3(b) shows another behavior of ZnO catalyst toward the evolution of mole number of H_2 in different modes. The test under (nsc) condition performs well and reaches a maximum of H_2 gas production (4 10^{-7} mole) during 12 min. It is followed then by (nb) and (nct) modes with 3 10^{-7} and 2.5 10^{-7} mole respectively. In the three modes, an equilibrium plateau is observed at 9-14 min (nsc), 6-14 min (nb) and 5-11 min (nct), revealing that great quantity of H_2 can be produced during these equilibriums. From these results, the performance of ZnO catalyst in (nsc) mode is best to that CuO and reached a double quantity of H_2 produced. However, the performances of CuO and ZnO in the (nb) mode still stable.

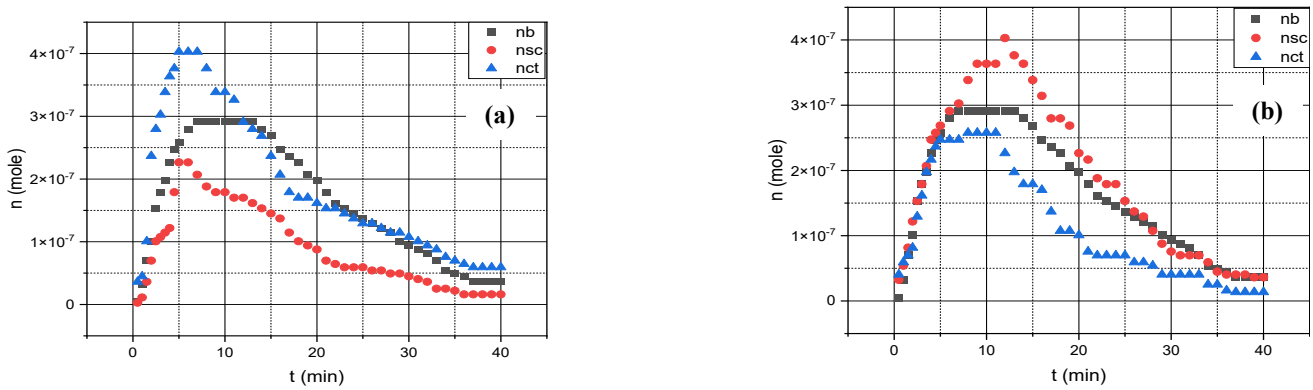

Fig.3. Evolution of mole number of H_2 in time under neutral medium using CuO (a) and ZnO(b) oxide catalysts at different modes (nb, nsc and nct)

Fig.4 shows the evolution in time of the mole number of H_2 gas produced in basic medium for CuO and ZnO oxide catalysts using KOH dissolved in water. All tests are carried out as used in the same way as those in neutral environment. From these results, the best tests for the production of H_2 are obtained in (nb) mode onto the CuO catalyst (2.6 10^{-7} mole) with a equilibrium plateau between 10-17 min. ZnO catalyst records a 3.25 10^{-8} mole of H_2 gas less than CuO. Comparing the obtained results Fig.3 and Fig.4, it is clearly that the two catalysts perform best in neutral media. These results are in agreement with those reported in the literature [6].
In this regard, the CuO and ZnO oxides are optically active semi conductors because of their chemical stability. They generate electron/hole (e−/h+) pairs according to the radicals OH• and/or O_2 • through valence (VB) and conduction (CB) bands with high oxidative aptitude to cause a destructive oxidation reaction. ZnO is known with its wide band gap (2.98 eV) requires an excitation in the UV region and CuO is a p type oxide with a thin band gap of 1.2 eV [7]. The production of H_2 gas can be achieved via a photo catalytic reaction onto p CuO and n ZnO according to the following mechanism:

$$CuO + h\,v \rightarrow (h^{+}_{VB})\ CuO + (e^{-}_{CB}) \quad \text{and} \quad ZnO + h\,v \rightarrow (h^{+}_{VB})\ ZnO + (e^{-}_{CB}) \qquad (1)$$

$$2SO_3^{2-} + (h^{+}_{VB}) \rightarrow S_2O_6^{2-} \qquad (2)$$

$$H_2O + 2(e^{-}_{CB}) \rightarrow H_2 + OH^{-} \qquad (3)$$

Due to the elevated energetic location of CuO and ZnO valence bands, the oxygen molecules do not compete with the water oxidation and it is necessary to reduce the photo holes which are scavenged by SO_2^{3-} (Eq.(2)). This reaction has a potential (E°) of about -0.2 V compared to that of the couple SO_4^{2-}/SO_3^{2-} of -1.2 V. This last potential is very negative and doesn't contribute in the oxidation reaction which explains the observed equilibrium plateau in Fig.3 and Fig.4. The phenomenon is due to the saturation of competitive reduction at the end product $S_2O_6^{2-}$.

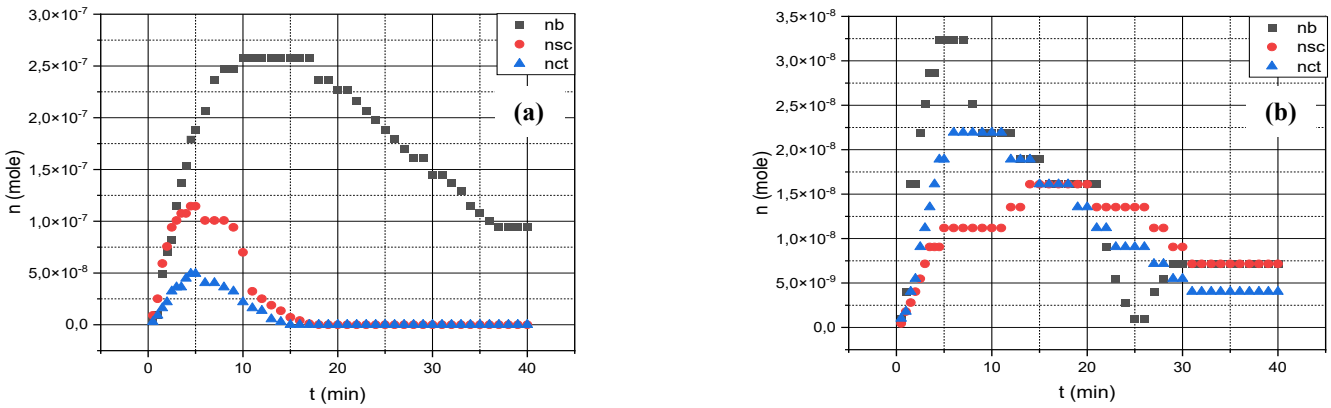

Fig.4. Evolution of mole number of H_2 in time under neutral medium using CuO (a) and ZnO (b) oxide catalyst at different modes (nb, nsc and nct)

4. CONCLUSIONS

CuO and ZnO catalysts have been prepared successfully in the production of H_2 gas by photo catalytic reaction. They have identified by XRD and the structural properties have highlighted by SEM and EDS analysis. Their optical gaps and stability allow them to be very interesting in the photo catalysis conversion reaction. The CuO and ZnO catalysts showed good performances in neutral media recording a maximum quantity of hydrogen of 4 10^{-7} mole. The hydrogen was produced in presence of SO_2^{3-} under UV-visible light and a mechanism process was proposed. The CuO and ZnO oxides are low cost and non toxic and can be attractive as photo catalysts for the production of green H_2 gas.

ABSTRACT

The effect of phthalocyanine with different central metals like cobalt and nickel in hydrogen evolution from hydrogen sulfide (H2S) is investigated. Impact of using different gas diffusion layers, i.e. nickel (Ni), titanum (Ti), and stainless steel (SS), as the support of metal phthalocyanines (MPc's) in the three-electrodes system are studied. The linear sweep voltametry (LSV) and electrochemical impedance spectroscopy (EIS) are measured to understand the behavior of the catalysts and supports. The cobalt phthalocyanine (CoPc) on nickel (Ni) gave the best electrochemical response in compare to other catalysts and supports. Long term performance aspect needs to be investigated.

Keywords: Hydrogen Sulfide, Hydrogen, Electrolysis, Phthalocyanine

1. INTRODUCTION

The predominant sources of hydrogen sulfide include the hydrogen desulfurization (HDS) process utilized for oil purification, as well as its occurrence in natural gas wells, jeothermal sources and during steel manufacturing (Hensen et al., 2001).
One of the common methods is the convertion of H2S by thermal methods like Claus. In Claus process H_2S is converted to sulfur and at a tempeature more than 1000°C:

$H_2S + 3/2O_2 \rightarrow SO_2 + H_2O$, and $2H_2S + SO_2 \rightarrow 2H_2O + 3S\downarrow$

The other product of this reaction is water. This method does not provide any hydrogen, but also consumes a huge amount of energy. On the other hand, the electrochemical technique remains the best option due to its unrivaled advantages such as quick response, cost effectiveness, environmental friendliness, and ease of operation. Therefore, H_2S electrolysis is a "killing two birds with one stone" technique that delivers a new cost-effective H_2 source while also removing the pollutant H_2S from the atmosphere(Dan et al., 2017). H_2S electrolysis involves cathodic H_2 and anodic sulfur oxidation reactions (SOR) at a low cell voltage of 0.14 V (Hakim et al., 2023). Replacing the oxygen evolution reaction (OER) with the sulfur oxidation reactions (SOR) reduces the electrolysis potential from 1,23 V (H_2O electrolysis) to 0,14 V (H_2S electrolysis), resulting in significant energy savings for pure H_2 generation (Kumar and Nagaiah, 2022). In the alkali solution H_2S is desolved in the solution(Yang et al., 2019):

$H_2S + OH^- \rightarrow H_2O + HS^-$

And then in the electrolysis reaction:

Anode: $2HS^- \rightarrow S + H_2S + 2e^-$, and $HS^- + OH^- \rightarrow S + H_2O + 2e^-$

Cathode: $2H_2O + 2e^- \rightarrow H_2 + 2OH^-$

and then, sulfur rapidly dissolves in the alkaline media forming polysulfides:

$S + HS^- + OH^- \rightarrow S_2^{-2} + H_2O$

Phthalocyanine with different central metals has distinctive benefits as a catalyst such as, the ease of large-scale production, distinctive redox behavior, high efficiency, ease of separation, and recyclability (Yang et al., 2021). An ideal system for conducting redox reactions is produced by MPcs with a metal cation in the middle of the macrocycle and long conjugated π-bonds (Osmanbas et al., 2008). Since the catalytic reaction has been driven in two different processes, including the metal-based and ligand-based reductions, the central metal plays a critical role in MPc performance (Koca et al., 2011). Therefore, by building complexes with redox active metal cations, Pcs' redox activity can be raised. If the

π-system is extended by substituting groups with conjugated double bonds, the redox behavior of MPc can be further enhanced (Özçeşmeci et al., 2013). The type of metal center, substitution, support, and aggregation of Pcs are some of the critical parameters that determine the total H_2 production rate for the photo- and electrocatalytic H_2 formation processes of Pc-based catalysts(Keshipour and Asghari, 2022). For a thorough understanding of the role of the central metal atom in a three-electrode cell electrolysis of H_2S for hydrogen production, cobalt, and nickel phthalocyanines were selected for this study.

2. MATERIALS AND METHODS

2.1. Materials

$Na_2S{\cdot}9H_2O$ was utilized as the source of H_2S. The original pH values of the Na_2S aqueous solution were adjusted with sodium hydroxide (from Riedel-DeHaen and LabKim). Cobalt phthalocyanine (CoPc) 96%, and nickel phthalocyanine (NiPc) 98% were bought from BLD Pharmatech GmbH. Tetrahydrofuran (THF, 99.9%) used as solvent. Support materials were 300 micron stainless steel fiber, 150 micron %56 porosity titanium fiber, and 200 micron %83 porosity nickel fiber from Bekaert.

2.2. Electrode Preparation

In order to prepare electrode ink, 10 mg of MPc's, 20 mg of 5% Nafion, 0,1 ml distilled water, and 140 mg THF were added in a container, and mixed in an ultrasonic bath. Then, surface of the electrode supports (porous nickel, titanium, and stainless steel) were either painted or spray-coated. The dyed materials were kept at 130°C for 10 minutes, then they were allowed to cool and weighed. Loading of cobalt phthalocyanine (CoPc), and nickel phthalocyanine (NiPc) on the surface of electrode's supports were measured and provided in Table 1.

Table 1. The amount of catalyst loaded on the surface of different types of porous supports

Support/Material	CoPc	NiPc
Stainless Steel (SS)	1.3631 mg/cm²	2.0248 mg/cm²
Titanium (Ti)	1.0179 mg/cm²	1.3913 mg/cm²
Nickel (Ni)	1.8882 mg/cm²	1.7205 mg/cm²

2.3. Electrochemical measurement

All electrochemical measurements have done by potentiostat Gamry 5000. A conventional three-electrode cell, wherein MPc (1cm^2) on diffusion support acts as a working electrode (WE), and a platinum wire as counter and 3.5M KCl Ag/AgCl as reference electrodes. The electrolyte solution was 0.1M Na_2S, and 0.1M NaOH. The SOR activity of the catalysts was illustrated by performing linear sweep voltammetry (LSV) over a potential range of -0,4 to 0,1 V vs. SHE at scan rate 50 mV/s. The electrochemical impedance spectroscopy (EIS) measurements were performed in a frequency range of 100 kHz to 200 mHz at open circuit potential (OCP) and 0.1 V vs. SHE.

3. RESULTS AND DISCUSSION

The electrocatalytic performance is done by LSV at 50 mV/s scan rate. The sulfide oxidation reaction (SOR) shows the different catalyst performance including NiPc on Ni and CoPc on Ni in compare to the porous Ni, Ti, and SS without catalyst and also platinum in 0.1 M Na_2S and 0.1 M NaOH electrolyte solution. As it is shown in **Figure 1a**, CoPc on Ni and NiPc on Ni have the lowest OCP around −380 mV vs. SHE. At 10 mA/cm² current density, the potential of CoPc on Ni, NiPc on Ni, and Ni are −32, −2, and +131 mV vs. SHE, respectively. As it is clear, CoPc on Ni has the minimum polarization. Besides, Pt with the maximum 2.21 mA/cm² current density at 200 mV is not a desirable electrode for H_2S, while the CoPc on Ni with maximum current density 20 mA/cm² at 173 mV seems to be a better choice.

By changing the support to Ti, the SOR behavior of the catalysts is almost similar to the Ni support; however, Ti without a catalyst shows a lower potential at 8 mA/cm² current density than NiPc on Ti and CoPc on Ti (Fig. 1b). The negligible current densities up to 350 mV vs. SHE in the LSV graph of Fig. 1c reveal that SS cannot be a desirable support for the H_2S system.

The electrochemical impedance spectroscopy (EIS) was performed at the beginning of the experiments at open-circuit potential (OCP) and 0.1 V vs. SHE to understand which electrode has lower impedance among Ni, Ni-coated catalysts, and platinum (Pt) as a reference for comparison. As shown in Fig. 2a, coated Ni electrodes (NiPc and CoPc) have lower charge transfer resistance (R_ct) compared to Ni and Pt. By fitting these results to the LSV data, one may conclude that

lower charge transfer resistance causes faster electron transfer on the surface of the electrodes. Platinum exhibits the highest resistance compared to other catalysts, possibly due to sulfur poisoning.

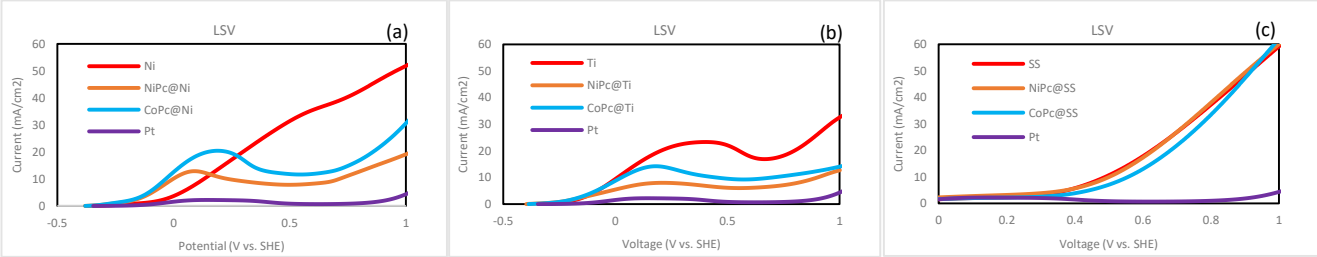

Figure 1. LSV measurements for CoPc and NiPc on a) Ni support, b) Ti support, and C) SS support (scan rate 50 mV/s, and the electrolyte solution 0.1MNa_2S+0.1NaOH)

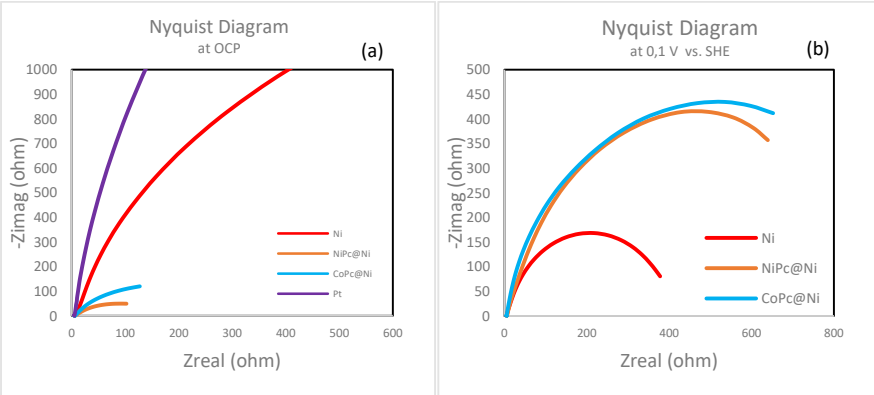

Fig. 2 EIS measurements for CoPc and NiPc at a) open circuit potential (OCP), b) 0.1 V vs. SHE (in the electrolyte solution 0.1MNa_2S+0.1MNaOH)

By comparing the LSV results of different types of supports (Fig. 3a and 3b), it is clear that the porous Ni is a better support for NiPc, while Ti has a better response when CoPc is coated on it.

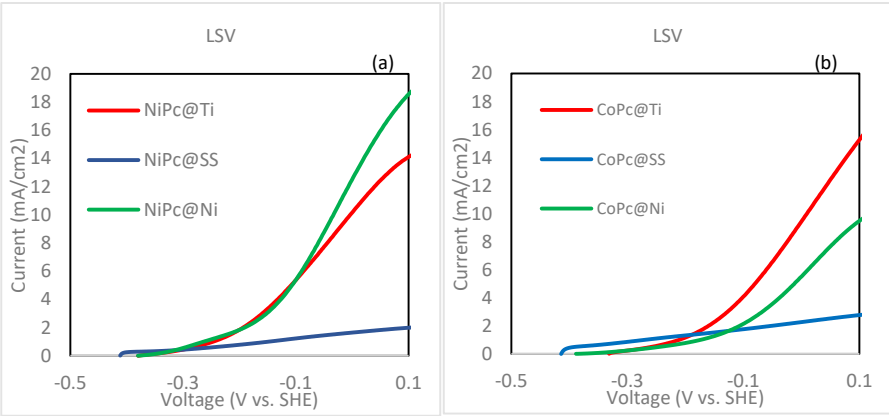

Fig. 3 Linear Sweep Potential measurements for a) NiPc, b) CoPc on Ti, Ni, SS. (electrolyte solution 0.1MNa_2S+0.1MNaOH)

4. CONCLUSIONS

The influence of phthalocyanine with different central metals including cobalt, and nickel in hydrogen evolution electrolysers from hydrogen sulfide is explored. Nickel (Ni), titanum (Ti), and stainless steel (SS) diffusion supports for metal phthalocyanines (MPc's) are compared in three-electrodes system. The linear sweep potential (LSV) and electrochemical impedance spectroscopy (EIS) are measured to understand the behavior of the catalysts and supports. The Cobalt phthalocyanine (CoPc) on nickel (Ni) exhibits the best reaction in relation to other catalysts and supports. In addition nickel and titanium are considered as effective supports for MPc's. Polarization potentials are lowered in the presence of H_2S.

ABSTRACT

In the present study, Fe_2O_3 and Clay/Fe_2O_3 were prepared by hydrothermal method for the hydrogen gas production. The Fe_2O_3 oxide was obtained from reactive reagents with a thermally treatment at 450°C during 6 h and during various anneals. Algerian clay was used as support to prepare Clay/Fe_2O_3 by dispersing method. All obtained samples were characterized by X-ray diffraction (XRD), scanning electron microscopy (SEM) and energy dispersive spectroscopy (EDS) for highlighted their textural properties. The results showed that the hematite α-Fe_2O_3 semiconductor phase was obtained successfully. Neutral and basic media were tested for the production of Hydrogen by photo chemical conversion under UV-visible irradiation in presence of Na_2SO_3 as hole sensor. These experiments showed promote results in gas H_2 production using the synthesised composite Clay/Fe_2O_3, semiconductors α-Fe_2O_3, CuO and ZnO in neutral medium.

Keywords: Hydrogen, Oxides, Fe_2O_3, Clay/Fe_2O_3, Photo conversion, Neutral and basic medium

1. INTRODUCTION

Actually, the explore of innovative energetic sources is an significant world subject due to the reduction of fossils energy [1-2]. The use of other clean energies as solar or UV-visible light can be attractive [3-4]. In this context, the hydrogen production is an environmentally friendly gas [5] and is produced from the methane (90%) which is responsible to liberate a great quantity of CO_2 pollution and changing the climate [6]. Several alternatives as thermal, photo conversion and photochemistry are like inexpensive and attractive means for water electrolysis. The gases separation from these processes makes them more difficult. In the opposite, the water photo electrolysis is an interesting way using oxides as semi conductors or composites prepared by oxides doping [7]. Nevertheless, the main obstruction limiting their uses is the wide band gap which limits the solar absorption to UV light since the small energy of the valence band made up of O_2:2p orbital (6.5 eV). Thus, the use of oxides as Fe_2O_3 can decrease the optical gap because it is reported to be active in photo catalysis [8-9] and its two electronic bands are joined together. This oxide is low cost and it is known
having a fine band semi conductor which can translate about 40% of the solar radiation [10] with n or p types. To improve the photo conversion, a new approach is used to apply composites [11-12]. The natural clays are used as support with different metals or oxides and revealed interesting activities in the electrochemical reduction [13]. The aim of the present work is the doping of the Algerian clay by hematite α-Fe_2O_3 which supposed to increase radiance to energy conversion and improve hydrogen production onto composite material by water reduction upon UV-visible light.

2. MATERIALS AND METHODS

The Fe_2O_3 oxide was prepared by hydrothermal method using $Fe(NO_3)_3.9H_2O$) nitrate salt from Merk with a purity of 99%. The mixture is stirred at room temperature and heated to 100 °C to remove water and then to 300 °C to denitrify it. After grinding, the homogenized powder is heated in the oven at a temperature of 450 °C for 6 h under several anneals to obtain the semiconductor hematite phase (α-Fe_2O_3). After, we prepared a heterogeneous composite by mixing clay and α-Fe_2O_3 by a hydrothermal process. The mixture is stirred for 2 h at room temperature and heated to 100 °C to remove water.
The H_2 production by photo catalysis was carried out in a double-walled glass reactor in neutral and basic media as reported in previously work [7] (Fig.1). The reactor (125 cm^3) is irradiated by tungsten lamps with a total power of 600 W. The photo activity was measured by the gas volume produced in these media solutions. All tests are carried out at 50°C under stirring of about 300 rpm. The bubble of solutions is used with He gas in the presence or without catalysts during 15 and 30 respectively.
The oxide and composite were identified by XRD using a Philips diffractometer type PW 1710. The morphology of the samples was observed by SEM using an equipment type XL20. The chemical composition of the samples was determined by EDS analysis coupled in the same SEM equipment.

3. RESULTS AND DISCUSSION

3.1. Characterization of samples

The Fig.2 shows XRD patterns of prepared Fe_2O_3 and Clay/Fe_2O_3. The XRD peaks in the range 2θ of 5 to 90° and identified as belong to the pure phases of hematite (α-Fe_2O_3) and clay according to the previously works [7, 9]. Fig.2(a) shows the XRD peaks of Fe_2O_3 at 2θ: 24°, 33°, 35°, 44°, 49°, 55°, 62° and 64° and Fig.2(b) illustrates the peaks of Clay/Fe_2O_3 at 9°, 19°, 21°, 22°, 24°, 27°, 29°, 33°, 35°, 42°, 50°, 55°, 62°, 64° and 73°. The results confirm that all peaks of hematite are present in the structure of clay and the decrease of their intensities is attributed to its good dispersion in the structure of final composite. These results are in agreement with those of Mekatel et al.[7].

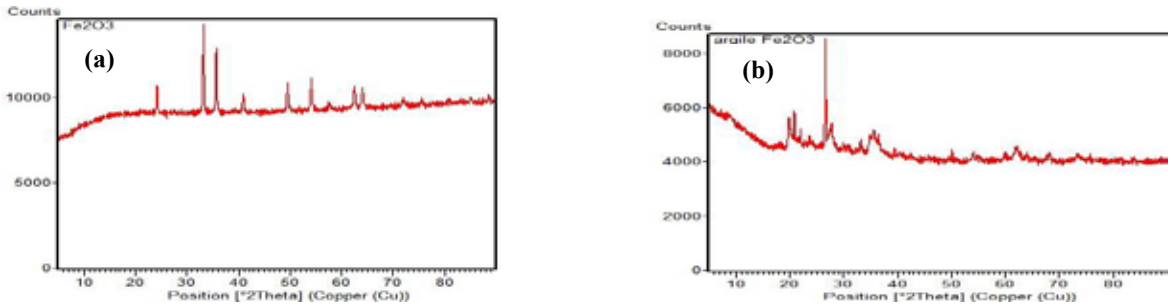

Fig.2. XRD patterns of Fe_2O_3 (a) Clay/Fe_2O_3 (b)

The morphology of the samples is observed by SEM micrographs as shown in Fig.3. From Fig.3(a), it can observe a fine particles of Fe_2O_3 with an average size of 0.1 to 0.2 µm and agglomerates of irregular forms of grains. However, Fig. 3(b) reveals a sheet forms of clay with a dispersed fine Fe_2O_3 particles on its surface, highlighted also by EDS analysis. The Table 1 shows the results of EDS analysis of prepared Clay/Fe_2O_3, confirming the presence of the main elements of clay matrix as Si, Al, Na, Mg, K and Ca and specially Fe incorporated in its structure. The carbon was used during EDS analysis as coating to make the sample conductive.

Wt. %	7.9	46.6	2.7	1.6	6.5	16.7	1.1	0.5	16.4

3.2. Hydrogen production by photo catalysis

The H_2 production reaction by photo conversion was carried out in three steps. The first one called blank test is used in neutral medium via an aqueous solution containing Na_2SO_4. In this case, a He gas bubbling was used to eliminate the dissolved gases in the solution. In the second step, we close the He flow and the glass reactor is placed under UV-visible light for produce H_2 gas. After saturation of gas production, the lamps are closed and 0.1 g of Fe_2O_3 is added in the solution with bubbling it during 15 min. Then, the production of H_2 is obtained in the presence of Fe_2O_3 or semi conductor (nsc). In the last step, the equilibrium is reached after a time, the lamps are turned off again and a quantity of 0.2 g of hole sensor (Na_2SO_3) is added to the previous solution (nct).

Fig. 4 shows the evolution in time of the mole number of hydrogen produced in this media for Fe_2O_3. According to the Fig. 4, it seems that the behavior of the two samples is different. In the case of Fe_2O_3 (Fig. 4(a)), the mole number of H_2 gas increases during the 10 minutes of the reaction to reach a maximum in the case of (nct) and (nsc) modes of 6 10^{-7} and 3.5 10^{-7} mole respectively. After this time, clear plateaus were observed during 10-14 and 8-12 min respectively and a decrease of the production of H_2 is observed until 40 min of reaction. The test of blank mode reveals a maximum of H_2 quantity of 1.75 10^{-7} mole reached at 11 min with a long plateau between 11 to 20 min, indicating an equilibrium step and a continuous production of H_2 gas. Moreover, Fig. 4(b) shows the behavior of Clay/Fe_2O_3 composite toward the evolution of the mole number of H_2 in different modes.

The test under (nsc) condition performs well compared to others where the evolution of the number mole of H_2 increases gradually to reach a maximum of 7 10^{-6} mole during 30 min. After, an equilibrium plateau is observed during 30 to 40 min. The tests modes (nct) and (nb) have also recorded 4 10^{-6} and 3.1 10^{-6} mole respectively with also a long plateaus between 10 to 40 min. These best performances can be explained by the use of semi conductor Fe_2O_3 with fine particles of 0.1 µm which allow a high surface and more photo electrochemical sites necessary to enhance the production of H_2 gas. These results are in good agreement with those reported in the literature [1-2].

In the other hand, the results of Fig.5 illustrates the evolution in time of the mole number of H_2 gas produced in basic medium for Fe_2O_3 and Clay/Fe_2O_3 using a aqueous solution of KOH. All tests are carried out as used in the same way as those in neutral medium. According the Fig.5(a), the production of H_2 gas started after 5 min and increased rapidly to reach a quantity value of 5.5 10^{-7} mole in (nct) mode and finally stopped suddenly at 14 min. There is no H_2 gas in (nsc) mode but in (nb) an equilibrium plateau is formed between 10 to 20 min in which the mole number of H_2 reach a quantity of 1.75 10^{-7} mole. It seems that the basic medium has a negative effect on the behavior of Fe_2O_3 towards the production of hydrogen. This can be due probably to the potential of H_2O/H_2 couple changes with pH (Eq.(3)), either to the valence and conduction bands of Fe_2O_3 which are pH insensitive or the optimal band bending at the junction Fe_2O_3 /solution as reported in [7].

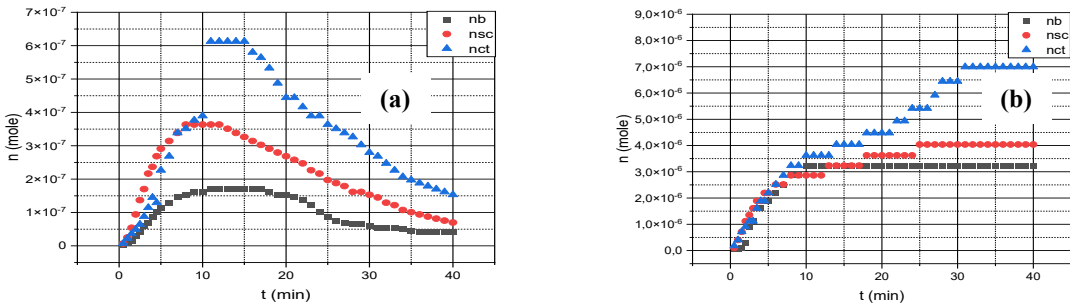

Fig.4. Evolution of mole number of H_2 in time under neutral medium using Fe_2O_3 (a) and Clay/Fe_2O_3 (b) at different modes (nb, nsc and nct)

The Fig. 5(b) shows also low performances in the production of H_2 gas using Clay/ Fe_2O_3 composite in the three modes recording a little amounts 1.5 10^{-7} mole (nsc), 1.0 10^{-7} mole (nct) and 3 10^{-8} mole (nb). This time, the test in (nsc) mode using Clay/ Fe_2O_3 was performed compared to that of Fe_2O_3. In this regard, the Clay/ Fe_2O_3 became optically active and bring more stability to the composite. According to the literature [1-2], Fe_2O_3 generate electron/hole (e−/h+) pairs according to the radicals OH• and/or O_2• through valence (VB) and conduction (CB) bands with high oxidative aptitude to cause a destructive oxidation reaction. The production of H_2 gas can be achieved via a photo catalytic reaction

conversion onto Fe_2O_3 according to the following mechanism:

$$Fe_2O_3 + h\,v \rightarrow (h^+_{VB})\ Fe_2O_3 + (e^-_{CB}) \quad (1)$$

$$2SO_3^{2-} + (h^+_{VB}) \rightarrow S_2O_6^{2-} \quad (2)$$

$$H_2O + 2(e^-_{CB}) \rightarrow H_2 + OH^- \quad (3)$$

Due to the elevated energetic location of Fe_2O_3 valence bands, the oxygen molecules do not compete with the water oxidation and it is necessary to reduce the photo holes which are scavenged by SO_2^{3-} (Eq.(2)). This reaction has a potential (E°) of about -0.2 V compared to that of the couple SO_4^{2-}/SO_3^{2-} of -1.2 V. This last potential is very negative and doesn't contribute in the oxidation reaction which explains the observed equilibrium plateau in Fig.4 and Fig.5. The phenomenon is due to the saturation of competitive reduction at the end product $S_2O_6^{2-}$.

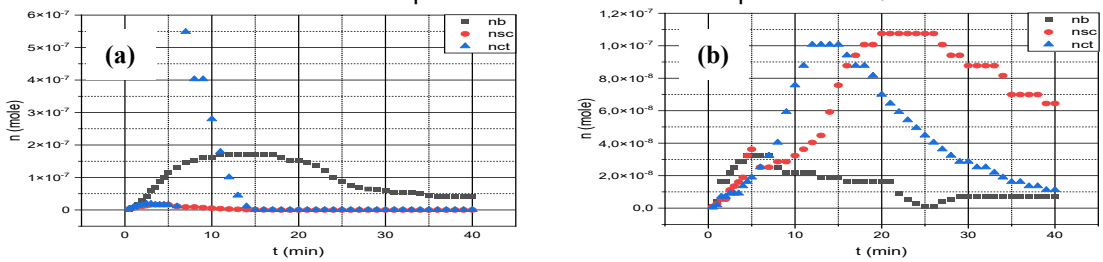

Fig.5. Evolution of mole number of H_2 in time under neutral medium using Fe_2O_3 (a) and Clay/Fe_2O_3 (b) at different modes (nb, nsc and nct)

4. CONCLUSIONS

Fe_2O_3 and Clay/Fe_2O_3 composite have been synthesized successfully in the production of H_2 gas by photo conversion reaction. They structural properties have highlighted by XRD, SEM and EDS analysis. The good dispersion of Fe_2O_3 particles in the surface clay allows an optical gap and a stability to use in the photo catalysis conversion reaction. The Clay/Fe_2O_3 composite showed best performances in neutral media recording a maximum quantity of hydrogen of 7 10^{-6} mole. The hydrogen was produced in presence of SO_2^{3-} under UV-visible light and a mechanism process was proposed. The Clay/Fe_2O_3 composite are low cost and non toxic and can be attractive as photo catalysts for the production of green H_2 gas.

ABSTRACT
The maritime industry is under increasing pressure to reduce greenhouse gas (GHG) emissions in line with EU regulations such as FuelEU and the EU Emissions Trading System (ETS). This study evaluates the environmental and economic impacts of using gray, blue, and green hydrogen as alternative marine fuels compared to marine diesel oil (MDO). Well-to-wake (WTW) emissions and associated regulatory costs were analyzed using data from the THETIS database and emission calculation models. The results show that while hydrogen-based fuels significantly lower tank-to-wake (TTW) emissions, gray and blue hydrogen still contribute to high WTW emissions due to upstream production processes. Consequently, gray hydrogen incurs the highest penalties, followed by blue hydrogen, making them less viable long-term solutions. Green hydrogen, however, demonstrates the lowest emissions and regulatory costs, emerging as the most sustainable option for decarbonizing maritime transport. The study highlights the need for policy incentives and technological advancements to enhance green hydrogen adoption.
Keywords: Decarbonization, EU ETS, FuelEU, Hydrogen fuel, Maritime emissions

1. INTRODUCTION

The maritime industry is a significant contributor to global greenhouse gas (GHG) emissions, prompting stringent regulations to reduce its environmental impact. The European Union (EU) has implemented policies such as FuelEU and the Emissions Trading System (ETS) to encourage the adoption of low-carbon fuels in shipping. As a result, alternative energy sources like hydrogen are gaining attention for their potential to decarbonize the sector. However, the environmental benefits of hydrogen vary depending on its production method. While green hydrogen, produced using renewable energy, offers the lowest emissions, gray and blue hydrogen, derived from fossil fuels, still contribute to carbon footprints. Understanding the emissions and regulatory implications of these hydrogen fuel options is crucial for assessing their viability in maritime transport.
This study assesses the well-to-wake (WTW) emissions and economic implications of hydrogen-based fuels in EU maritime transport compared to marine diesel oil (MDO). Using data from the THETIS database, the analysis explores the impact of hydrogen on tank-to-wake (TTW) emissions while accounting for upstream production emissions and regulatory costs. By evaluating policy-driven penalties and emissions performance, the research provides insights into the feasibility of hydrogen adoption in the maritime sector.

2. METHODOLOGY

In this section, gray, blue, and green hydrogen fuels are investigated regarding the GHG emissions they produce and their impacts on recent regulations in the EU region. During the analysis, data obtained from the THETIS database under the European Maritime Safety Agency (EMSA) [1] are presented in Table 1. It shows the ships involved in trading activities at EU ports in 2023. A total of 12,182 vessels arrived at or departed from EU ports in 2023, while 40,142,214 tons of fuel were combusted. Although the types of combusted fuel are not specified, it is assumed during the analysis that all the ships combusted MDO, since currently, there are 715 LNG-powered, 150 LPG-powered, and 62 methanol-powered ships [2] out of 109,000 ships [3].

Table 1. Retrieved data from the THETIS Platform

Ship types	Number of ships	Fuel consumption (mtons)	CO_2 emissions at sea (mtons)	CO_2 emissions from voyages to ports under MS jurisdiction (mtons)	CO_2 emissions from voyages to ports under a MS jurisdiction (mtons)	CO_2 emissions at ports (mtons)
Bulk carrier	3545	4,464,219	1,354,171	5,412,741	6,535,307	696,531
Chemical tanker	1304	2,445,271	2,298,620	2,083,528	2,474,135	800,205
Combination carrier	7	12,269	4,528	15,266	16,492	1,659

General cargo ship	1121	1,516,878	1.326,824	1,584,990	1,599,460	261,015
LNG carrier	359	3,377,706	479,440	4,252,929	4,399,828	413,557
Oil tanker	1841	5,181,798	2,089,401	5,795,521	6,777,898	1,580,109
Other ships	343	702,907	561,915	754,448	771,614	111,704
Passenger ship	205	2,336,208	4,069,381	1,050,016	1,073,751	1,093,170
Cruise passenger ship	9	33,653	55,344	16,562	15,876	17,747
Refrigerated cargo ship	136	338,524	116,034	395,607	510,124	37,742
Ro-pax ship	391	4,214,439	9.968,419	1,153,783	1,129,187	910,712
Ro-ro ship	213	1.,700,121	2.525,124	1,289,693	1,259,570	228,942
Vehicle carrier	456	1,328,839	707,967	1,511,077	1,706,638	172,710

For hydrogen cases, hydrogen is combusted in an internal combustion engine with 85% hydrogen and 15% pilot diesel fuel developed by BeHydro [4]. Another important aspect is that, according to FuelEU and EU ETS regulations, if a ship departs from an EU port and arrives at a non-EU port, or vice versa, 50% of the emitted CO_2eq needs to be included. Once the assumptions and boundaries are defined, WTW emissions can be calculated using Equation 1.

$$WTWCO_2eq = WTTCO_2eq + TTWCO_2eq \quad (1)$$

In the equation WTT is well-to-tank and TTW is tank-to-wake. To determine WTTCO_2eq, equation 2 is used.

$$TTWCO_2eq = TTWCO_2 + TTWCH_4 \times CFCH_4 + TTWN_2O \times CFN_2O \quad (2)$$

In equation 2, the coefficient factor (CF) for CH_4 is 28, while 265 for N_2O [5]. TTW emissions for MDO are specified in FuelEU Regulation [5], but for hydrogen, it is obtained from GREET Model 2023 [6]. Additionally, WTTCO_2eq is calculated by equation 3.

$$WTTCO_2eq = (FC \times WTTCO_2eq \times LCV)_{Pilot\ fuel} + (FC \times WTTCO_2eq \times LCV)_{Primary\ fuel} \quad (3)$$

In the equation, FC represents fuel consumption and LCV is a lower calorific value. Also, during the WTT calculations, MDO and gray hydrogen are given in the FuelEU Regulation, yet for blue and green hydrogen it is gathered from GREET Model 2023. All the variables considered in the study are presented in Table 2.

Table 2. Parameters that are used in the study

Variables	**MDO**		**Gray hydrogen**		**Blue hydrogen**		**Green hydrogen**	
	WTT	TTW	WTT	TTW	WTT	TTW	WTT	TTW
$CFCO_2$	N/S	3.206	N/S	0	0.00006	0	0.000002	0
$CFCH_4$	N/S	0.00005	N/S	0	0.0000004	0	0.000000003	0
CFN_2O	N/S	0.00018	N/S	0.001037	0.000000003	0.001037	0.00000000002	0.001037
CO_2eq	14.4	3.2551	132	0.2747	75.6	0.0275	1.8	0.2747
LCV (MJ/g)	0.0427		0.12		0.12		0.12	

The WTW emissions are presented in Fig. 1, and the results show that container shipping is the highest contributor, with a 28% share. Therefore, in this paper, the calculations are made based on container ships transversing in EU regions.

After WTW emissions are determined, GHG intensity and FuelEU penalty cost can be calculated using equations 4 and 5 [5].

$$GHG_{intensity} = \frac{WTWCO_2eq}{(FC \times LHV)_{Primary\ fuel} + (FC \times LHV)_{Pilot\ fuel}} \quad (4)$$

$$Penalty\ cost = \frac{(GHG_{intensity} - TargetGHG_{intensity}) \times (FC \times LHV)_{Primary\ fuel} + (FC \times LHV)_{Pilot\ fuel}}{GHG_{intensity} \times Euro/MJ} \quad (5)$$

In Equation 5, the target GHG intensity represents the limit determined by the FuelEU regulation. Moreover, the EU ETS quota cost is calculated three times: in 2025, 40% of the CO_2eq will be reported; in 2026, 70% of the CO_2eq will be reported; and in 2027 and beyond, 100% of the CO_2eq will be reported [7]. Therefore, Equations 6–8 are utilized to determine the impact for each year.

$$EU\ ETS\ cost = 0.4 \times TTWCO_2 \times Quota\ cost \quad (6)$$

$$EU\ ETS\ cost = 0.7 \times TTWCO_2eq \times Quota\ cost \quad (7)$$

$$EU\ ETS\ cost = TTW\,CO_2eq \times Quota\ cost \quad (8)$$

During the calculations, quota costs are estimated at $90 as was the case in 2023 [8].

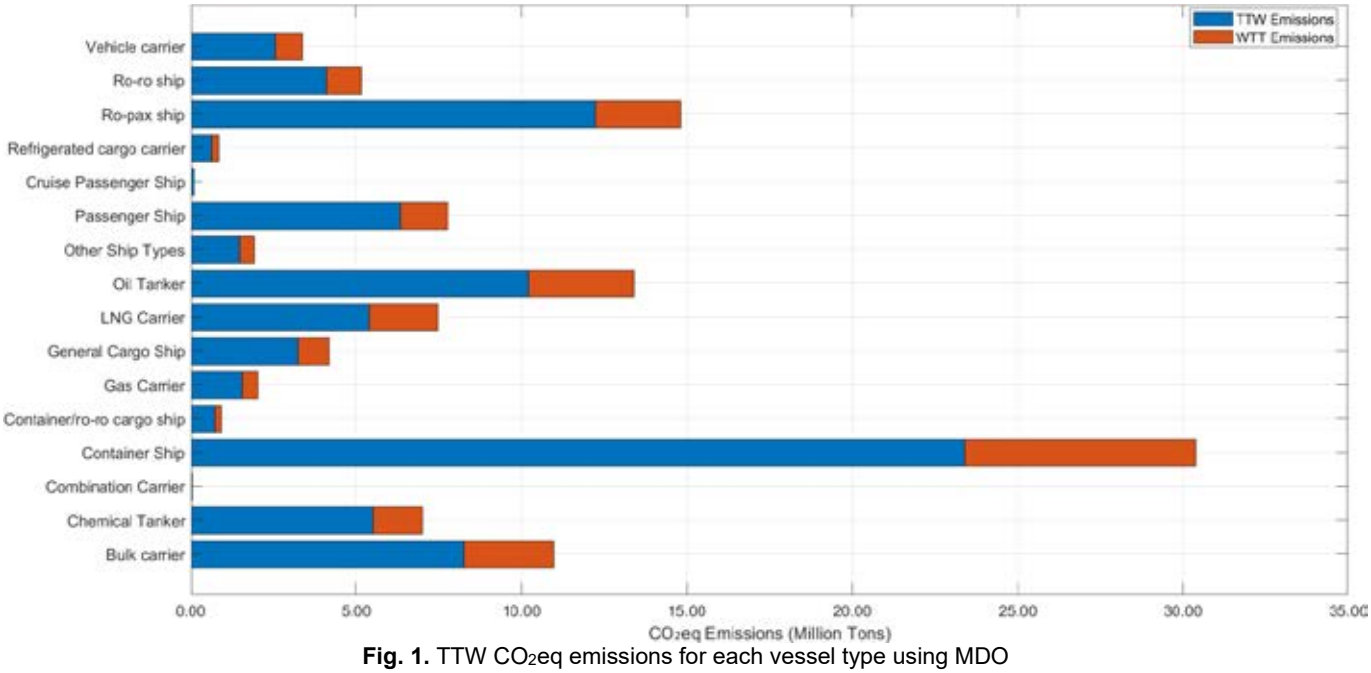

Fig. 1. TTW CO_2eq emissions for each vessel type using MDO

3. RESULTS AND DISCUSSION

Fig. 2 shows the FuelEU penalty costs for each fuel selection. The findings highlight that gray hydrogen has the highest GHG impact, resulting in higher penalties, followed by blue hydrogen and MDO, while no additional expenses arise from utilizing green hydrogen. Despite the TTW CO_2eq for hydrogen options being almost one-fourth of MDO's—23,406,842 tons for MDO and 6,481,237 tons for hydrogen derivatives—the WTT CO_2eq of gray hydrogen is 694% higher and that of blue hydrogen is 361% higher than the MDO option. On the other hand, green hydrogen WTT CO_2eq is 74% lower compared to MDO's. The cumulative outcomes indicate that by using gray hydrogen, penalties will begin in 2025, for blue hydrogen in 2035, and for continued use of MDO, penalties will start after 2040.

In Fig. 3, EU ETS quota prices are illustrated for each case. According to the results, MDO incurs the highest expense, while the others have the same outcome since the EU ETS considers TTW emissions rather than WTW emissions. Consequently, the outcome does not change because each case utilizes a fuel blend of 15% pilot diesel and 85% hydrogen. However, in 2025, only CO_2 emissions are considered; thus, MDO has 319% higher costs, while in subsequent years, the cost difference decreases to 261% as N_2O and CH_4 emissions are also included.

In Table 3, costs are listed for all fuel options. FuelEU and EU ETS costs are annual costs, and penalties will be paid each year. The findings reveal that compared to FuelEU costs, EU ETS costs are much lower; therefore, gray hydrogen does not provide the desired benefits. Additionally, blue hydrogen is only attractive in the period between 2035 and 2040, as the EU ETS benefit outweighs the harms from FuelEU penalties. However, green hydrogen is a prominent choice across all years.

Table 3. Fuel EU penalty and EU ETS quota costs for each fuel choice

Fuel types	FuelEU 2025	FuelEU 2030	FuelEU 2035	FuelEU 2040	Fuel EU 2045	FuelEU 2050	EU ETS 2025	EU ETS 2026	EU ETS 2027
MDO	-	-	-	-	$12,686M	$20,099M	$822M	$1,474M	$2,106M
Gray Hydrogen	$8,518M	$9,327M	$11,046M	$14,383M	$20,651M	$24,291M	$196M	$408M	$583M
Blue hydrogen	-	-	$650M	$5,992M	$16,031M	$21,859M	$196M	$408M	$583M
Green hydrogen	-	-	-	-	-	-	$196M	$408M	$583M

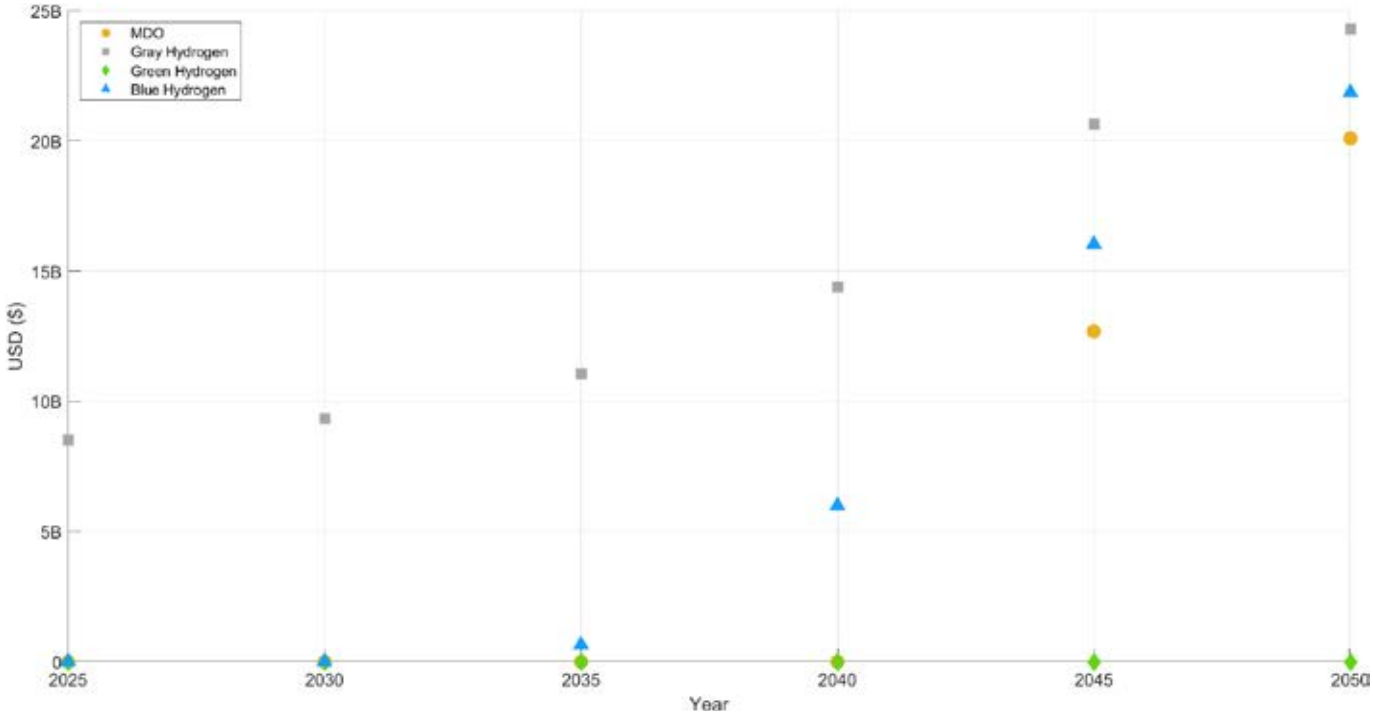

Fig. 2. FuelEU penalty costs across five-year intervals

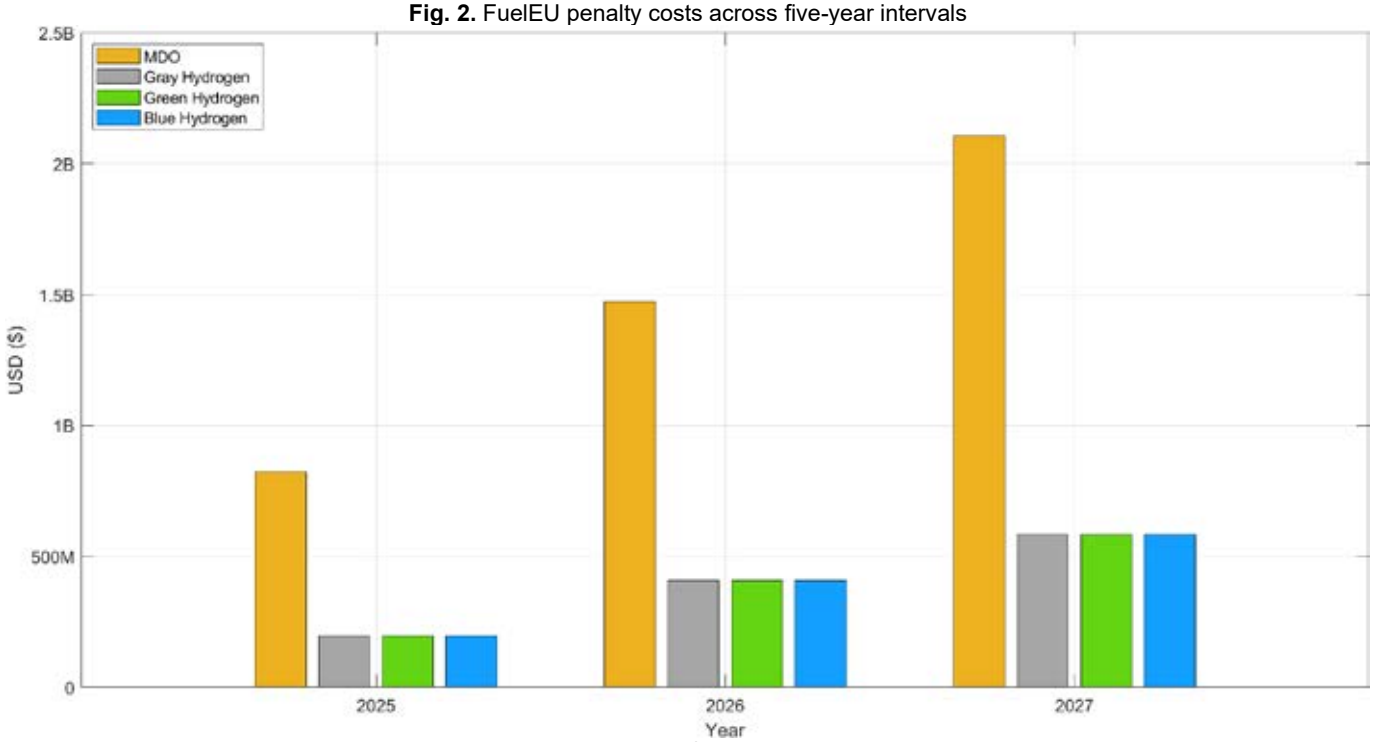

Fig. 3. EU ETS quota costs

4. CONCLUSIONS

This study evaluated the GHG emissions and regulatory impacts of using gray, blue, and green hydrogen fuels in maritime transport within the EU. The findings indicate that while hydrogen-based fuels significantly reduce TTW emissions compared to MDO, their WTW emissions and associated costs vary substantially. Gray hydrogen has the highest GHG intensity and incurs the highest penalties under FuelEU and EU ETS regulations, making it an unfavorable option. Blue hydrogen offers moderate benefits, particularly between 2035 and 2040, but its long-term viability remains limited due to rising penalties. In contrast, green hydrogen emerges as the most sustainable alternative, with the lowest emissions and regulatory costs, making it a viable solution for decarbonizing the maritime sector. In future research, various ammonia production pathways will be considered to evaluate the environmental impact of ammonia as a fuel. Additionally, an economic analysis will be conducted, encompassing both capital and operational expenditures.

Furthermore, while this study focuses solely on container ships, future studies will expand the analysis to include all types of vessels to determine whether the outcomes differ across ship types.

ABSTRACT
Hydrogen energy is a clean and alternative solution to global warming which is enhanced by using fossil fuels. Catalytic decomposition of methane produces hydrogen and valuable carbon product. This study examines microwave assisted catalytic decomposition of methane using SiC supported Ni/La catalysts at different temperatures. Effects of nickel loading as well as lanthanum loading were investigated and it was found that reaching to total initial conversion was seen at 700°C. Lanthanum addition amount and the reaction temperature was found to be the key to conversion and stability of the catalysts. With increasing temperature, the conversion values increased generally, however some catalysts showed a decrease in activity due to thermal sintering of metals and high metal doping amounts.

Keywords: Catalytic methane decomposition, microwave reactor, Lanthanum promoter, SiliconCarbide

1. INTRODUCTION

Fossil fuels play a significant role in energy production. However, the utilization of fossil fuels causes major source for greenhouse gas emissions, contributing to global warming. Hydrogen energy is an alternative and promising way to replace fossil fuels, as hydrogen only produces water when burned, and has a calorific value of 39.4 $kWh.kg^{-1}$, which is higher than liquid hydrocarbons [1]. Methane has a high H/C ratio which makes it an abundant reserve for hydrogen. Catalytic decomposition of methane is a green way to produce hydrogen without the need for separation from other products, since this reaction only results in hydrogen and high-quality carbon [2]. One of the advantages of this process is that the produced carbon can be used for various application, increasing the feasibility of this reaction. Despite the positive aspects, the reaction can only take place at temperatures above 1200°C owing to methane's thermodynamic stability necessitating catalyst utilization [3]. Nickel-based catalysts are frequently employed for their high activity in the catalytic decomposition of methane however, at high temperatures they are prone to sintering and deactivation [4]. Lanthanum addition to nickel-based catalysts improved both the activity and stability of the catalyst by enhancing nickel dispersion, attributed to lanthanum's unique 4f electron structure, which inhibits graphite layer formation [5]. Microwave heating is a novel heating method because of its unique heating characteristics like volumetric and fast heating, heating without contact and formation of hot spots, however, its application on the catalytic methane decomposition reaction is limited. There are still challenging points to be discussed. It is necessary to employ materials that absorb microwave energy and silicon carbide (SiC) is indicated as one of the most promising microwave absorbers due to its excellent dielectric properties, high thermal conductivity, and thermal stability [6]. In the present study, investigations were carried out on the microwave assisted methane decomposition reaction using SiC supported Ni catalysts with La promoter.

2. MATERIALS AND METHODS

2.1. Synthesis and Characterization of Catalysts

SiC supported lanthanum promoted nickel-based catalysts were synthesized using wet impregnation method. Lanthanumnitratehexahydrate ($La(NO_3)_3{\cdot}6H_2O$), and nickelnitratehexahydrate ($Ni(NO_3)_2{\cdot}6H_2O$), salts were utilized and catalysts were synthesized keeping the nickel loading at a high (50%), and low value (10%), and changing the Ni/La mol ratio as 0.45/0.1, 2/0.25, 2/0.1, and 2/0.002. The metal solution was prepared by putting the Ni and La metal precursors into a beaker simultaneously and adding 20 ml of distilled water. This metal solution is added drop by drop to a solution of SiC and 20 ml of ethanol. The resulting solution was left on the magnetic stirrer at 60°C, 200 rpm until it dried. Then, the catalysts were dried in an oven for 18h before it is calcined and reduced. Calcination and reduction conditions were 700°C-5h and 600°C- 4h respectively. The synthesized catalysts were subjected to different characterization studies such as ICP-OES, XRD analysis and N_2 adsorption-desorption analysis. The conversion of methane was calculated using the data obtained from the effluent gas.

2.2. Reaction Studies

The reaction studies were carried out using 0.7/0.3 nitrogen/methane gas with a flow rate of 20 ml/min in the microwave reactor system with a microwave generator (SAIREM). In each experiment 0.1 g of reduced catalysts were inserted into the quartz reactor and reaction temperature were changes in the range of 500 and 700°C by adjusting the microwave power. The products were analysed using Gas Chromatography equipped with Carboxen column and TCD detector. The

conversion of methane was calculated using the data obtained from the effluent gas.

3. RESULTS AND DISCUSSION

Activity results for catalysts prepared at high nickel loading (50wt%) with different La loading at 500 and 700°C are presented in Fig.1a and 1b, respectively. The Ni/La raito in these catalysts was kept as (0.45/0.1) and (0.2/0.02). At 500°C, 50Ni-La(0.45/0.1)@SiC catalyst, showed the highest activity, when the temperature was raised to 700°C, the initial methane conversion increased to 75%. However, a very fact deactivation was recogined at 700°C over this catalyst, implying that 21wt% the lanthanide additives causing thermal sintering at higher temperatures [5]. The 50Ni-La(2/0.002)@SiC catalyst, containing 0.17 wt% lanthanum as per ICP-OES results, showed an initial activity of 43% at 500°C but deactivated rapidly. At 600°C, while its initial conversion remained similar at 38%, its stability improved significantly. Interestingly, at 700°C, both its activity and stability increased, suggesting that this lanthanum loading, although insufficient to enhance activity at lower temperatures, helps prevent pore blockage, nickel sintering, and coke deposition, contributing to improved performance at higher temperatures.

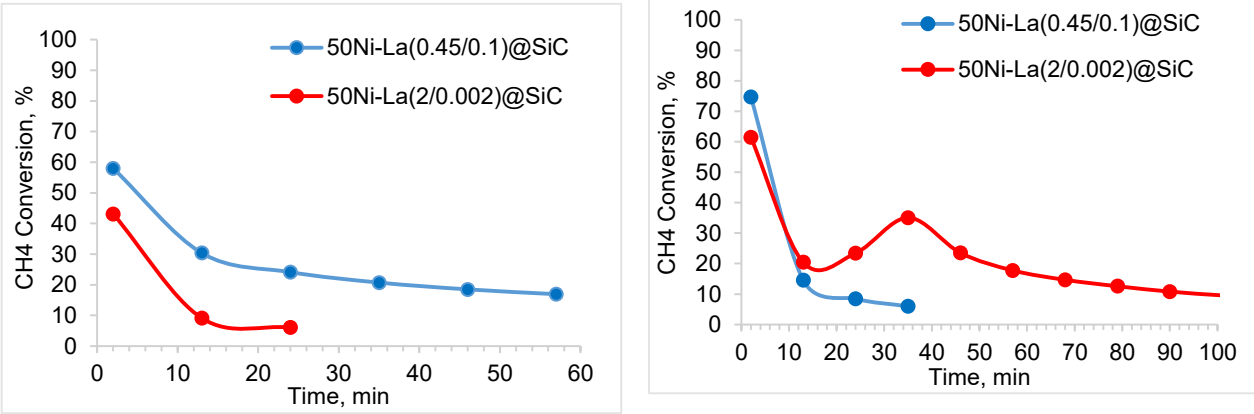

Fig. 1. Activity of catalysts with high nickel loading with different La loading, at a)500°C, b)700°C

When compared to 50% wt nickel loaded catalysts, 10% wt nickel loaded catalysts showed no obvious superiority in the long term, and initial conversion values when the reaction was carried out at 500°C and 700°C (Fig.2). Using higher amount of La may be effective when the catalysts were run at higher temperatures. In literature, catalytic methane decomposition is mostly studied in conventional reactors. Ying et al. [7] reported a 25% conversion at 500°C using Ni-La-Si (0.45:0.45:0.1 mol ratio), while Anjaneyulu et al.[8] achieved 36% conversion at 600°C with Ni-La-SiO2 (2:0.1:0.9 mol ratio). In our study, higher conversion values at comparable temperatures highlight the potential of microwave energy for more efficient methane decomposition. Characterization of spent catalysts will reveal the impact of microwave energy on carbon product.

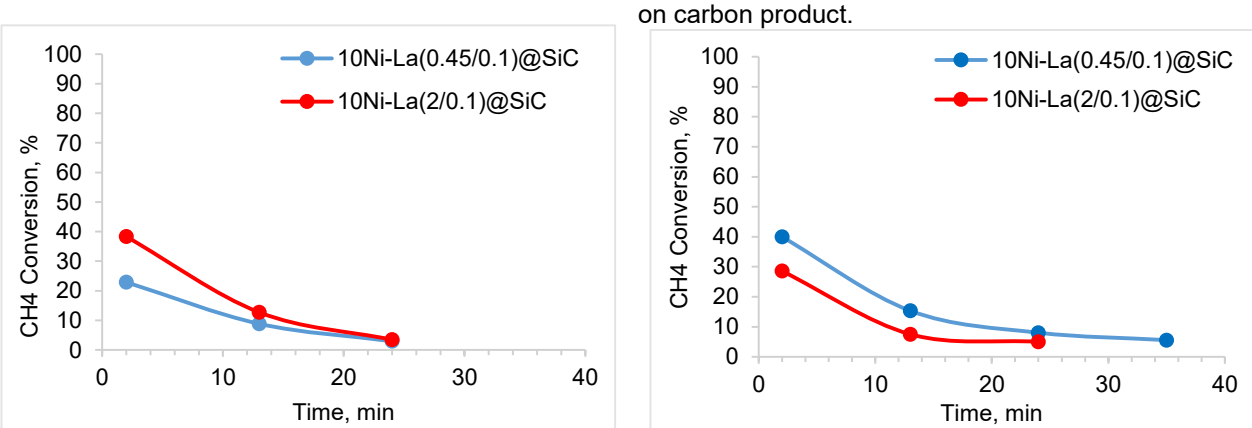

Fig. 2. Activity of catalysts with low nickel loading with different La loading, at a)500°C, b)700°C

SEM images of the 50Ni-La(0.45/0.1)@SiC and 50Ni-La(2/0.002)@SiC catalysts which were used in the reaction at 500oC were presented in Fig.3. The carbon nanotube structures (shown by red arrow) were observed besides the encapsulated carbon structres (shown by yellow arrow) for 50Ni-La(0.45/0.1)@SiC. Whereas encapsulated carbon was seen for 50Ni-La(2/0.002)@SiC catalyst as an indication of lower activity.

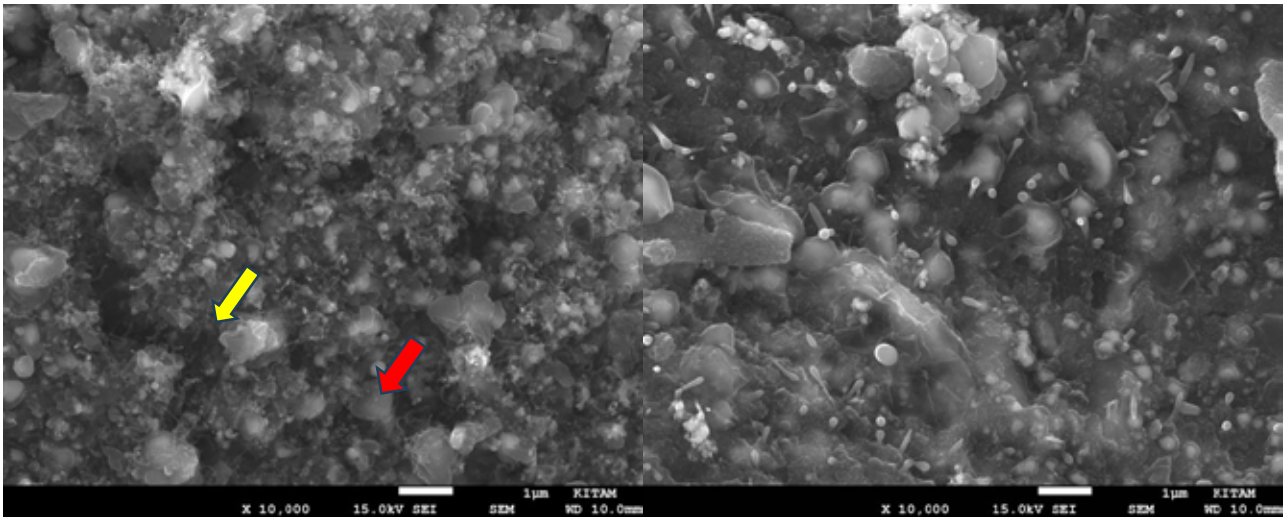

Fig. 3. SEM images of 50Ni-La(0.45/0.1)@SiC (left), 50Ni-La(2/0.002)@SiC(right) catalysts used at 500°C

4. CONCLUSIONS

In this study SiC supported Ni/La catalysts were tested in the reaction of catalytic methane decomposition, which is an alternative way for producing clean hydrogen without carbon emissions. Results obtained under microwave reactor show the effect of metal (Ni and La) loadings as well as the temperature had a great effect on the performance of the catalysts.. Among the catalysts 50Ni-La(0.45/0.1)@SiC gave the better performance at 500°C, even though higher reaction temperature favored the reaction, it caused faster deactivation. Indeed, at higher reaction temperatures such as 700°C, using significantly low amount of lanthanum, containing 0.17 wt% lanthanum as per ICP-OES results, enhanced the activity of the catalyst with 50 wt% Ni loading (50Ni-La(2/0.002)@SiC). Characterization of fresh and spent catalysts will give some insight of the performance of the catalysts under microwave exposure.

ABSTRACT

In this study catalytic methane decomposition is carried out using carbon supported Ni-Fe bimetallic catalysts in the microwave reactor system. Silicon carbide was selected as the supporting material due to their high microwave absorptive properties. The catalyst synthesis was carried out by impregnation process. Before the catalytic tests calcination and reduction process were done. In the activity studies, microwave energy was used as the heating system. Activity studies conducted at 500°C, 600°C and 700℃ revealed that the catalysts exhibited greater stability at 600°C. High methane conversions were observed at 700 degrees, but the catalysts were deactivated in a short time.

Keywords: Methane decomposition, microwave energy, hydrogen, catalyst, silicon carbide

1. INTRODUCTION

As a clean fuel, hydrogen is gaining popularity as a desirable product for renewable energy sources. In addition, hydrogen has drawn a lot of interest due to its significance in fuel cell technology. The catalytic decomposition of methane (CDM) ($CH_4 \rightarrow C + H_2O$, $\Delta H°_{298}$ = 74.8 kJ mol^{-1}), primarily on Fe, Co, Ni, has gained popularity recently as a promising method for creating hydrogen and carbon products. Moreover, the catalytic decomposition of methane eliminates the need for laborious procedures for purifying reaction products, which greatly streamlines the process and could lower the cost of producing hydrogen in comparison to the steam reforming method. CDM is an endothermic process that occurs at high temperatures, such as around 1200℃, can be carried out at lower temperatures in the presence of a catalyst. As catalyst, nickel is the most active catalyst for the CDM process. At high temperatures, however, nickel-based catalysts are readily deactivated. Adding additional metals creates an intriguing path to boost the CDM reaction's stability and carbon output at higher temperatures [1]. Due to its high stability at elevated temperatures, iron is a promising candidate for incorporation alongside nickel metal [2]. Conventional heating is extensively utilized in literature as a heating method, however, microwave-based heating has been found to boost catalytic reaction rates and selectivity [3]. Additionally, compared to conventional heating for chemical reactions, microwave heating offers several advantages, such as high heating power, volumetric and quick heating, contactless heating, easy drying or heating control, and smaller equipment sizes [2]. In this study, microwave assisted methane decomposition reaction was investigated by using SiC supported Ni-Fe bimetallic catalysts.

2. MATERIALS AND METHODS

In the synthesis process, impregnation procedure was followed, and silicon carbide (SiC) were used as support material. Bimetallic catalysts have been prepared using nickel nitrate hexahydrate and iron nitrate nonahydrate salts. Calcination and reduction conditions for nickel-iron catalyst supported by silicon carbide were 750°C for 5h and 450°C for 3h. Catalysts were called as (A)Ni-(B)Fe@SiC where A refers to nickel metal loading (10wt % and 50 wt%) and B refers to iron metal loading (6-15 wt%). The fresh form of the synthesized catalysts was characterized via XRD, SEM/EDS analyses. XRD and RAMAN analyses were performed as after reaction characterization. A microwave reactor was used for utilizing catalytic performance under atmospheric pressure using 0.1g of catalyst with the gaseous feedstock (0.7/0.3 nitrogen/methane mixture gas) at a flow rate of 20 mL/min. Microwave generator was adjusted to reach the necessary reaction temperature. Reactant and products were analyzed with a gas chromatography device equipped with Thermal Conductivity Detector (TCD) and Carboxen column. Methane conversions were calculated using Eq. (1). Characterization investigations are ongoing because the research is continuously under progress.

$$X = \frac{F^0_{CH_4} - F_{CH_4}}{F^0_{CH_4}} \times 100\% \quad (1)$$

3. RESULTS AND DISCUSSION

Results of XRD analysis, the characteristic peaks of nickel, iron and SiC were observed. Fe_3C structures were formed after the reaction [4]. It was observed in the SEM images before the reaction that the loaded metals adhered to the

surface due to its 8.5 m^2/g surface area. In the catalytic tests, 50% nickel loaded catalysts with 15% iron loaded catalyst exhibited the highest initial conversion at 500℃ reaching to 70% shown in Fig1a. The other two catalysts provided approximately 30% conversion. However, it has been observed that they quickly had a loss of activity, with conversion levels dropping below 10%. In catalysts with 10% nickel loading, the 10% iron-loaded catalyst achieved the highest conversion at 500°C, reaching 60%. Reaction was stopped at 25 min due to faster deactivation of catalysts (Fig.1b). When the temperature was increased to 600°C, it is expected to see better activity over the catalysts. However, it is observed that much lower methane conversion was seen with 50Ni-15Fe@SiC, impliying sintering at higher at this temperature may cause this results (Fig.2a). For longer period of time, up to 100min, catalysts were still active and show the same conversion values regardless of their metal loading. For the low nickel loaded catalysts, it was seen that the stability of these catalysts was greater at 600°C compared to 500°C, maintaining a stable conversion rate of 10% across all three catalysts for up to 100 minutes (Fig.2b). However, all three catalysts experienced deactivation within approximately 30 minutes. Catalysts were also run for 700 ℃ and all of these studies indicated that 600℃ was seen to be the optimum temperature and 50Ni-6Fe and 50Ni-10Fe catalysts gave the best results. Charahterization studies which will be carried out over the spent catalysts will give insights to the microwave assisted methane decomposition reaction.

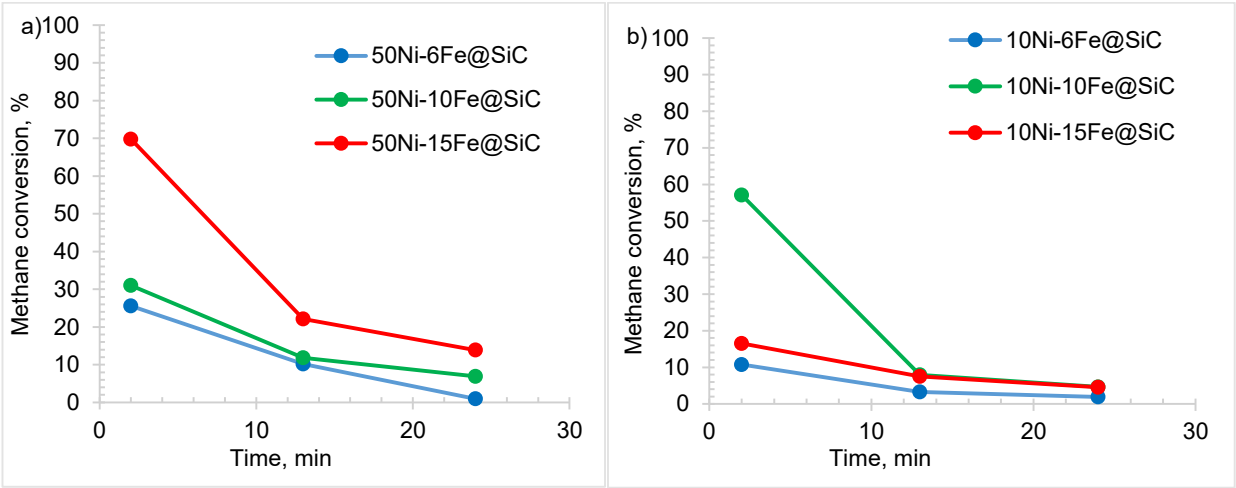

Fig. 1. Methane conversion values for 50 wt% Ni (a) and 10 wt% (b) Ni loaded catalysts at different Fe loadings at 500℃

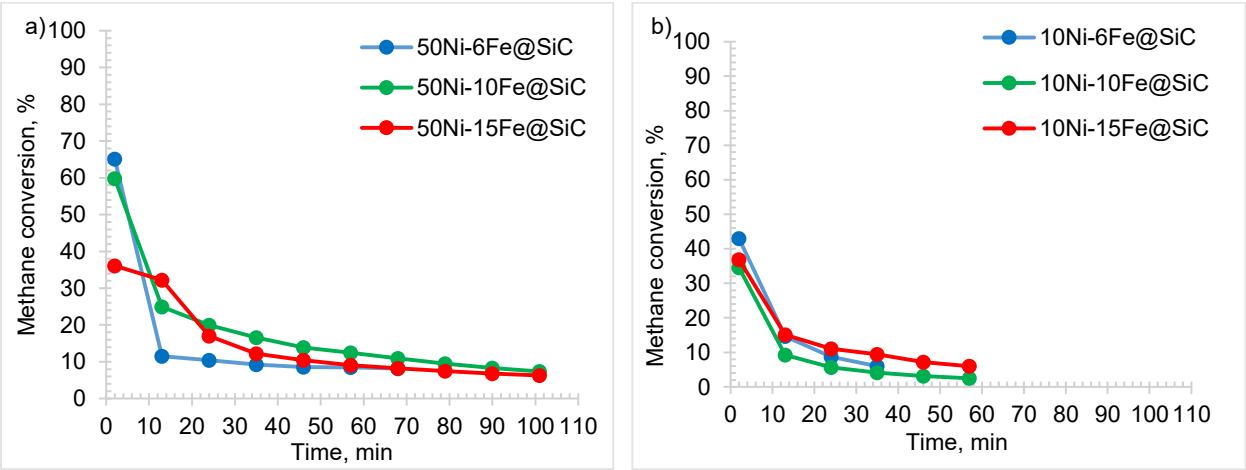

Fig. 2. Methane conversion values for 50 wt% Ni (a) and 10 wt% Ni (b) loaded catalysts at different Fe loadings at 600℃

4. CONCLUSIONS

In this work, catalysts synthesis, characterization and activity studies of SiC supported catalysts for catalytic decomposition of methane using microwave reactor system were conducted. At 500°C, methane conversions were observed to be high; however, the catalysts experienced rapid deactivation. At 600°C, while a slight reduction in methane conversion was noted, the catalysts demonstrated enhanced stability. For 700℃, even if high methane conversions were

seen, stability could not be achieved. The optimal temperature for the reaction was determined to be 600°C, at which both the 50Ni-6Fe and 50Ni-10Fe catalysts demonstrated favorable performance in terms of stability and methane conversion. Characterization studies, which are continued over spent form of the catalysts, will provide information about the carbon structures.

ABSTRACT

Metal-organic frameworks (MOFs) have attracted considerable attention in recent years due to their high specific surface area and highly porous structures. These materials find applications in a variety of fields with particular significance as adsorbents. Solvothermal method is the most extensively used synthesis technique, due to its effectiveness in producing high-quality crystalline structures. However, its practical application is often constrained by prolonged reaction durations and significant energy demands, prompting the exploration of more efficient synthesis alternatives. In this context, microwave-assisted synthesis emerges as a promising alternative, offering substantial reductions in reaction time. This study investigates the synthesis of MOFs via both solvothermal and microwave-assisted methods for potential use as adsorbents in the purification of hydrogen. Synthesized MOFs were characterised using X-ray diffraction (XRD). The findings reveal that the microwave method offers a promising alternative to the solvothermal method.

Keywords: Cu-BTC, MOF, Microwave assisted method, Adsorbent, Hydrogen purification

1. INTRODUCTION

MOFs are a class of porous materials composed of metal ions or clusters connected by organic ligands, forming a highly structured and tunable network. Lattice topologies and pore structures of MOFs can be designed using different metal centres and ligands [1]. MOFs have several applications, including adsorption, catalysis and gas storage. They have gained importance as adsorbents due to their higher surface area, thermal stability and gas selectivity compared to other adsorbents such as activated carbon and zeolites.

MOFs can be synthesized through various methods, with the solvothermal method being the most traditional and widely used. It is simple but time-consuming and energy intensive. Alternative techniques, such as microwave-assisted and sonochemical methods, offer faster reaction times, lower energy consumption, and influence MOF properties by affecting pore morphology and particle size, which are crucial for separation and gas storage applications [2,3].

The microwave-assisted synthesis of MOFs utilizes microwave radiation to heat a solution of metal salts, ligands, and solvent within the temperature. This method enables reactions to occur within a short time frame, usually between 4 minutes and 4 hours, significantly faster than traditional solvothermal techniques [2,4]. In this study, Cu-BTC synthesized using two distinct methods: the solvothermal method and the microwave-assisted method. The synthesized MOFs were characterized using X-ray Diffraction (XRD). This study aims to investigate the potential of microwave-assisted synthesis as an alternative to solvothermal method for the development of MOFs.

2. MATERIALS AND METHODS

2.1. MOF Synthesis

Cu-BTC (copper benzene-1,3,5-tricarboxylic acid) was synthesized by two different methods based on previously reported procedures [5,6]. For the solvothermal method, 1,3,5-benzenetricarboxylic acid and ($Cu(NO_3)_2 \cdot 3H_2O$) were dissolved in ethanol and deionized water, then mixed and stirred. The mixture was subjected to thermal treatment in a sealed reactor. In the microwave-assisted method, the same precursors were used, and the procedure was similarly followed, except that the reaction was carried out using microwave irradiation. In both cases, the resulting blue solid was washed with a water–ethanol mixture, centrifuged, and dried under vacuum. The final products were labeled as Cu-BTC-S and Cu-BTC-M, respectively.

2.2. Characterization

Crystallinity of Cu-BTC were determined with XRD analysis on a Rigaku Miniflex 600 using Cu-Kα radiation at 40kV and 30 mA. A scanning speed of 0.02° and a scan speed of 2°/min with a scan angle of 5-45°.

3. RESULTS AND DISCUSSION

3.1. Characterization of MOF

XRD patterns of Cu-BTC samples synthesized with different synthesis method given in Figure 1. The characteristic peaks at 2θ=6.8°, 9.6°, 11.7°, 13.5° belong to Cu-BTC [7] and can be observed in the MOF synthesized by both solvothermal and microwave-assisted methods. No peaks corresponding to CuO and Cu_2O were detected in either of the MOFs, which suggests that pure MOF was successfully synthesized.

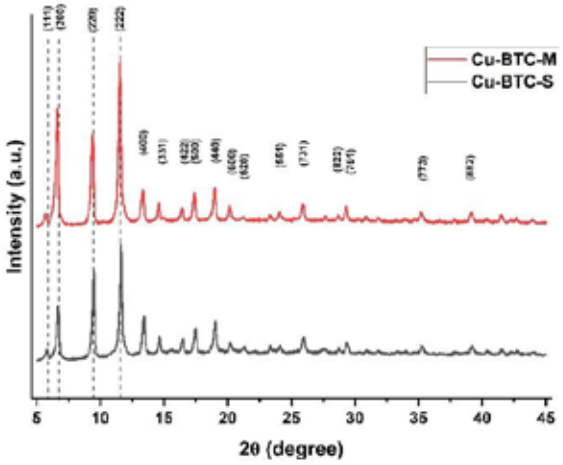

Fig. 1. XRD patterns of Cu-BTC with solvothermal and microwave assisted method

4. CONCLUSIONS

In this study, Cu-BTC was synthesised via solvothermal and microwave-assisted synthesis methods to investigate the influence of synthesis techniques on the structural properties of the resulting MOFs. The synthesized materials were subsequently characterized through X-ray Diffraction (XRD). It was seen that both methods successfully yielded crystalline Cu-BTC structures. The microwave-assisted synthesis significantly reduced the reaction time, making it a more efficient and practical approach for MOF production. Future studies will involve detailed micropore structure analysis and surface characterization using BET.

ABSTRACT

In this study, hydrogen-rich gas synthesis through the gasification and steam reforming of sugar beet pulp was investigated using Ni-La/Dolomite catalyst. The catalyst was synthesized using the impregnation method and were characterized by FT-IR and SEM-EDX. Gasification experiments examined the effect Ni-La on the resulting gas composition. Gasification studies were conducted in a 316 stainless steel updraft tubular reactor (900 mm length, 10 mm inner diameter) equipped with a peristaltic pump. The highest hydrogen concentration was 50.3% by mole, and the calorific value was 6,268 kJ/m^3. The experimental results demonstrate that the Ni-La/Dolomite catalyst employed in this study efficiently converts sugar beet pulp into hydrogen-rich syngas. Additionally, the findings indicate that sugar beet pulp has significant potential for biomass utilization and bioenergy production.

Keywords: Sugar Beet Pulp, Steam Reforming, Catalyst, Ni-La, Dolomite

1. INTRODUCTION

The rapid increase in global energy demand driven by population growth, industrialization, economic development, and climate change, coupled with the environmental hazards of fossil fuels like petroleum, coal, and natural gas, has started a transition toward renewable and cleaner energy sources such as biomass and hydrogen. Hydrogen is the most abundant element in the universe, and it is a clean energy carrier with the highest energy content per unit mass, that offers significant advantages such as releasing only water vapor upon combustion and presenting a sustainable alternative to mitigation of carbon emissions [1], [2], [3], [4]. Hydrogen can be sustainably produced from biomass via thermochemical conversion processes like gasification, pyrolysis, and catalytic steam reforming, therefore providing a renewable and environmentally friendly alternative to fossil fuels [5].

Steam reforming can be an alternative to gasification when higher hydrogen yield and concentration in the resulting syngas are the main objective. The use of various catalysts like Ni can enhance reaction rates and selectivity toward hydrogen. Coke formation can be reduced by incorporating rare earth metals like La which improves catalyst stability and prevents metal sintering. Additionally, La promotes the water-gas shift reaction and reacts with CO and CO_2 to also reduce coke deposition [6], [7]. The catalytic process also facilitates the water-gas shift reaction, maximizing hydrogen output while reducing the concentration of impurities, therefore making the catalytic steam reforming process a preferred method for hydrogen production from biomass.

Among the sources of biomass, sugar beet is a vital crop in Turkey, due to its economic significance as a key material for sugar production [8], [9]. Sugar beet is also emerging as a promising energy crop within the European Union (EU) with its pulp serving as a valuable co-product of the sugar refining industry [10]. Rich in hemicellulose, cellulose, and pectin, sugar beet pulp offers potential as lignocellulosic biomass for producing hydrogen-rich gas [11], although it is mainly used as an animal feedstock in Turkey.

Therefore, this study aims to investigate the potential of sugar beet pulp obtained as a sugar factory by-product for hydrogen-rich syngas production by hydrothermal gasification. Within the scope of this study, dolomite-supported bimetallic Ni-La catalyst was synthesized by the wet impregnation method. Activity of this catalyst was tested in a tubular updraft gasification reactor at a steam-to-biomass ratio of 3:1 and a gasification temperature of 700 °C and then compared to the uncatalyzed condition.

2. MATERIALS AND METHODS

2.1. Synthesis and characterization of the catalysts

Synthesis of the Ni-La/Dolomite catalyst by the wet impregnation method was described in detail in a previous work [12]. For the characterization of the catalyst, Zeiss Supra 50 VP was used for the SEM imaging, Thermo Fisher Scientific Nicolet IS10 spectrometer in ATR mode was used for recording the FTIR spectra.

2.2. Steam reforming of the sugar beet pulp

Steam reforming studies were conducted in an updraft 316 stainless steel tubular reactor. Steam was generated using a peristaltic pump to feed water through a 1.5 m heated line maintained at 150 °C. Steam-to-biomass ratio was 3:1 by mass. Each experiment utilized 2 g of sugar beet pulp mixed with 0.4 g of catalyst (20 wt% catalyst-to-biomass) and was

carried out over a reaction duration of 15 minutes. The resulting product gas was collected and analyzed using a µ-GC.

3. RESULTS AND DISCUSSION

Fig. 1 shows the FTIR spectra of the 10-5% Ni-La/Dolomite catalyst.

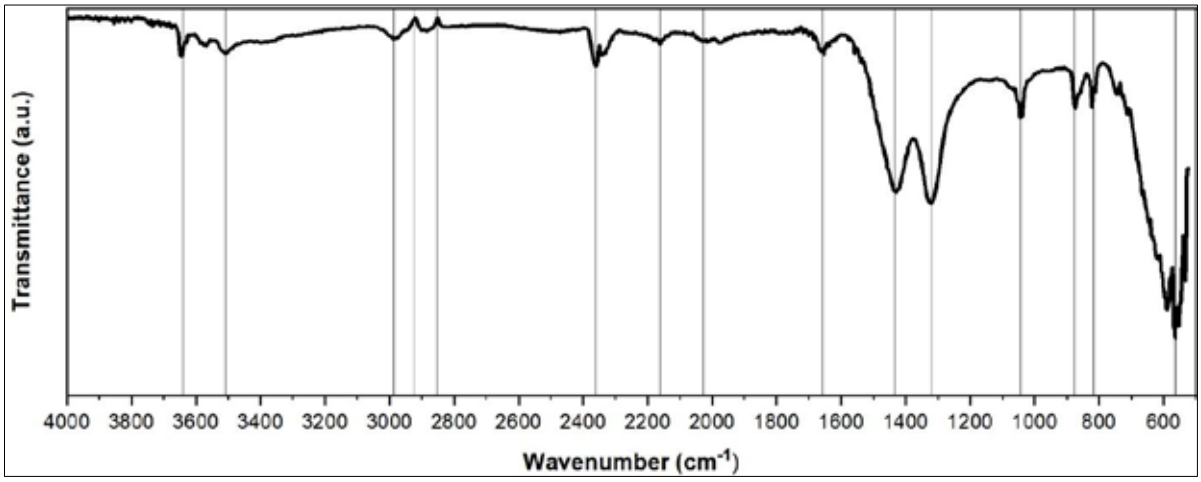

Fig. 1. FTIR spectra of 10-5% Ni-La/Dolomite

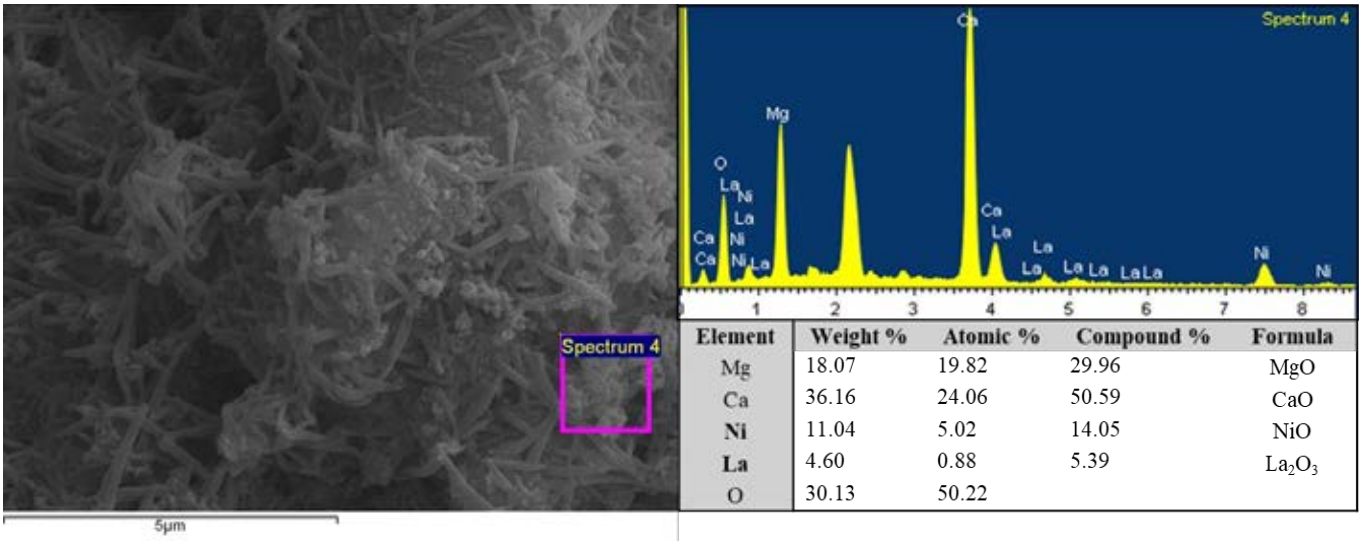
O-H groups on the Ni-La/Dolomite surface exhibit a peak at about 3570 cm^{-1} originating from CaO and MgO. Metal oxide vibrations appear in the range 600-750 cm^{-1} reflecting the presence of La and Ni metals. In addition, the peaks observed at 1300-1715 cm^{-1} indicate the stretching vibration of carbonate groups formed on the catalyst surface because of the interaction between CO_2 and CaO, MgO [13].
The SEM images and the Energy Dispersive X-ray Spectroscopy (EDS) results of the %10-5 Ni-La/Dolomite catalyst are given in Fig. 2.



Element	Weight %	Atomic %	Compound %	Formula
Mg	18.07	19.82	29.96	MgO
Ca	36.16	24.06	50.59	CaO
Ni	11.04	5.02	14.05	NiO
La	4.60	0.88	5.39	La_2O_3
O	30.13	50.22		

Fig. 2. SEM-EDS analysis results of %10-5 Ni-La/Dolomite catalyst

The SEM image shows a rough and aggregated surface morphology consisting of interconnected, randomly oriented needle-shaped structures, along with dispersed particulate clusters. Furthermore, specific elements such as NiO, LaO, CaO, and MgO that have been confirmed through XRF analysis are also evidenced by SEM-EDS. Fig. 3 illustrates the influence of this catalyst on the syngas yield.

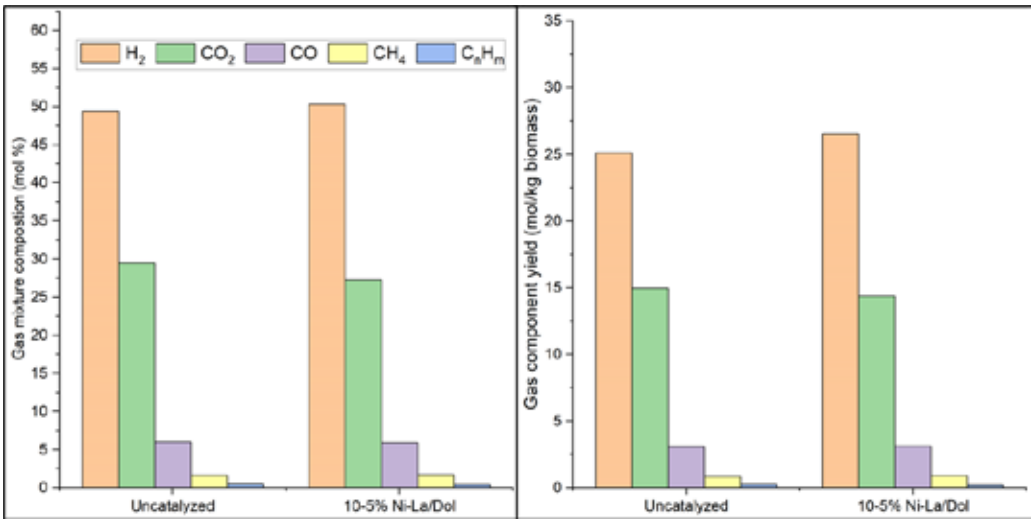


Fig. 3. The effect of 10-5% Ni-La/Dolomite catalyst on gas concentrations and gas product yields obtained during the steam reforming process (15 minutes, 700 °C, 3:1 S:B ratio).

The effectiveness of the 10-5% Ni-La/Dolomite catalyst in sugar beet pulp gasification can be seen on the figure given above. While the catalyst did not significantly alter the gas composition percentages, it notably enhanced the overall gas yield per kilogram of biomass, particularly increasing the hydrogen (H_2) yield. The results align with the findings in the literature [14]. This suggests that the catalyst promotes gasification efficiency, resulting in higher hydrogen production, thus improving the suitability of sugar beet pulp for hydrogen-rich syngas generation. One of the reasons for the higher yields obtained in experiments using catalysts is the use of dolomite as the catalyst support material. Dolomite is known to enhance the conversion of tar produced during the reaction at high temperatures [15], [16]. It was observed that the CO and CO_2 yields were approximately at similar levels. This enhancement is due to the breakdown of C-H, Caryl-C, and aromatic C=C bonds in tar molecules on the basic sites of the dolomite material, forming active carbon. This process involves water dissociation, which generates OH* and H* free radicals, with OH* radicals reacting with active carbon to form formates and other oxygenate intermediates, ultimately converting into gas products [17].
The concentrations of the components forming the gas mixture obtained from the experiments and their yields per unit of biomass are presented in Table 1.

Table 1. The effect of catalyst on gas concentrations, gas volumes, and yields obtained during the steam reforming process

Catalyst	Gas Volume (mL)	Gas Component Concentration (% mol)							Gas Component Yield (mol component/kg pulp)				
		H_2	CH_4	CO	CO_2	C_nH_m	O_2	N_2	H_2	CH_4	CO	CO_2	C_nH_m
Uncatalyzed	2525	49.4	1.6	6.0	29.4	0.5	1.6	4.5	25.1	0.8	3.1	15.0	0.2
10-5% Ni-La/Dolomite	2625	50.3	1.7	5.9	27.3	0.4	2.1	8.2	26.5	0.9	3.1	14.4	0.2

It was observed that in experiment conducted without a catalyst, the primary component of the gas mixture was hydrogen (49.4% mol). One of the critical parameters in gasification processes is the calorific value of the resulting gas product. The most critical determinant of the gas mixture's calorific value was hydrogen. Additionally, the concentration of carbon dioxide in the gas mixture was sufficiently high (~15 mol/kg) to significantly influence the calorific value. Therefore, the calorific value was 6,268 kJ/m^3 for the catalytic gasification experiment.

4. CONCLUSIONS

Improvements in the hydrogen yield obtained from the steam reforming of sugar beet pulp were achieved using bimetallic Ni-La/Dolomite catalyst. Using 10-5% Ni-La/Dolomite catalyst resulted in a syngas with the calorific value of 6,268 kJ/m^3 and hydrogen concentration of 50.3%. The findings of this study reveal that sugar beet pulp is an effective biomass for hydrogen-rich gas production via steam reforming, with Ni-La/Dolomite catalyst presenting a viable alternative to conventional catalysts.

ABSTRACT
The use of electrified reactors appears promising for reducing CO_2 emissions in industries. The potential emission reduction can reach close to 100%, depending on the H_2 production process, as in the case of natural gas (NG) plasma pyrolysis, which sequesters carbon in a solid state as a valuable by-product. Employing renewable feedstocks, such as biogas, is another strategy for achieving nearly emission-free industrial processes. This work presents results of NG dry reforming using a plasma reactor, which produces syngas with reduced emissions compared to conventional fired reactors. Furthermore, the dry reforming produces hydrogen and carbon monoxide without the consumption of water, as occurs in the methane steam reforming process, which is the most used hydrogen production process worldwide. The technology primarily utilizes methane and CO_2, key components of biogas, making it suitable for CO_2-neutral e-fuel production pathways. Additionally, it offers the potential for co-producing high-quality syngas and reduced graphene oxide, demonstrating its capability for generating valuable products.

Keywords: Plasma Reactor, Dry Reforming, Synthesis Gas, E-fuel, Nanostructured Carbon

1. INTRODUCTION
Dry reforming can utilize biogas as a feedstock and holds significant interest to produce e-fuels, such as diesel, Sustainable Aviation Fuel, and methanol. However, a major drawback of catalytic dry reforming is coke formation [1] and has hampered its full development. Plasma reactors, powered by clean electrical energy, offer a substantial reduction in emissions compared to conventional fired reactors. This article presents results from an electrified reactor that produces high-quality syngas through non-catalytic CH_4 dry reforming with CO_2 thermal plasma, eliminating the issue of carbon formation. Additionally, the reactor has the flexibility to produce reduced graphene oxide, potentially enhancing its economic viability. Carbon materials formation occurs when the molar ratio “n” of CH_4 to CO_2 slightly exceeds unity, as shown in Equation (1).

$$nCH_4 + CO_2 + \text{Electricity} \rightarrow 2nH_2 + 2CO + (n-1).C \quad (1)$$

The reaction described may not form carbon materials when the molar ratio n equals 1. For values of n greater than 1, both graphene oxide (GO) and thermally reduced graphene oxide (rGO) can be produced [2].

2. EXPERIMENTAL
The CO_2 plasma torch used in this study is schematically shown in Fig. 1a. It has two natural gas (NG) injections to allow for a wider range of NG volumes to be introduced into the electric arc. A schematic diagram of the experimental setup is presented in Fig. 1b. The produced gases are cooled and then combusted in a flare, as described in the previous article [2]. CO_2 and NG (~90% CH_4) were used, yielding the following products: H_2, CO, C, and C_2H_2. Product yields also depend on plasma power.

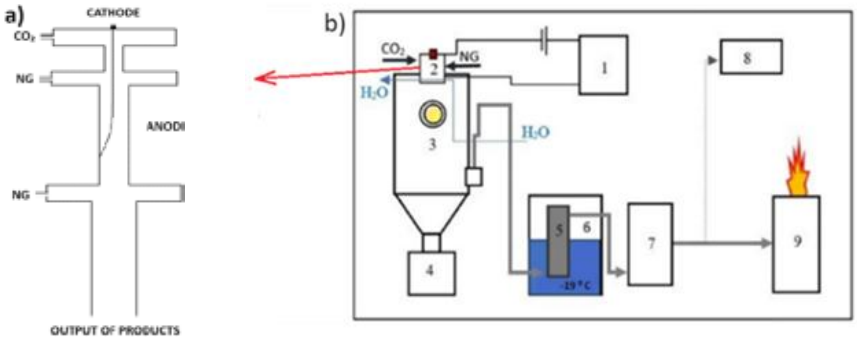

Fig. 1. Diagrams of (a) plasma torch and (b) experimental setup

3. RESULTS AND DISCUSSION

Fig. 2a shows the molar fraction of each product (C, H_2, CO, and C_2H_2) for four different NG flow rates (VNG) with a fixed CO_2 flow rate (VCO_2) of 151 mol/h. Fig. 2b presents the mass spectrum for an NG flow rate of 566 mol/h.

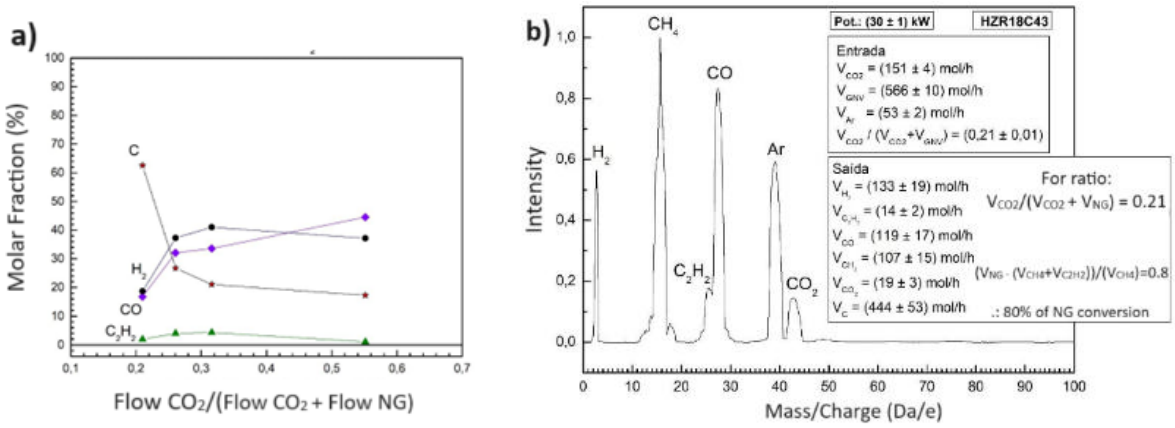

Fig. 2. (a) Molar fraction of products; (b) Mass spectrum at VNG/VCO2~ 3.7

Figure 3 presents transmission electron micrographs (TEM) of two samples of carbon materials, revealing the presence of graphene derivatives as semi-transparent thin films. The images display edges, folds, and pores within the structure.

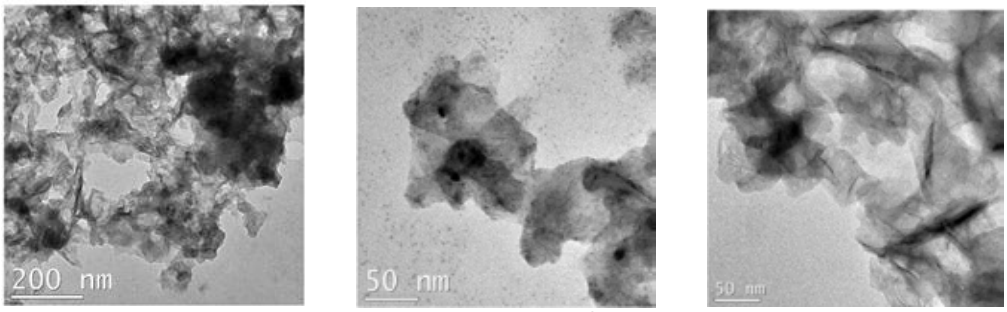

Fig.3. TEM images of samples

Figure 4 shows Raman spectra for two samples of carbon materials. They spectra exhibit three dominant bands (G, D, and 2D). The G band at ~1574 cm^{-1} arises from carbon atoms with sp^2 hybridization, indicating the presence of graphenic material. The D band at ~1337 cm^{-1} suggests disorder in the crystalline structure, likely caused by oxygen. The D band also indicates other imperfections, such as edge defects. The 2D band, along with the G band, confirms the presence of graphene. The ratio IG/I2D is typically used to estimate the number of layers in a graphene derivative sample [3]. The observed Raman spectra are consistent with literature reports for rGO and/or GO.

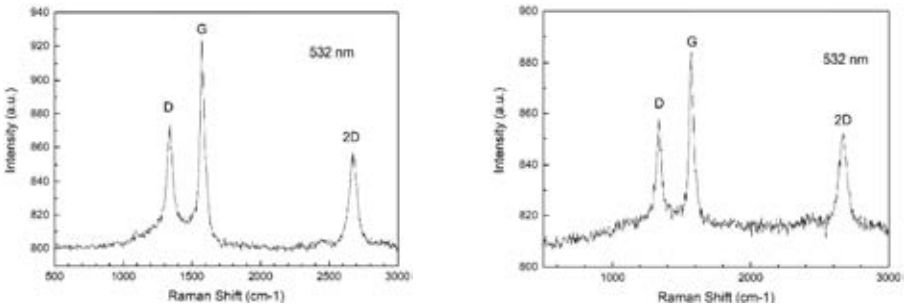

Fig.4: Raman spectra of two samples

4. CONCLUSIONS

This plasma torch demonstrated the ability to produce carbon materials with molar fractions ranging from 15% to 62%. The highest yield (62%) was achieved at a molar ratio of [NG]/[CO_2] ~ 3.7 with 80% NG conversion, generating high-quality syngas. Oxygen atoms from CO_2 bonded with NG carbon, forming CO gas and solid-phase graphene oxide. Reduced graphene oxide was also detected in both current and previous experiments, suggesting thermal reduction due to high process temperatures. This technology demonstrates successful production of high-quality syngas without the use of catalysts or fuel combustion and can therefore be effectively used in the production of synthetic fuels with reduced CO2 emissions and without water consumption. Additionally, it has the potential to synthesize larger quantities of valuable graphene derivatives compared to top-down synthesis processes. Graphene oxide and reduced graphene oxide are versatile materials with applications in sensors [3], energy storage, water treatment, and desalination. These experiments highlight the capability to produce carbon nanomaterials and syngas using clean electricity. Its potential to utilize biogas (CH_4 and CO_2) as feedstock enables the production of green syngas, facilitating the creation of green synthetic liquid fuels. Furthermore, the commercialization of produced carbon nanomaterials could enhance the economic viability of e-fuels.

ABSTRACT
Hydrogen is increasingly recognized as a crucial element in the decarbonized global energy framework. Serving both as a fuel and as an energy storage medium, the interest in hydrogen is growing steadily. As a result, the development of hydrogen production methods with minimal environmental impact has emerged as a critical area of research [1-3]. The objective of the present study is to examine hydrogen generation through methane conversion utilizing a catalyst in an ultra-high-frequency discharge, while ensuring the elimination of CO_2 emissions. This investigation focuses on the use of ultra-high-frequency discharge in conjunction with a catalyst for methane pyrolysis, a combination that facilitates the achievement of optimal conditions for efficient methane decomposition. This methodology significantly reduces the reaction time and improves the yield of the desired products.

Keywords: Hydrogen energy, Hydrogen, Methane conversion, Microwave discharge, Catalyst

1. INTRODUCTION

One of the main threats to global climate change is the combustion of fossil fuels. For this reason, hydrogen is considered a promising alternative fuel. Many developed countries are actively developing and implementing national hydrogen energy strategies to meet the growing global demand for clean energy [4,5]. In 2024, the Minister of Energy of the Republic of Kazakhstan approved Order No. 342, which outlines the Concept for the Development of Hydrogen Energy until 2030 [6]. The primary objective of this concept is to promote hydrogen energy in Kazakhstan to reduce carbon emissions and stimulate economic growth. As part of the implementation plan, it is proposed to establish hydrogen clusters, scientific and technological infrastructure, and launch pilot projects. The plan also envisions the integration of low-carbon hydrogen into industry and transport, the development of infrastructure for hydrogen transportation, and local energy systems. An essential aspect of the plan is government support for research, investment, and production, as well as the creation of mechanisms for regulating carbon dioxide emissions and subsidizing hydrogen projects, which will enhance the competitiveness of hydrogen.

However, the primary challenge lies in the fact that hydrogen is rarely found in its pure form on Earth, as it tends to form covalent bonds with other elements. This necessitates the development of environmentally safe and economically viable methods for hydrogen production. There are many widely used methods for hydrogen production, such as coal gasification, water electrolysis, steam methane reforming, and others. Currently, numerous studies are being conducted to optimize hydrogen production with minimal atmospheric emissions. One such method is plasma-catalytic methane conversion, which is an environmentally clean and efficient way to produce hydrogen [7-9], provided renewable energy sources are utilized.

This work examines the application of ultra-high-frequency discharge and a catalyst to achieve the necessary conditions for efficient methane decomposition. This method significantly reduces reaction time and increases the yield of target products [10-13]. It is known that the methane decomposition process is complex and follows the Kassel scheme [14, 15]. One of the key factors influencing catalyst efficiency is the increase in their temperature, as it improves gas-catalyst contact, thereby accelerating the methane decomposition process. Among the most effective catalysts, nickel and iron stand out for their high activity in methane decomposition [16-19].

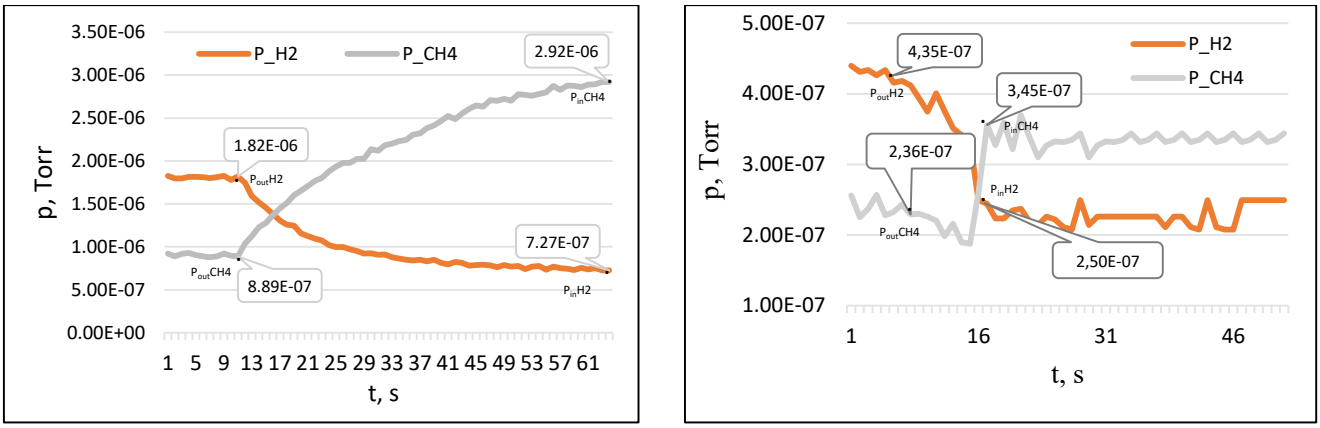
The National Nuclear Center of the Republic of Kazakhstan (RSE NNC RK) is implementing a scientific program focused on the development of hydrogen energy. The research cycle includes the development of methods for hydrogen production, storage, and its application for electricity generation. At the Center for Technological Competencies in Hydrogen Energy of RSE NNC RK, the process of hydrogen production through methane pyrolysis is being studied. For this purpose, the PM-6 experimental setup has been developed [20].

The aim of this study is to analyze the effect of a catalyst with varying nickel content on its surface on the methane pyrolysis process and its interaction with ultra-high-frequency discharge technologies.

2. MATERIALS AND METHODS

The experiments were conducted on the PM-6 installation for applied research. The main components of the setup include a microwave generator with a power output of up to 6 kW and a frequency of 2450 MHz. The reaction chamber is a quartz tube with a diameter of 30 mm, which intersects a rectangular waveguide perpendicularly. The working gas (mixture) is introduced into the center of the quartz tube from above, where a plasma discharge is initiated. The operating principle of the installation and its external appearance have been described in previously published works [20-23].

The catalyst used was a steel cylinder with a length of 20 mm and a diameter of 25.5 mm, with an elemental composition of 30 at.% carbon, 26 at.% iron, 22 at.% oxygen, 8 at.% chromium, 5 at.% aluminum, and 8 at.% nickel. The flow rates of the working gases (methane and argon) were determined by the maximum conversion efficiency during the experiments. The magnetron power was 0.6 kW. The temperature of the gas mixture flow during methane decomposition ranged from 580°C to 720°C. Argon was used to generate the plasma, into which methane was gradually introduced. The analysis of the methane decomposition products was performed using a mass spectrometer, and the results are shown in Figure 1.



a) with the use of a catalyst b) without the use of a catalyst

Fig. 1. Diagrams of partial pressures of gases resulting from methane decomposition

3. RESULTS AND DISCUSSION

Using the data from the mass spectrometric analysis presented in Fig. 1, both qualitative and quantitative assessments of methane decomposition and hydrogen formation selectivity were carried out. The conversion degree was calculated using the following equation:

$$K_{CH_4} = \frac{P_{CH_4}(in) - P_{CH_4}(out)}{P_{CH_4}(in)} \cdot 100\% \quad (1)$$

The qualitative evaluation, which determines the fraction of methane from the chemical reaction that goes to the formation of the target product, i.e., hydrogen, is called hydrogen selectivity. It was calculated using the equation:

$$S_{H_2} = \frac{1}{2} \cdot \frac{P_{H_2}(out) - P_{H_2}(in)}{P_{CH_4}(in) - P_{CH_4}(out)} \cdot 100\% \quad (2)$$

The results of the study showed that in experiments without the use of a catalyst, the conversion degree was 82% and hydrogen selectivity was 15%. Under conditions where a catalyst was used, the methane conversion degree and hydrogen selectivity reached 32% and 85%, respectively. The use of a catalyst also significantly reduces gas consumption, which directly impacts the energy efficiency of the methane conversion process.

4. CONCLUSIONS

During the experiments, the maximum degrees of methane decomposition and hydrogen selectivity in the super high-frequency discharge on the PM-6 installation were determined, depending on the use of a catalyst. The results showed that the use of a steel catalyst is effective in increasing hydrogen selectivity. The integration of methane pyrolysis with super high-frequency discharge and the use of metallic catalysts could lead to the creation of closed cycles, ensuring cleaner and more sustainable hydrogen production. The experimental results presented in this paper demonstrate the effectiveness of plasma-catalytic methane decomposition in super high-frequency discharge.

ABSTRACT
Green hydrogen production is being advanced through Anion Exchange Membrane (AEM) technology, which is highly compatible with renewable energy sources. The research investigates the use of NiMo-based catalysts at the cathode and NiFe-oxide-hydroxide (LDH) catalysts at the anode in AEM water electrolysis. These catalysts are coated on carbon-based supports, with Ni felt used for diffusion. The catalysts are synthesized using co-precipitation and gas reduction methods, and their physico-chemical and electrochemical properties are analyzed with various techniques. Membrane electrode assemblies (MEAs) are developed by spray-coating the catalysts onto Ni foam and carbon paper supports. Electrochemical tests, including polarization curves, impedance spectroscopy and galvanostatic durability tests, are performed to assess the MEA performance and degradation. The optimal configuration for AEM electrolysis was found to involve NiFe-LDH at the anode, unsupported NiMo at the cathode, a 10% ionomer included in the electrodes, and specific membrane.

Keywords: Water electrolysis, Hydrogen, anion exchange membrane, NiFe catalyst, NiMo catalyst.

1. INTRODUCTION

In recent decades, due to global warming, alternative and renewable methods have been sought to avoid the use of fossil fuels. The most common renewable energy sources are solar, hydroelectric and wind energy. Even Hydrogen's function as an energy vector is increasly looking like a wise decision. Most hydrogen production comes from fossil fuels. There are four different technologies for the production of Hydrogen green which are based on the splitting of water through electrolysis: polymer electrolyte membrane-based (PEM); liquid electrolyte alkaline-based (AEL); anion exchange membrane-based (AEM); solid oxide-based at high temperature (SOEC).
The Anion Exchange Membrane (AEM) technology is ideal for linking up with renewable energy sources because have some advantages: low cost of components, low quality of water used as feed, use of non-critical raw materials and non-fluorinated membranes, high pressure and purity of hydrogen. [1]
It is relevant to optimise and further develop base components that have demonstrated suitable properties in the AEMWE environment. With regard to the catalyst development the approach addresses the use of NiMo-based catalyst at the cathode and NiFe-oxide-hydroxide (Layered Double Hydroxide, LDH) catalyst at the anode coated on carbonaceous structures and Ni felt as diffusion media for the hydrogen evolution reaction (HER) and oxygen evolution reaction (OER), respectively. [2]

2. MATERIALS AND METHODS

The synthesis of NiFe-LDH and NiMo electrocatalysts are based on co-precipitation method. A gas reduction was adopted in the case of the cathode catalysts.
To study the physico-chemical and morphological properties of the electrocatalysts, different characterization techniques were used: x-ray diffraction (XRD), x-ray fluorescence (XRF), transmission electron microscopy (TEM), Brunauer–Emmett–Teller (BET), thermogravimetric analysis (TGA), Temperature-programmed reduction (TPR).
Membrane electrode assemblies (MEAs) were produced by spray-coating catalyst onto the anode and cathode supports (Ni foam from Bekaert and Carbon paper from Sigracet, respectively). These assemblies were then electrochemically tested in a 5 cm² square single cell. Galvanostatic polarization curves and electrochemical impedance spectroscopy (EIS) measurements were carried out at 1.5V, 1.8V, and 2V at 50°C, by a galvanostatic durability test at 1 A/cm², to evaluate both the performance and degradation behaviour of the MEAs.

3. RESULTS AND DISCUSSION

To optimize and analyse AEM technology, an assessment of ionomer percentage on the anode in the MEA preparation was carried out by electrochemical measurements; for the cathode, a comparison was made between supported and unsupported NiMo. The most promising configuration involves NiFe-LDH at the anode, unsupported NiMo at the cathode, 10% ionomer configuration, Piperion membrane, densified Ni felt at the anode and Sigracet diffusion layer at the cathode.

4. CONCLUSIONS

In conclusion, the development of green hydrogen production technologies, particularly through AEM electrolysis, represents a promising avenue for reducing dependence on fossil fuels and combating global warming. Continued optimization of the key components, such as catalysts and ionomer, is essential for improving efficiency and performance. The results of this study, particularly the promising combination of NiFe-LDH and unsupported NiMo catalysts, suggest

that AEM technology holds great potential for large-scale, sustainable hydrogen production, making it a vital part of the clean energy transition.

ABSTRACT
Developing low-cost electrocatalysts is key to improving proton exchange membrane (PEM) water electrolysis for sustainable hydrogen production. In the research for alternative catalyst materials, molybdenum disulfide (MoS_2) has shown great potential for the hydrogen evolution reaction (HER). This study investigates MoS_2-based catalysts synthesized via a hydrothermal method, including an unsupported variant and two supported on Ketjenblack EC carbon (KB). Physico-chemical characterization was conducted using different techinques, while electrochemical performance was evaluated in a PEM single cell through polarization, electrochemical impedance spectroscopy (EIS) , and durability tests. The supported MoS_2 catalyst, incorporating KB during synthesis, exhibited superior performance with higher current densities, lower polarization resistance and higher durability, demonstrating its potential as a viable alternative to noble metal-based cathodes.

Keywords: PEM electrolyzer, non-Noble catalysts, MoS_2, Hydrogen, Proton Exchange Membrane

1. INTRODUCTION

The increasing global energy demand and the environmental impact of CO_2 emissions from fossil fuel combustion make the research for sustainable alternative energies crucial. Hydrogen is considered one of the most promising options, offering a more sustainable solution with a lower environmental impact in the context of modern energy consumption, and its combustion results exclusively in water [1]. Among the available technologies, proton exchange membrane (PEM) water electrolysis is distinguished by its efficiency and reliability, though the reliance on noble metal catalysts such as platinum and iridium limit its economic sustainability. In the context of today's scientific efforts to advance hydrogen production, there is a growing focus on developing non-precious catalysts to make water electrolysis more accessible and cost-effective [2].
Molybdenum disulfide (MoS_2) has emerged as a promising alternative due to its abundance and favorable catalytic properties, offering a viable pathway for sustainable hydrogen production.

2. MATERIALS AND METHODS

2.1. Catalyst preparation

Three MoS_2 catalysts were synthesized for cathode applications using a suitable and low-cost hydrothermal method: one unsupported and two supported on Ketjenblack EC carbon (KB). The difference between the two supported catalysts lies in the preparation: one was mechanically mixed with KB (supported-1), while in the other, KB was incorporated with the precursors (supported-2) to enhance catalytic efficiency while reducing the metal catalyst loading.

2.2. Physico-chemical characterization

To investigate the physico-chemical properties of the synthesized electrocatalysts, various characterization techniques were employed. X-ray Diffraction (XRD) was used to analyze the crystal structure and to evaluate crystallite size, while X-ray Fluorescence (XRF) was performed to determine the elemental composition of the catalysts. Transmission Electron Microscopy coupled with Energy-Dispersive X-ray Spectroscopy (TEM-EDX) allowed to know the powders morphology, structure, and elemental distribution. Additionally, Thermogravimetric Analysis (TGA) was conducted to monitor mass variations as a function of temperature under controlled atmospheric conditions.

2.3. PEM electrolyser setup

The electrochemical performances of the synthesized MoS_2 and MoS_2/C catalysts were investigated in a single PEM cell with a 5 cm² active area by polarization corves and electrochemical impedance spectroscopy (EIS) in a range of temperature between ambient to 90°C; galvanostatic durability tests were performed at an operating temperature of 80°C. The cells were assembled using a commercial IrO_2 as the anode and the three synthesized MoS_2 catalysts as the cathodes. A NAFION 212 membrane was placed between the electrodes to complete the PEM-based MEA assembly.

3. RESULTS AND DISCUSSION

The comparative analysis of the three catalysts revealed that the supported-2 MoS_2 catalyst exhibited superior electrochemical performance. In polarization measurements, it achieved higher current densities at lower voltages compared to both the unsupported and supported-1. Electrochemical impedance spectroscopy (EIS) further confirmed lower polarization resistance at different voltage values, which suggests enhanced charge transfer efficiency; additionally,

galvanostatic durability showed greater stability.
These findings confirmed the supported-2 MoS_2 as the most operative cathode catalyst for hydrogen evolution reaction in PEM electrolisis.

4. CONCLUSIONS

In this work is reported a screening of catalysts based on MoS_2 and MoS_2/C for hydrogen evolution reaction (HER) in acid environment. Non-CRM (non critical raw material) catalysts were synthetized by hydrothermal processes and characterized by physico chemical analyses, as XRD, XRF, TGA and TEM. The electrochemical characterization was carried out in terms of polarization curve, EIS at different potential value and galvanostatic durability test. The electrochemical evaluation of MoS_2 and MoS_2/C as cathodes in a PEM single cell revealed improved performance and stability for the supported MoS_2 catalysts, particularly for the one incorporating Ketjenblack EC carbon in the initial step with precursors.

ABSTRACT
The constraints of existing electrolysis techniques, which depend on crucial raw materials (CRMs) like Ir, Pt, and Ru, are brought to light by the rising need for green hydrogen. The endurance and scalability of proton exchange membrane (PEM) electrolysis are hampered by these expensive materials. An alternative method that uses non-CRM materials is anion exchange membrane electrolysis (AEMEL), which presents a viable solution. This strategy supports a circular economy by concentrating on materials like Ni, Fe, Mo, and Cu that may be obtained from waste products. In order to achieve high efficiency, low cell voltage, and little degradation, the novel electrocatalysts were tested throughout a range of temperatures and their performance was assessed. The comprehension of membrane and electrode contributions to overall system performance is further improved by the application of impedance analysis.

Keywords: green hydrogen, non-critical raw materials, nanocatalysts, sustainable energy supply

1. INTRODUCTION
Due to the limited performances and durability of critical raw materials (CRMs), state-of-the-art electrolysis methods are unable to effectively meet the significant increase in demand for green hydrogen. In this context it takes on particular importance the use of a technology based on non-critical raw materials.
High loading of precious metal electro-catalysts, such as Ir, Pt, and Ru, as well as expensive titanium bipolar plates and Ti/Pt-based porous transfer layers, are actually necessary for high throughput water electrolyzers based on proton exchange membrane (PEM) technology. An alternative technique, the anion exchange membrane electrolysis (AEMEL), has the potential to be created with diffusion layers, stack plates and catalysts that are not based on CRMs. [1,2]
The novel electrolysis prototypes utilize materials free of CRM based on Ni [3], Fe, Mo, and Cu and offer pathways for recycling and upscaling in a circular approach using secondary raw materials as starting sources. [4] It's important to highlight that utilizing waste as raw material for nanomaterial synthesis is the key to supporting the concept of a circular economy, which views waste as a valuable resource. Transforming conventional waste into nanomaterials could help reduce the need for primary resource extraction and prevent future shortages of raw materials.

2. MATERIALS AND METHODS
2.1. Catalysts and electrodes preparation
Nanocatalysts synthesis were carried out using environmentally friendly techniques, such as chemical bath deposition (CBD), electroless deposition (ELD) and the hydrothermal (HT) method. The synthesized catalysts were used to prepare electrodes, focusing on optimizing their electrochemical activity for hydrogen evolution reaction (HER) and oxygen evolution reaction (OER). Membrane-electrode assemblies (MEAs) were prepared by spray deposition of the cathodic catalyst on sigracet and the anodic catalyst on Ni felt as supports and combined with a commercial membrane, Fumatech FAA-3.

2.3. Physico-chemical and electrochemical characterization
Different techniques were used to study structure, morphology and composition of the novel catalysts. Physical-chemical properties were studied by Scanning Electron Microscope (SEM), Transmission Electron Microscopy (TEM), X-ray Diffraction Spectroscopy (XRD), X-ray Fluorescence Spectroscopy (XRF) and X-ray Photoelectron Spectroscopy (XPS). Electrochemical tests were performed in single cells (5 cm^2) using polarization curves, alternating current (AC) impedance spectroscopy and galvanostatic durability tests to evaluate performances and stability of electrocatalysts.

3. RESULTS AND DISCUSSION
The new electrocatalysts were tested in a AEM single cell of 5 cm^2 in a temperature range from ambient to 60°C; the cells were supplied with diluted KOH (0.1-1 M) or pure water.
By using polarization curve a current density of 1 A/cm^2 at a cell voltage below 2V was obtained and a degradation rate under 10 μV/cell, during a durability test, was observed. The goal was also to separate the contributions of the membrane and electrodes to the overall performance using AC impedance analysis across a wide frequency range.

4. CONCLUSIONS
In summary, the electrochemical performance of electrodes for hydrogen and oxygen evolution processes (HER and OER) has been successfully improved by the ecologically friendly production of new nanocatalysts. The promising

structural and compositional characteristics of these catalysts were validated by characterisation using a variety of physico-chemical techniques. Their durability and performance in membrane-electrode assemblies (MEAs) were further demonstrated by electrochemical testing, which emphasized obtaining a high current density at low cell voltage and minimizing degradation rates. These discoveries open the door to electrochemical energy conversion systems that are more sustainable and effective.

ABSTRACT
The aim of this work was to develop electrocatalysts with high catalytic activity for oxygen evolution reaction (OER) consisting of low noble metal loading, such as Pt and Ir. IrRuOx-based anodic catalyst with a core-shell structure having Ru in the core and a high amount of Ir on the surface was developed through modified Adams synthesis [1].
This catalyst was in the form of dispersed nanocrystals (≤ 9 nm) and with a high surface area (155 m²/g) such as to allow a reduced loading in the membrane electrode assembly (MEA) while maintaining high activity and stability for operation at high current density. A recombination catalyst based on Pt-Co alloys through sulphite synthesis route was also developed. This catalyst was integrated with the anode catalyst in order to reduce the crossover of hydrogen permeated through the membrane [2].

Keywords: Renewable Energies, Hydrogen production, Proton exchange membrane

1. INTRODUCTION
Proton Exchange Membrane (PEM) water electrolysis is a very promising alternative to the more conventional liquid electrolyte alkaline water electrolysis for the production of “green” hydrogen. The membranes used for this type of technology are based on sulfonated perfluoropolymers (PFSA), which allow the crossing of proton charges from cathode to the anode side, leading to the formation of oxygen and hydrogen gases.

2. MATERIALS AND METHODS
Physical-chemical properties of anode and recombination catalysts developed were studied by Xray-diffraction (XRD), Xray-fluorescence (XRF), scanning and transmission electron microscopy (SEM/TEM). After a structural, compositional, superficial and morphological characterization of the catalysts, MEAs were prepared by spray deposition, using an automatic system. Electrochemical tests were performed in single cell (5 cm^2) using the protocols of harmonization developed by JRC (European Commission).

3. RESULTS AND DISCUSSION
To evaluate performance different electrochemical techniques were used such as polarization, spectroscopy impedance and durability tests over a temperature range of 30 to 90 °C. A Pt/C-based catalyst was used at the cathode while the anode was based on IrRuOx (Ir:Ru=70:30). The quantities of catalyst used were 0.3 $mg_{Pt}cm^{-2}$ and 0.37 $mg_{IrRu}cm^{-2}$ + 0.2 $mg_{PtCo}cm^{-2}$ at the cathode and anode, respectively.

4. CONCLUSIONS
Polarization, impedance spectroscopy and stability measurements were conducted to evaluate materials developed for hydrogen generation under specific operating conditions in the PEM electrolysis system. A "steady state" durability test at 90 °C, with an initial conditioning phase at 1 $A{\cdot}cm^{-2}$ for approximately 250 h and subsequently at 4 A cm^{-2} demonstrates good stability after more than 1400 hours of testing.The next step will be to reach new goals in terms of crossover (H_2 conc. in O_2 stream) by using the recombination catalyst-based MEAs.

ABSTRACT
This paper presents a modular, object-oriented simulation tool to analyze the technical and economic performance of renewable hydrogen production plants. Users define key components (PV plant, electrolyzer, compressor, battery storage, grid connection, hydrogen storage, and demand), and the tool simulates their interactions on an hourly basis over a 20-year horizon. By modeling energy flows, hydrogen production, storage utilization, and grid exchanges, it supports plant promoters in optimizing design and operation. The tool also conducts an economic analysis, calculating the levelized cost of hydrogen, CAPEX, and OPEX. Results highlight the trade-offs between off-grid and grid-connected scenarios: while off-grid operation achieves a lower LCOH (5.95 €/kg vs. 6.05 €/kg), the grid-connected setup enables higher hydrogen production (240,020 tons vs. 95,593 tons) but with increased OPEX. These findings emphasize how system configuration influences costs and production capacity. The modular approach ensures flexibility, allowing integration of new technologies and scalability of existing systems. This tool bridges the gap between technical feasibility and economic viability, facilitating the development of sustainable hydrogen production plants aligned with global decarbonization goals.

Keywords: Hydrogen Production Simulation, Renewable Energy Integration, Plant Design Decision Support

1. INTRODUCTION

The transition to renewable hydrogen production is critical for decarbonizing hard-to-abate sectors, yet scaling these plants requires significant upfront investment. Given the financial risks and technical complexity of such projects, rigorous techno-economic analysis across multiple phases – from design to long-term operation – is essential to ensure viability and attract stakeholders. Existing tools aimed at supporting decision-making often lack the granularity to model interactions between critical components (e.g., electrolyzers, PV plants, storage systems) or rely on oversimplified assumptions, limiting their utility for real-world project planning.

A review of current simulation frameworks reveals three key shortcomings: (1) insufficient modularity to adapt to diverse plant configurations, (2) simplified temporal resolution that overlooks hourly variability in renewable energy supply and hydrogen demand, and (3) insufficient integration of equipment-specific performance dynamics. These gaps hinder promoters' ability to assess operational trade-offs, such as balancing battery buffering against grid reliance or optimizing electrolyzer sizing to match intermittent solar generation.

To address these challenges, this work introduces a modular, object-oriented simulation tool designed for high-resolution, long-term analysis of renewable hydrogen plants. By □ulfil□nc hourly interactions between all core components – PV arrays, electrolyzers, compressors, storage systems, and grid connections – over a 20-year timeframe, the tool provides actionable insights into energy flows, hydrogen output, and storage utilization. It further integrates economic metrics (e.g., LCOH, CAPEX/OPEX) to quantify the impact of design choices on financial viability. This approach empowers decision-makers to test scenarios, identify bottlenecks, and optimize plant configurations with robust technical and economic data, ultimately de-risking investments in the emerging hydrogen economy.

2. MATERIALS AND METHODS

The user begins by creating each module (e.g., PV plant, electrolyzer, compressor, hydrogen storage) and specifying its characteristics, such as capacity, efficiency, and operational constraints.

Once the components are defined, the user establishes the connections between them, determining how energy and hydrogen flow throughout the system. Additionally, a priority hierarchy is set, which dictates the order in which each component □ulfil□ the requirements of its successors. This priority system ensures that energy distribution and hydrogen supply are managed efficiently, optimizing the overall plant operation.

With this modular approach, the tool provides flexibility in configuring different plant layouts while maintaining a structured simulation process.

2.1. Tool Architecture and Modular Design

The simulation tool is developed using an object-oriented programming (OOP) approach in Python, enabling modular representation of plant components (e.g., PV, electrolyzer, hydrogen storage). Each component is □ulfil□n as a class with defined attributes (e.g., efficiency, capacity) and methods to calculate hourly performance (e.g., energy output, degradation). Interactions between components are managed through a central controller that synchronizes energy flows, storage levels, and grid exchanges. This modularity allows users to add, remove, or scale components without

restructuring the entire framework, aligning with best practices for energy system □ulfil□nc. The operation of the entire plant is dependent on hydrogen demand (demand itself and storage requirements). At each simulated hour, the demand dictates the operation of each component, with each system responding to the specific needs of the plant. Components work in a request-response manner, where each piece functions in response to the existing hydrogen demand, ensuring the plant operates efficiently and meets the required hydrogen supply.

2.2. Component modelling

The renewable energy supply can be modelled by 3 different manners: Photovoltaic plant, PPA contract or grid connection.

PV Plant: Users input an hourly electricity production profile via an Excel file. Current simulations utilize simulated data generated by a software, which provides location-specific solar irradiance and temperature profiles. This enables site-specific □ulfil□nc of PV output variability.

Grid connection: The grid is □ulfil□n as an unlimited backup source to meet unmet demand. Users assign electricity prices (€/MWh) to evaluate the grid's influence on the levelized cost of hydrogen (LCOH).

Electrolyzer system: The electrolyser model is implemented with a variable efficiency dependent on its load factor following the work developed by Koponen et al. [1]. Additionally, electrolyser's degradation is considered at a fixed rate of 0.25% per 1,000 operating hours [2]. The entire efficiency curve decreases over time according to this factor, ensuring that long-term performance degradation is accounted for in the simulation.

Compressor: The compressor is □ulfil□n using theoretical thermodynamic equations. Since different compressor models exhibit varying behaviors, a generic approach based on fundamental thermodynamic principles was chosen First, the number of compression stages (N) is calculated using [3]:

$$N = \frac{\log(P_{out}/P_{in})}{\log(x)} \quad (1)$$

Where P_{in} and P_{out} are the outlet and inlet pressures, respectively, and x is the compression ratio per stage.

The energy required for compressing hydrogen is calculated assuming an insenthropic compression with an □ulfil□ncy of 80%. Finally, the power required by the compression system (P) to □ulfil the plant's hydrogen needs is given by [3]:

$$P = N\left(\frac{k}{k-1}\right)\left(\frac{z}{\eta}\right)T_{in}\,Q\,R\left[\left(\frac{P_{out}}{P_{in}}\right)^{\left(\frac{k-1}{Nk}\right)} - 1\right] \quad (2)$$

Where z is the compressibility factor, k is the ratio of specific heat under constant pressure to to specific heat under constant volume, T_{in} is the inlet temperature [K], Q is the molar flow rate [mol/s], η is the efficiency and R the universal gas constant [J/(K.mol)].

Importantly, the compressor does not act as a bottleneck in hydrogen supply, as its capacity is determined only after the simulation, based on the peak power demand observed during the simulation period.

Hydrogen Storage: Hydrogen storage is modeled based on user inputs, including the maximum storage pressure and the maximum hydrogen mass capacity.

Demand: Hydrogen demand is modeled based on user input. It can be set as a fixed value or as a variable profile, in which case it is defined through an Excel file provided by the user.

2.3. Graphical interface

The tool's graphical interface was developed using Streamlit, an open-source Python framework, to ensure user-friendliness and efficient analysis of simulation outputs. The GUI simplifies input parameterization (e.g., component specifications) and enables interactive visualization of results, such as hourly hydrogen production, energy flows, and cost breakdowns. Key design principles include: (1) Modular Workflow: Input forms are structured to mirror the plant's physical components, aligning with the tool's object-oriented architecture. (2) Dynamic Visualization: Outputs are displayed as interactive time-series plots and summary tables, allowing users to toggle between technical and economic metrics. (3) Data Export: Results can be exported in standardized formats for further analysis or reporting.

3. RESULTS AND DISCUSSION

The tool's performance was validated through two case studies analyzing a solar-driven hydrogen production plant under distinct configurations: Scenario 1 (off-grid, renewable-only) and Scenario 2 (hybrid, grid-connected). Key parameters for both scenarios are summarized in Table 1, while Fig. 1 illustrates the plant layout and component interactions.

Table 1. Case study scenarios summary table

Item	Off-grid scenario	Grid-connected scenario
Photovoltaic Plant [MW]	300	
Photovoltaic Plant Location	Sines, Portugal	
Grid connection	x	✓
Electrolyser [MW]	100	

Low pressure hydrogen storage [kg]	10000
High pressure hydrogen storage tank [kg]	15000
Low pressure hydrogen demand [kg/hour]	750
High pressure hydrogen demand [kg/hour]	375

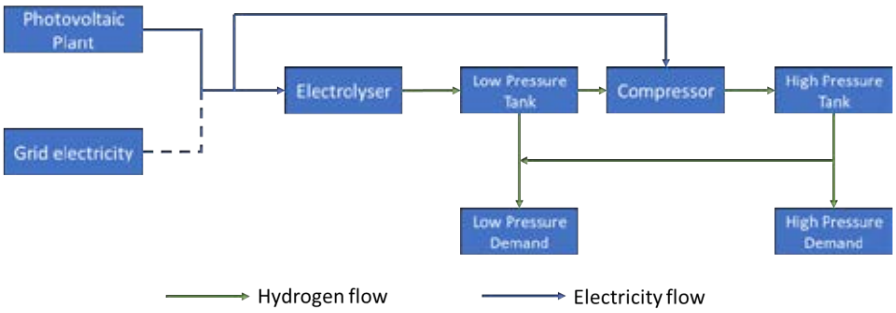

Fig. 1. Layout for simulated case study

Lastly, for the simulated case studies, it is considered that the remaneiscence electricity produced by the photovoltaic plant is sold for a quarter of the price it is bought to the grid.

3.1. Tool results

The case study outcomes (Table 2) demonstrate how operational strategies – specifically grid integration – impact hydrogen production volumes and cost structures. Despite identical initial capital expenditures (CAPEX), the two scenarios diverge significantly in LCOH due to differences in output and operational expenses (OPEX).

Table 2. Case study scenarios results summary table

Item	Off-grid scenario	Grid-connected scenario
Plant CAPEX [M€]	333	333
Electrolyser CAPEX [M€]	108	108
Total OPEX [M€]	235	861
Total Hydrogen produced [ton]	95,593	197,121
CAPEX percentage on LCOH [%]	58.7	27.9
OPEX percentage on LCOH [%]	41.3	72.1
LCOH [€/kg]	5.95	6.06

The comparative analysis of two hydrogen production plant configurations – off-grid scenario and grid-connected scenario reveals critical insights into the trade-offs between renewable autonomy and grid dependency. Despite identical initial capital expenditures (CAPEX) for the whole plant which €108 million was for the electrolyzer, the operational strategies yield stark differences in hydrogen output and cost structures.
Off-grid scenario, reliant solely on a 300 MW photovoltaic plant, produced 95,593 tons of hydrogen over the 20-year simulation. While its LCOH is marginally lower at €5.95/kg, the system's dependence on intermittent solar energy led to significant downtime, limiting production volume as represented in the photovoltaic plant alocations in determined timeframe – Fig 2. The LCOH is dominated by CAPEX (58.7%), reflecting underutilization of infrastructure due to renewable variability.

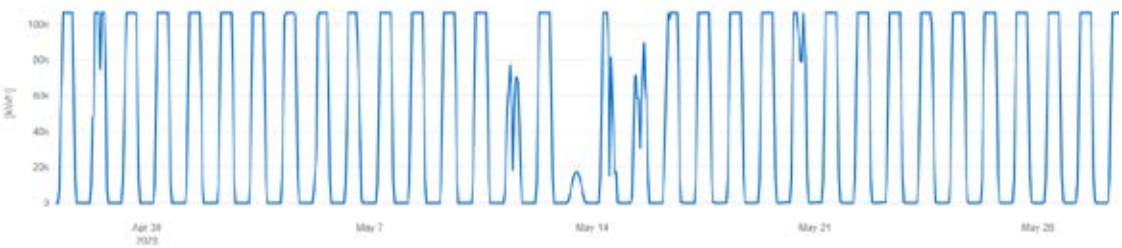

Fig 2. Photovoltaic alocations in a determined timeframe

In contrast, grid-connected scenario leveraged grid connectivity to achieve 240,000 tons of hydrogen - 2.5 times more

than the first one. The grid stabilized production by ensuring near-continuous electrolyzer operation (Fig. 3), but this came at a cost: higher reliance on grid electricity inflated operational expenditures (OPEX), which account for 72.1% of the LCOH. Consequently, while the larger output diluted the CAPEX impact (27.9% of LCOH), the total LCOH rose to €6.06/kg.

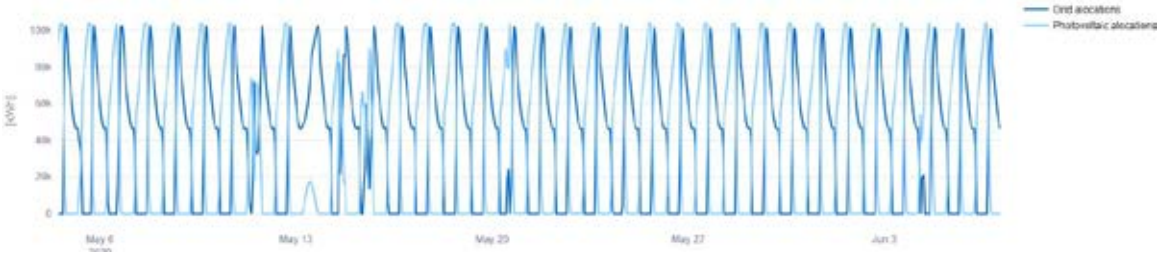

Fig 3. Photovoltaic and grid alocations in a determined timeframe

This paradox - higher production but higher costs in grid-connected scenario - stems from the grid's dual role. While it enables consistent operation and maximizes electrolyzer utilization, electricity costs also burden OPEX.
However, off-grid scenario's lower LCOH masks operational risks. Its CAPEX - heavy structure leaves investors vulnerable to prolonged low-irradiance periods, which could further reduce output and extend payback periods. Grid-connected scenario's higher output, meanwhile, aligns better with industrial-scale hydrogen demand, suggesting it may be preferable for markets prioritizing volume over marginal cost savings.
Ultimately, the choice between these configurations hinges on regional energy prices, policy incentives and demand profiles. Hybrid models - combining limited grid use with battery storage - could balance cost and reliability, though further analysis is needed to optimize such systems.

4. CONCLUSIONS

The developed tool equips hydrogen plant promoters with valuable techno-economic insights, enabling more informed decision-making by improving the quality and granularity of available information. By modeling interactions between key components and simulating their performance over a long-term horizon, the tool helps assess the feasibility of different plant configurations.
The case study demonstrates that grid connection significantly enhances production stability, making it a more reliable option for industrial-scale hydrogen supply. However, this stability comes at the cost of higher operational expenditures, resulting in a higher LCOH. This trade-off highlights the challenge of balancing cost efficiency with production reliability, which is crucial for ensuring hydrogen's competitiveness in the energy market. It is also important to acknowledge that the economic assumptions in this study are based on literature values, which may introduce some uncertainty in the final results.
To refine the accuracy of the analysis, future work will focus on incorporating real-world business case data, enabling a more precise economic evaluation. Additionally, a comprehensive sensitivity analysis will be conducted to assess the impact of variations in component costs, efficiency degradation, and market fluctuations, further strengthening the tool's applicability in decision-making processes.

ABSTRACT
Renewable gases can become an important piece in the decarbonization wave occurring in the energy sector. Renewable gases can be injected in the gas network and contribute as a gradual replacement of natural gas. The mixing of renewable gases and natural gas can be somehow complex from a technical standpoint to ensure that all the infractructure from a macro point of view can continue to be manageable and from a local point of view does not endanger the transport of gas or be a possible hazard. It is also important to know where are the major natural gas consumption points and the relevant points of the network to plan the quantities of renewable gases demanded and necessary resources to produce them. A tool to aid in the planning and management of renewable gases injections in the the Portuguese natural gas network was developed. The information on the natural gas consumption and renewable gases requirements were aggregated and the results are displayed in a map with all the important references.
Keywords: Renewable gases, Gas network, Power2Gas

1. INTRODUCTION

The introduction of renewable gases into the energy mix is something that has been discussed in recent years and follows on from the impossibility of completely electrifying the energy mix as a measure to decarbonize the economy. The gradual integration of renewable gases into the Portuguese gas network has been part of the country's plans since 2020, with the advent of the National Hydrogen Strategy [1] and later, in 2024, with the release of National Action Plan for Biomethane [2]. The idea has already been tested, with the Green Pipeline Project [3], since 2021, allowing a mixture of natural gas and hydrogen to circulate in the gas network and be made available to 80 consumers of different types. The injection of renewable gases into the network will allow a reduction in emissions from the sector equivalent to the reduction in natural gas consumption achieved. Renewable hydrogen is known to be carbon neutral as long as it is produced using renewable electricity. Biomethane is considered a low-carbon gas and its carbon intensity necessarily depends on the origin and life cycle of the organic waste from which it is produced. It is currently known that the current infrastructure is capable of receiving up to 20% of hydrogen (by volume) into the network and that there are no known restrictions on the physical limit of biomethane that can be integrated into the network, since it is interchangeable with natural gas.

The diversification of energy sources makes it possible to create a system that is resilient to uncertainty and to adapt the most appropriate energy sources to the most suitable means and purposes. Fossil fuels are highly energy-dense substances and therefore make it possible to produce a reliable and uninterrupted flow of high energy with relatively simple and affordable technology. This makes them attractive and useful for high-temperature, energy-intensive processes. Natural gas is known to be probably the least polluting of all known fossil fuels. Furthermore, of all the fossil fuels, it is the one that has maintained the most constant consumption in recent years (despite the slight drop since 2020). This is an indication that there is a substantial dependence on natural gas consumption in Portugal and in other countries, and that this is therefore a difficult energy vector to decarbonize. It's not just the easy accessibility of the current gas transportation and distribution network, it's the reliability of the fuel and the maturity of the technological processes that feed into it. It is against this backdrop that renewable gases are positioning themselves to take on a possible decarbonization role in the natural gas sector.

As far as legislation is concerned, the Portuguese Order No. 806-B/2022 already refers to the introduction of renewable gases into the network, already allowing the network to operate with up to 100% renewable or low-carbon gases. The order also refers to the need to ensure the interoperability of gas infrastructures and to comply with ISO 13686 or other technically applicable standards. The portuguese quality-of-service regulation (RQS) for the gas network also refers to the parameters for regulating the quality of service in the gas sector, with specific reference to the characteristics of the gas, namely, ranges of admissible values for properties of the gas circulating in the gas network, as well as values for compounds or contaminants.

2. ANALYSIS OF THE TOOL

General planning for the injection of renewable gases into the grid has become a necessity. It is imperative to know the distribution of natural gas consumption in the country, to understand which municipalities consume more natural gas, where the gas transmission network and its points of interest are located, where the renewable gas producers already registered with Directorate-General for Energy and Geology (DGEG) are located, and where the autonomous gas units (AGU) are located.

2.1. Data and Structure of the tool

The data was collected from several sources. The national gas grid and the location of its relevant points were collected from REN (the national transmission system operator (TSO) [4]. The information regarding the location of the renewable gases producers pre-registered was collected from DGEG [5]. The consumption of natural gas per municipality in the year of 2023 was collected also from DGEG [6]. To perform the calculation, some assumptions were made. The calculation of the demand of hydrogen upon definition of a value of integration of hydrogen, in volume, was made assuming the energy flow should be exactly the same. The same was made with the integration of biomethane. The calculus of the new volume of the mixture will be like:

$$V_{mixture} = \frac{LHV_{NG} * \dot{V}_{i_{GN}}}{(LHV_{NG} * X_{NG} + LHV_{H_2} * X_{H_2} + LHV_{Biomethane} * X_{Biomethane})} \quad (1)$$

The demand of water regarding the demand of hydrogen is calculated like the following way, considering that the water need to produce 1 kg of hydrogen is of 9 kg of water:

$$Water\ demand\ [10^3\ m^3] = H_2\ demand\ [10^3\ m^3] * \rho_{H_2} \left[\frac{kg}{m^3}\right] * 9 \left[\frac{kg_{H_2O}}{kg_{H_2}}\right] \quad (2)$$

The required electrical renewable energy to produce the hydrogen demanded, assuming that the need of electric energy is of 55 kWh per kg of hydrogen, is calculated like:

$$Renewable\ energy\ [MWh] = H_2\ demand\ [10^3\ m^3] * \rho_{H_2} \left[\frac{kg}{m^3}\right] * 55\ \left[\frac{kWh}{kg_{H_2}}\right] \quad (3)$$

The demand of urban solid biorresidues (UBR), considering there are 73 m3 of biomethane being produced per ton of bio municipal solid waste, is calculated according to:

$$UBR\ [ton] = Biomethane\ demand\ [10^3\ m^3]\ /73\ [\frac{m^3 biomethane}{ton\ RBU}] \quad (4)$$

A parameter to evaluate if there is necessary urban solid biorresidues per municipality to meet the necessary biorresidues to produce the demanded biomethane was created. If this parameter is superior to 1, it means there are not sufficient urban solid biorresidues to meet the requirement, if it is inferior to 1, there are more urban solid biorresidues than the required. The parameter is calculated like this:

$$R = \frac{biorresidues\ required}{biorresidues\ needed} \quad (5)$$

3. RESULTS AND DISCUSSION

Figure 1 shows the compilation of data on natural gas consumption per municipality, the gas network, the relevant points of the natural gas network, renewable gas producers and autonomous gas units. This figure is part of the tool which was developed in Power BI to hold a complete database with relevant data to the process and hold this interface, of this map, which was developed in ArcGIS PRO.

According to figure 1, some interesting conclusions can be drawn about the current layout of the plan. The areas with the highest consumption of natural gas are generally located close to the gas transmission network. Reference should also be made to the northern region of the country, which has considerable consumption and is fairly evenly distributed in terms of area, despite not being completely covered by the gas transmission network. Renewable gas producers are registered in regions with a high demand for natural gas and in the vicinity of the gas network, with the exception of the Chaves area, there will be renewable gas production, but there is no access to the transmission network, it should be noted, however, that gas consumption in the region is ensured by autonomous gas units. It can be seen that there are still plenty of areas and regions in the country with potential for renewable gas production, given the large number of areas with high gas demand.

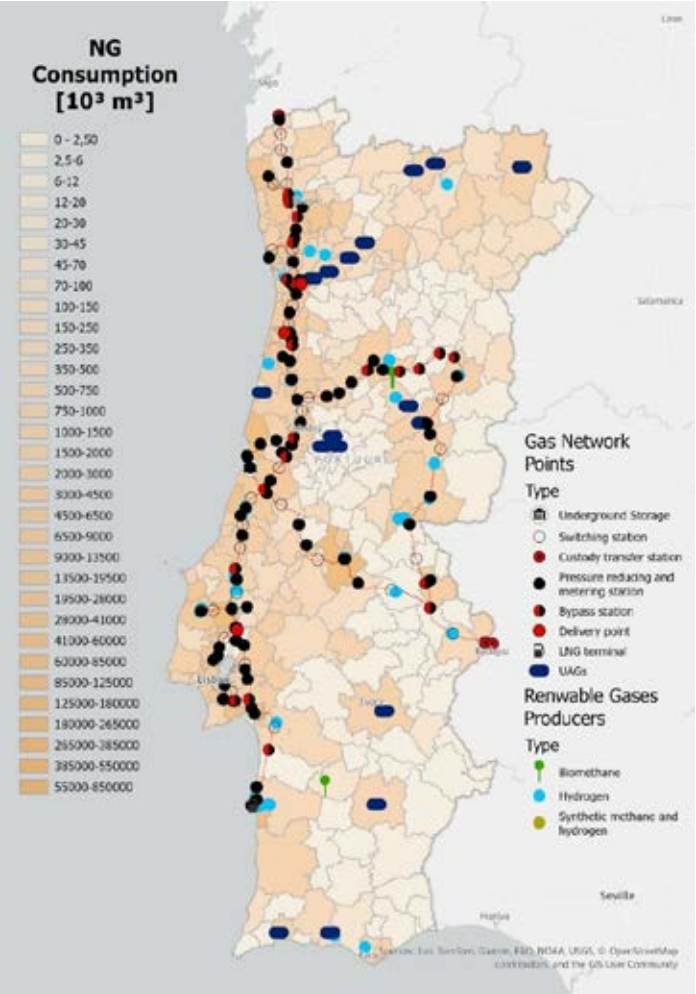

Fig. 1. Portugal Map with the gas network and points of interest localization, consumption of natural gas per municipality, location of renewable gas producers and autonomous gas units.

Assuming the 20% introduction of hydrogen into the gas network as a limit scenario, some data was gathered on the demand for renewable gases and the resources needed to produce them.

The demand for hydrogen will be closely linked to the demand for natural gas by region, so regions with a higher consumption of natural gas will necessarily represent a higher demand for hydrogen. The tool developed for the effect was used and some results were generated on how much water would be needed to produce this annual hydrogen demand, as well as renewable electricity. In order to meet the target of 20% hydrogen in the gas network by volume, while maintaining the energy flow supplied, it would be necessary, just to get a perspective in numbers, to install around 2.8 GW of photovoltaic power, taking into account the average Portuguese capacity factor of 19% [7]. As for water availability, the total amount of water needed to produce hydrogen demand at national level is negligible, way below 1%, when compared to the amount of water captured annually, according to the national institute of statistics (INE) data [8].

Assuming a biomethane integration scenario of between 10% and 50%, considering it to be an interchangeable gas and therefore with no physical limit to its integration into the network, calculations were made of the demand created for biomethane, the amount of municipal bio solid waste needed to be collected and also a fraction ratio between the amount of municipal solid waste needed and the municipal solid waste available, by municipality. Values of this ratio of less than 1 mean that the municipality in question generates enough biodegradable municipal solid waste to produce the biomethane needed to meet the target. To calculate this ratio, based on data published in the Portuguese Environment Agency's Annual Report on Municipal Waste 2023 [9], it was assumed that, on average, each inhabitant produced 505 kg of municipal waste in 2023, 38% of which was bio-waste. Assuming this average value per inhabitant and knowing the population of each municipality, an estimate was made of the amount of bio-waste produced per municipality. In figure 2, it can be seen that, for a value of 10% biomethane integration into the network, there are a fairly large number of municipalities that manage to generate enough bio-waste to meet the local need for biomethane production. However, it is important to note that of these, 31 municipalities do not account for any natural gas consumption and others account for very low natural gas consumption. The municipality with the highest natural gas consumption does not generate enough bio-waste to meet the need created by 10% biomethane in the gas network, proof of which is that the

municipalities with a ratio of less than 1 only account for around 25% of national gas consumption. Even so, it is interesting to note that the generation of solid urban biowaste in Portugal in 2023 would be enough to supply 82% of the need for biowaste to produce the biomethane needed to reach the target of 10% biomethane injected into the grid. Important to note that this analysis is only theoretical as it does not account for the total logistics associated. Also, this analysis only takes into account municipal solid biowaste and that many other types of waste could be used to produce biomethane.

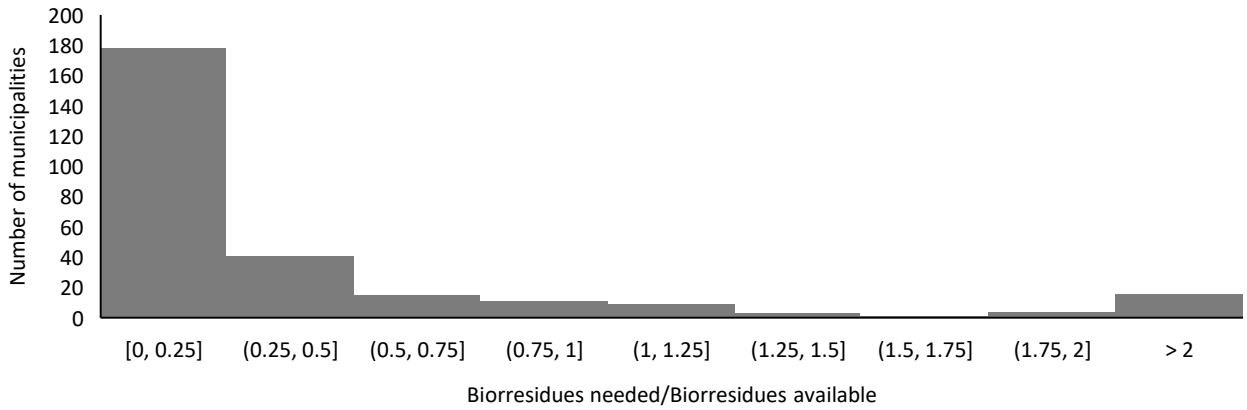

Fig. 2. Histogram of reason demand UBR vs availability UBR per municipality, for 10% biomethane integration in the gas grid.

If we consider an injection of 50% biomethane by volume into the network, the data shows that the municipal solid biowaste currently generated over the course of a year would represent a very small amount of biomethane production potential within the demand created for biomethane. Therefore, municipalities with a biomethane demand vs biomethane availability ratio greater than 1 would correspond to 99% of the country's natural gas consumption. And looking at the generation of solid urban biowaste at national level, this would be enough to ensure 14% of the national demand created to supply 50% of the gas network, by volume, with biomethane.

4. CONCLUSIONS

The development of this tool to support the management of operation of renewable gases injection in the Portuguese national gas grid allowed the aggregation of some relevant data and the elaboration of some interesting conclusions:

- Relevant locations to install renewable gases producers and inject renewable gases into the gas grid.
- Renewable gases demand to meet the expectations and requirements defined in the national plans.
- Requirements to meet the production of the desired renewable gases. For example, the water needs, the renewable energy needs and the residues needed to produce the required biomethane.

ABSTRACT
Electrochemical hydrogen production has recently become a focal point of research because of the increasing global energy demand, impending depletion of fossil resources, and the associated environmental impacts. Although precious metals such as platinum provide the highest catalytic efficiency for hydrogen evolution reactions (HER), their limited availability and high cost have driven the search for alternative catalysts that are both abundant and economically viable. Two-dimensional materials, particularly reduced graphene oxide (rGO) and $Ti_3C_2T_x$ MXenes, are promising candidates because to their unique intrinsic properties. rGO has been widely investigated for HER applications; however, achieving the desired catalytic efficiency using rGO alone remains a challenge. MXenes, a recently discovered family of materials, offer superior properties for HER and have emerged as promising alternatives. The combination of rGO and MXene is expected to create a synergistic effect that enhances HER performance. MXenes were synthesized from the MAX phase precursor (Ti_3AlC_2) through an in-situ hydrofluoric acid etching process, whereas rGO was synthesized using Hummers' method. Post-synthesis X-ray diffraction (XRD) and X-ray photoelectron spectroscopy (XPS) confirmed the successful formation of the desired structures. These results validated the successful synthesis and characterization of the hybrid materials, and electrochemical measurements confirmed their potential applicability in electrochemical hydrogen production.

Keywords: MXene, Hydrogen Evolution Reaction (HER), Catalyst, Graphene

1. INTRODUCTION

Hydrogen energy has emerged as a key focus in both global energy strategies and scientific research because of its potential as a clean, renewable energy source, which aligns with the global sustainability goals. The growing demand for energy, depletion of fossil fuel reserves, and urgent need to address environmental concerns have positioned hydrogen as not only an environmentally advantageous energy carrier but also a strategic element in ensuring energy security and fostering economic development. Among the various methods available for hydrogen production, electrocatalytic water splitting has gained significant attention, as it offers a promising route for generating ‘green hydrogen’ while minimizing harmful environmental impacts and ensuring both economic and technological sustainability. Although platinum-based catalysts have long been considered the most efficient for HERs, their high cost, limited availability, and scarcity of other precious metals have created significant obstacles for large-scale applications. This has accelerated the need to identify alternative catalysts that are both cost-effective and readily available [1,2,3,4].

Recent research has identified two-dimensional materials, particularly rGO and MXenes, as promising candidates for enhancing the HER performance. These materials offer a range of advantages, such as high surface area, good electrical conductivity, and potential for modification to further improve their catalytic properties. However, when used independently, each material has its own limitations that can hinder its overall efficiency. The development of hybrid materials has emerged as a particularly attractive strategy to overcome these challenges. By combining the complementary properties of rGO and MXenes, this approach enhances catalytic activity by improving charge transfer efficiency, increasing active site density, and ensuring greater structural stability, ultimately leading to superior HER performance [2,3,5,6].

In this study, a hybrid material was developed by combining $Ti_3C_2T_x$ MXenes with rGO. This hybrid structure is expected to significantly improve the HER efficiency by leveraging the complementary properties of both materials. The combination of MXenes and rGO creates a synergistic effect, which not only enhances the adsorption of hydrogen ions, but also accelerates the reaction kinetics. This synergy allows the hybrid material to overcome the individual limitations of MXenes and rGO, leading to an overall improvement in long-term stability and catalytic performance. As a result, the hybrid material holds considerable promise as a cost-effective and high-performance electrocatalyst for sustainable hydrogen production with strong potential for future commercial applications.

2. MATERIALS AND METHODS

2.1. Synthesis of MXene ($Ti_3C_2T_x$) via In-Situ HF Etching Method

To synthesize $Ti_3C_2T_x$, 2 mg of LiF was gradually added to 20 mL of 12 M HCl with constant stirring. The mixture was then vigorously stirred for 40 min. Next, 500 mg of Ti_3AlC_2 (MAX) was added to the solution and stirred continuously for

one week at 45 °C. After the reaction, the product was washed with deionized water to increase the pH above 6 and then allowed to dry under ambient conditions. The final product was $Ti_3C_2T_x$ powder form [3].

2.2. Synthesis of Graphene Oxide (GO)

To obtain graphene oxide (GO), 1 g of graphite powder was added to 25 mL of cooled H_2SO_4. Subsequently, 0.5g $NaNO_3$ and 3 g of $KMnO_4$ was added to the mixture and stirred for 30 min both in an ice bath and at the room temperature. Afterwards, 45 mL of deionized water was slowly added, and the mixture was stirred for an additional 30 min. To complete the process, 150 mL of deionized water and 8.5 mL of a 30% H_2O_2 solution were added. The mixture was then washed five times with 5% HCl solution to remove metal ions. The final product was washed with deionized water until the pH became neutral. The mixture was dried in an oven at 60 °C, and then in a vacuum oven at 60 °C for 24 h. The final product, GO, was obtained [7].

2.3. Synthesis of Reduced Graphene Oxide (rGO)

A reduction process was applied to the obtained graphene to produce reduced graphene oxide (rGO). Deionized water (900 mL) was added to 3 g of powdered GO and the mixture was stirred at 35 °C for 24 h. The mixture was then ultrasonicated for 2 h. Hydrazine hydrate (90 mL, H_6N_2O) was then added to the mixture and stirred at 95 °C for 24 h. The mixture was then placed in an oil bath which is connected to a reflux system. After cooling to room temperature, the mixture was washed with acetone, followed by washing with deionized water, and filtered. The resulting material was dried in an oven at 40 °C for 24 h to yield rGO in powder form [8].

2.4. rGO@MXene Hybrid Structure

To form the 2D/2D $Ti_3C_2T_x$@Graphene heterojunctions, 0.5 g of MXene ($Ti_3C_2T_x$) and 0.5 g of rGO were dissolved in 70 mL of ultrapure DI water. Ethylene glycol (10 mL) was added to this solution, and the mixture was stirred to form a homogeneous solution. The mixture was then placed in a Teflon-coated container and allowed to react at 150 °C for 14 h. The resulting suspension was washed with deionized water and dried in a vacuum oven at 80 °C [9,10].

2.5. Electrocatalytic Performance of Materials

Electrocatalytic performance analysis was performed using a Gamry Reference 3000 potentiostat/galvanostat/ZRA device. Three glassy carbon working electrodes were used in the experiments, with each electrode loaded with 3 µL of the catalyst ink. The catalyst ink was prepared by dispersing 5 mg of the solid catalyst in 250 µL water, 750 µL alcohol, and 50 µL nafion. Ag/AgCl electrode was used as the reference electrode, and a graphite electrode served as the counter electrode. A 0.1 M H_2SO_4 solution was used as the electrolyte. The structural and chemical properties of the catalysts were characterized using X-ray diffraction (XRD) and X-ray photoelectron spectroscopy (XPS).

3. RESULTS AND DISCUSSION

3.1. Characterization Results

The synthesized GO, rGO, and MXene samples were characterized using XRD (5º–90º, Cu Kα) and XPS techniques. The XRD patterns for GO and rGO are presented in Fig. 1, while those for $Ti_3C_2T_x$, synthesized via in-situ etching from Ti_3AlC_2, are shown in Fig. 2. These results align with those of previous studies, and further investigations are ongoing to explore the structural and surface characteristics of these materials [11-17].

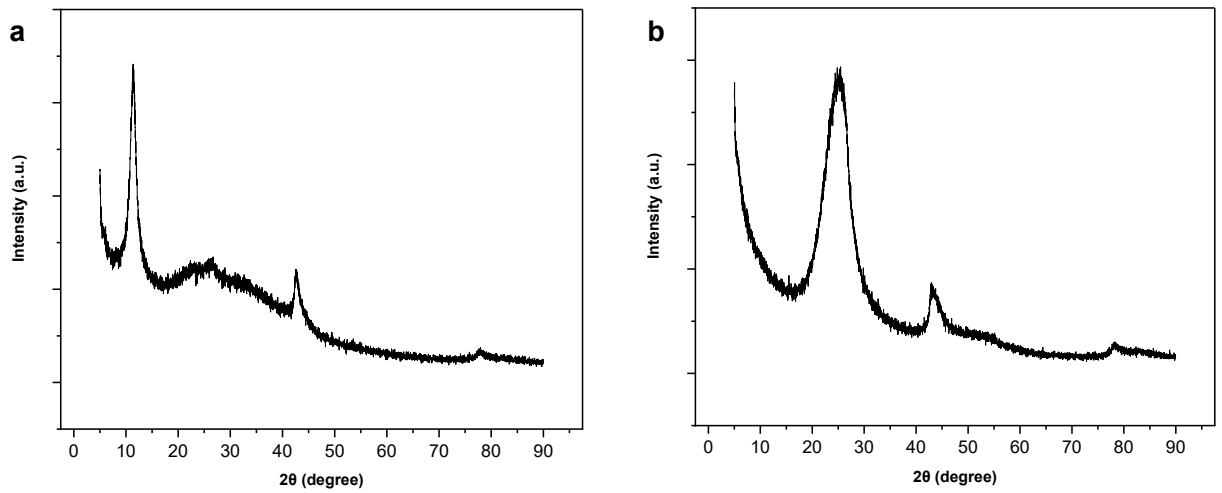

Fig. 1. XRD Analysis of (a) Graphene Oxide (GO) and (b) Reduced Graphene Oxide (rGO)

Figure 1a presents the XRD pattern of GO. The prominent peak at 2θ = 11.35° corresponds to the characteristic reflection of GO, which arises from the oxidation of the graphene. This oxidation resulted in an increase in the interlayer spacing, allowing for the incorporation of oxygenated functional groups and water molecules within the carbon structure. The smaller peaks observed at 2θ = 23.2° and 2θ = 26.4° suggest that the oxygen groups were not fully bonded, indicating some degree of incomplete oxidation in the GO structure [11]. The peak at 2θ = 42.56° reflects the short-range ordering in the stacked graphene layers, corresponding to the turbostratic arrangement [12,14].
Figure 1b presents the XRD pattern of rGO, revealing its structural characteristics. The pronounced peak at 2θ = 25.24° indicates rGO, which was synthesized by the removal of oxygen-containing functional groups from GO. This peak suggests that a significant portion of the conjugated π bonds was restored during the reduction [13,14]. Additionally, the peak at 2θ = 43.08° reflects short-range ordering in the graphene layers, a feature that is also observed in GO, further confirming the existence of disordered stacking [12,14].

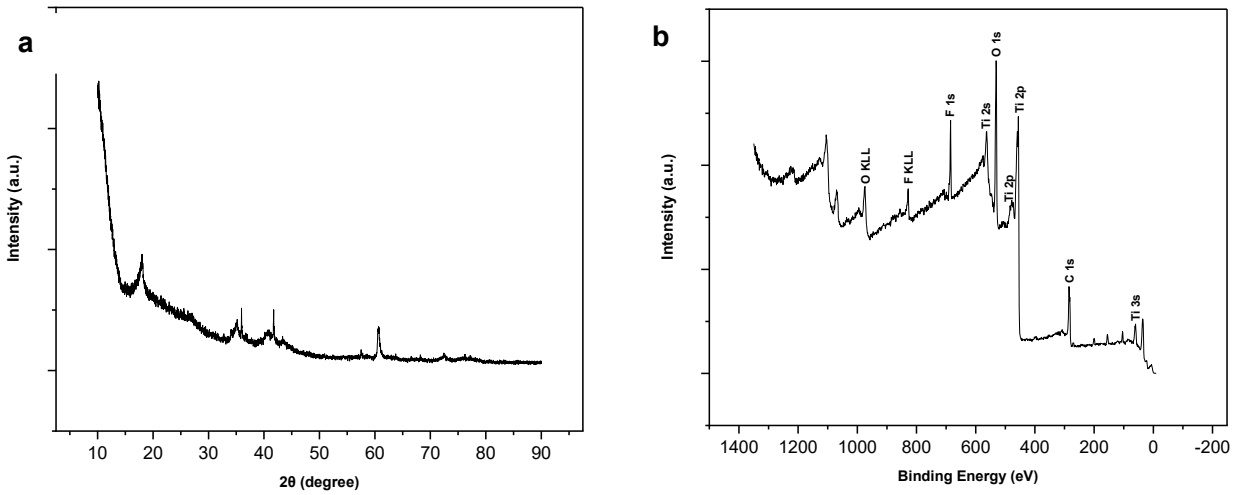

Fig. 2. Ti_3C_2 Characterization: (a) XRD Pattern and (b) XPS Spectrum

Figure 2-a a presents the XRD pattern of the synthesized MXene. The absence of the characteristic peaks corresponding to Ti_3AlC_2 MAX (2θ = 10°, 39°) and the observed shifts and intensity reductions in the remaining peaks (2θ = 19.1°, 34.0°, 41.8°, 48.4°, 56.4°, and 60.2°) provide strong evidence that the Ti_3C_2 structure of MXene was successfully obtained, indicating the complete removal of Al from the MAX phase. Figure 3b shows the XPS spectrum of the same sample. Upon examination, the absence of any peaks corresponding to Al or associated bonding states further supports the XRD findings, confirming the successful synthesis of the $Ti_3C_2T_x$ MXene structure, free from Al contamination [15,16,17].

3.2. Electrochemical performance of $Ti_3C_2T_x$ MXene@rGO *hybrids*

The polarization curves for $Ti_3C_2T_x$ MXene, rGO, and their $Ti_3C_2T_x$ MXene@rGO hybrid structures were evaluated for the HER reactions. MXene exhibited a lower overpotential compared to rGO, and the hybrid structure showed improved performance in both overpotential and Tafel slope. These results suggest that the combination of MXene and rGO can enhance the electrocatalytic performance for HER.

4. CONCLUSIONS

In this study, $Ti_3C_2T_x$ from the MXene family and rGO were successfully synthesized. GO was prepared using the Hummers method, followed by its reduction to rGO. Both materials were characterized using X-ray diffraction (XRD), and the results confirmed the successful synthesis of the intended structures. $Ti_3C_2T_x$ MXene was synthesized via the in-situ HF etching method. XPS and XRD characterization revealed the successful removal of the Al layer from the Ti_3AlC_2 MAX precursor, confirming the formation of the desired MXene structure. Finally, the $Ti_3C_2T_x$ MXene@rGO hybrid structure demonstrated promising Tafel slopes and low overpotential values for the HER. These results highlight the potential of the hybrid structure to enhance electrocatalytic efficiency.

ABSTRACT
An increasing number of airport operators around the world are realizing their responsibilities in protecting the environment and are changing their perspectives towards the natural environment. In this context, it is seen that environmental awareness is being established in operators with the efficient use of resources, reduction of waste and recycling, and reductions in costs. Among various biomass-to-hydrogen conversion technologies, dark fermentation has attracted great attention due to its high energy efficiency potential and ability to use a wide range of waste substrates. This study focuses on evaluating the efficiency of the dark fermentation process for hydrogen production using various wastes originating from airports. Various wastes from airports have been found to be rich in organic matter and are potentially suitable raw materials for hydrogen production through the dark fermentation process. As a result of the analysis, it was determined that approximately 1800-2000 ml of gas was formed in the studies and that 25% to 40% of the gas formed contained hydrogen. As a result, a feasible model for our country is presented that is compatible with the zero waste and circular economy approach in terms of energy and raw material recovery from alternative sources, environmental technologies and renewable energy.
Keywords: Airport-Derived Wastes, Dark Fermentation, Hydrogen Energy, Waste to Energy

1. INTRODUCTION

The European Green Deal aims to make Europe a climate-neutral continent by 2050; to achieve zero greenhouse gas emissions, to switch to a circular economy model; and to achieve the goals of clean, reliable energy use. The implementation of waste-to-energy processes supports the overarching goals of the circular economy by converting waste into useful energy carriers. Hydrogen is an important energy carrier that can be used in sustainable energy systems due to the high efficiency in the production, conversion and use of hydrogen energy systems. Hydrogen has emerged as a promising alternative because it can be produced from a wide range of renewable sources, including biomass [1,2]. It is predicted that hydrogen production will increase with a growth of approximately 10% by 2050 and the balances in the hydrogen market will change [3]. Hydrogen energy is the cleanest among alternative energy sources and has "zero emissions" since it produces water as the only combustion product [4,5,6]. Among hydrogen production technologies, biohydrogen production is the most sustainable method as it occurs at ambient temperature and therefore requires only a low energy input. Among various biomass-to-hydrogen conversion technologies, dark fermentation has attracted great attention due to its high energy efficiency potential and ability to use a wide range of waste substrates [2]. The production and use of bioenergy with a sustainable management helps support energy security and price stability, while also providing social and economic benefits that support the achievement of the United Nations Sustainable Development Goals, including the promotion of rural economic activities.
An increasing number of airport operators around the world are realizing their responsibilities in protecting the environment and are changing their perspectives towards the natural environment. In this context, it is seen that environmental awareness is being established in the operators with the efficient use of resources, reduction of waste and recycling, and reductions in costs. In terms of environmental awareness, recycling/recovery of waste and management according to sustainable waste management principles are important. This study focuses on evaluating the efficiency of the dark fermentation process for hydrogen production using various wastes originating from airports. With this study, an alternative that will make a positive contribution to both the clean and circular economy and sustainability goals aimed at the "zero emission for 2053" target in the 12th Development Plan prepared in line with our country's 2053 vision and the "Net Zero CO_2 Emission" commitment declared by Istanbul Airport by 2050 will be obtained.

2. MATERIALS AND METHODS

2.1. Design and Commissioning of the Experimental Setup

In order to evaluate the efficiency in hydrogen production by the dark fermentation method, the experimental setup where the studies will be carried out was designed. The designed experimental setup consists of a reactor, gas pipe, isolation

valve and Tedlar bag. The schematic of the experimental setup and laboratory scale experimental setup given in Figure 1. Due to the nature of the anaerobic process, mixing must be provided. As seen in Figure 1, 500 ml (and later 1000 ml) volume reactors are positioned on a variable speed shaker. The shaker is a FOURE's Scientific Brand (Figure 2). The minimum and maximum shaking speeds are 30 and 500 rpm, respectively. The shaker speed will be fixed at 140 rpm and the experiments will be started. The experiments will be carried out in a Miprolab Brand MSI Model 250 lt capacity incubator (Figure 3). The incubator temperature can be adjusted between -10 and +80 ^{o}C. In the first stage, a constant temperature of 35 ^{O}C will be applied. The gas formed in the 500 ml volume PE reactors will be transmitted to the 2 lt volume tedlar bags (higher volume tedlar bags (gas collection bags) are planned to be used later) via PE 5 mm diameter pipes. 2 valves will be installed between the reactor and the tedlar bag. In case the tedlar bags need to be separated from the reactor for gas measurement or if the tedlar bag needs to be renewed while production is continuing, gas leakage will be prevented in this way. Gas measurements will be made in the ABB brand Continuous Gas Measurement Device located in the Istanbul University Cerrahpaşa Environmental Engineering Department Laboratory (Figure 4). CO, CH4, H2, O2, CO2 gases will be measured in this device. The measurement values detected by the gas analyzer will be transferred to the computer via a data transfer cable and will be recorded with the “Alp Teknik- BACA” software loaded onto the computer. The photograph of the experimental setup is given in Figure 5.

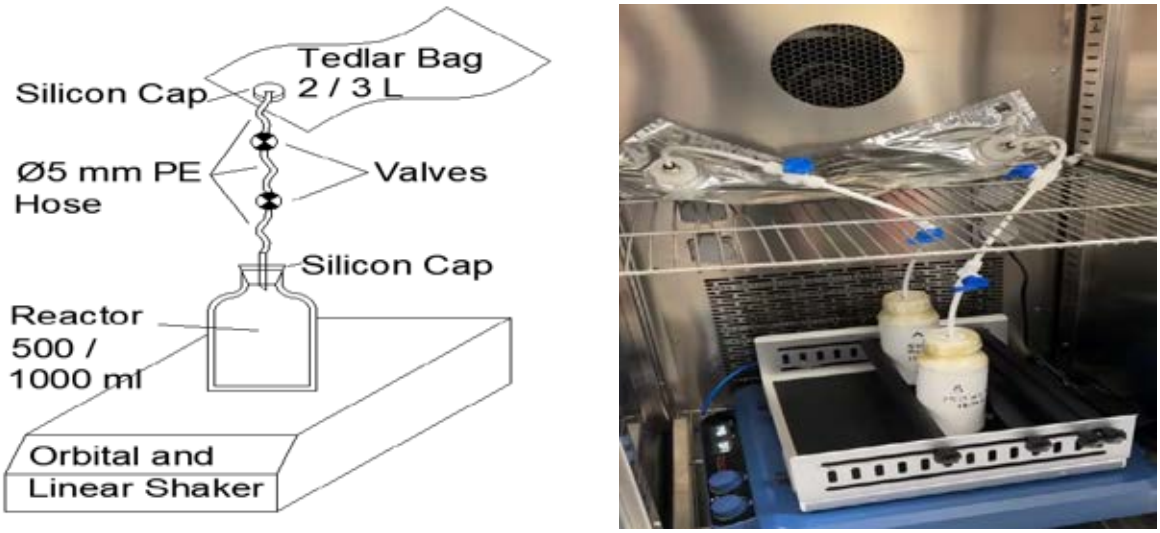

Figure 1. The schematic of the experimental setup and laboratory scale experimental setup

Figure 2. Orbital and linear shaker

Figure 3. Incubator

Figure 4. ABB AO2020 model gas analyzer

In the experimental set, the efficiency of hydrogen production through dark fermentation of various wastes generated as a result of airport activities will be determined.

2.2. Waste Characterization

Wastes originating from airports were separated into four different types: organic wastes originating from places such as cafeterias and restaurants, wastes resulting from de-icing and anti-icing applications, wastes originating directly from aircraft, and biological wastewater treatment plant return sludge. Visuals of the wastes used for analysis are provided in Figures 6, 7, 8, and 9.

Figure 6. Wastewater from Aircraft (WWA)

Figure 7. De/Anti Icing Wastewater (DAIW)

Figure 8. Food Waste (FW)

Figure 9. Recirculated Sludge (RCS)

It was determined that these various waste streams are rich in biodegradable organic matter and are potentially suitable raw materials for hydrogen production via dark fermentation process. Hach brand DR1900 model spectrometer device was used to evaluate the composition and properties of the waste streams generated from airports for hydrogen production via dark fermentation process. After waste characterization, hydrogen production studies were carried out by laboratory scale dark fermentation. In the studies carried out in batches, hydrogen production potentials of different wastes under different conditions were evaluated.

3. RESULTS AND DISCUSSION

The results of the analyses yielded the following average values for WWA: COD 11685 mg/lt, Ammonia 2604 mg/lt, TSS 1350 mg/lt, VSS 1200 mg/lt, Alkalinity 8281 mg/lt, pH 9.2, Conductivity 19994 μS/cm, Total Phosphorus 302 mg/lt. The results of the analyses yielded the following average values for the DAIW: COD 1039 mg/lt, Ammonia 1.1 mg/lt, TSS 42.8 mg/lt, VSS 36.8 mg/lt, Alkalinity 300 mg/lt, pH 7.2, Conductivity 520 μS/cm, Total Phosphorus 2.3 mg/lt. The results of the analyses yielded an average COD value of 463 mg/g for FW. As a result of these analyses, the average analytical results of RCS were calculated as COD 18960 mg/lt, Ammonia 123 mg/lt, TSS 12290 mg/lt, VSS 9123 mg/lt, Alkalinity 650 mg/lt, pH 6.9, Conductivity 1616 μS/cm, Total Phosphorus 336 mg/lt. In laboratory-scale dark fermentation hydrogen production studies, experiments were carried out with different conditions and wastes. As a result of the experiments, gas formation was observed and gas analysis was performed. As a result of the analysis, it was determined that approximately 1800-2000 ml of gas was formed in the studies and that 25% to 40% of the gas formed contained hydrogen.

4. CONCLUSIONS

The aim of study focuses on evaluating the efficiency of the dark fermentation process for hydrogen production using various wastes originating from airports. For this purpose, the potential of various wastes from the airport for hydrogen production by dark fermentation method was investigated. The results of the study are given below.

- Various wastes from airports have been found to be rich in organic matter and are potentially suitable raw materials for hydrogen production through the dark fermentation process.
- As a result of the analysis, it was determined that approximately 1800-2000 ml of gas was formed in the studies and that 25% to 40% of the gas formed contained hydrogen.
- As a result, a feasible model for our country is presented that is compatible with the zero waste and circular economy approach in terms of energy and raw material recovery from alternative sources, environmental technologies and renewable energy.
- It is possible to evaluate the outputs of this study for full-scale applications. It is essential to conduct studies on the pilot-scale system to facilitate full-scale applications.

Acknowledgments

This study was partially based on a Ph.D. thesis pursued by H.F. Altay.

ABSTRACT

Anion Exchange Membrane (AEM) water electrolysis represents a cost-effective and sustainable alternative for hydrogen production, due to its ability to operate with non-precious metal catalysts. Leveraging a rapid and scalable electrodeposition procedure, the research addresses the industrial need for efficient and economically viable fabrication techniques. The study focuses on the synthesis and optimization of Ni-based layered double hydroxides (LDHs) as electrocatalysts for AEM electrolysers. The tailored electrocatalysts exhibit excellent overpotential and reaction kinetics, optimizing the energy efficiency of the process. Surface modifications and doping strategies are investigated to enhance the catalytic activity and durability under operating conditions. Metallic foams outperform carbon paper as gas diffusion layers (GDLs), achieving high current densities due to superior conductivity and capillary effects. This work provides a pathway for industrial-scale production of high-performance electrodes, advancing the development of AEM technology.

Keywords: hydrogen, water electrolysis, anion exchange membrane, layered double hydroxides.

1. INTRODUCTION

In the last decade, AEM water electrolysis has emerged as promising technology for sustainable hydrogen production, combining the advantages of traditional systems such as alkaline and proton exchange membrane (PEM) electrolysers. By operating under alkaline conditions, AEM electrolysers enable the use of non-precious metals as electrocatalysts, significantly reducing material costs. Critical bottleneck in the process is the Oxygen evolution reaction (OER), as a multistep, four-electron transfer reaction that requires significant overpotential. Developing efficient and cost-effective catalysts for OER is thus a key challenge for improving the performance and viability of AEM water electrolysers.

1.1. Layered double hydroxides as promising OER electrocatalysts

Layered double hydroxides (LDHs) are lamellar compounds consisting of positively charged metal hydroxide layers intercalated with charge-balancing anions and water molecules [1]. Also known as hydrotalcite-like compounds, LDHs are characterized by high surface area and tunable composition. By incorporating various metal cations into the hydroxide layers, LDHs offer excellent opportunities for tailoring their electronic and catalytic properties. When electroactive metals are inserted in the structure, these compounds are redox active systems that can be used as electrocatalysts. Regarding OER performance, LDHs containing Ni, Co, and Fe showed low onset potential values and fast kinetics, therefore a huge appeal for electrocatalytic applications (Fig. 1) [2].

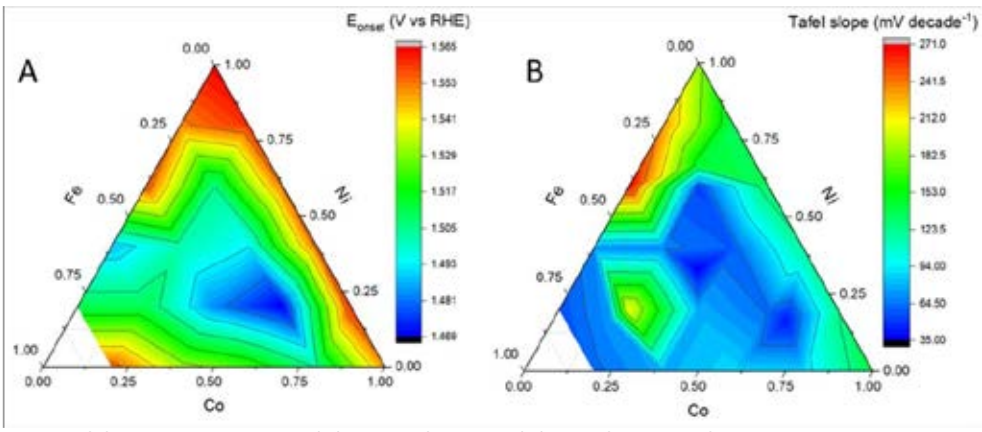

Fig. 1. Ternary diagram of OER onset potential (A) and Tafel slope (B) as a function of the electrosynthesis bath composition [2]. Data are obtained from LSV recorded in 1.0 M KOH.

2. MATERIALS AND METHODS

Electrodes fabrication occurred via potentiodynamic electrodeposition of LDHs on gas diffusion layers as carbon paper and Nickel foams [3]. Bare supports (geometric area: 6.25 cm²) were immersed in an electrolytic bath containing catalysts precursors in form of nitrates, and two cycles of cyclic voltammetry (CV) were performed at cathodic potentials between 0 and -1.3 V vs SCE. The induced electrochemical reduction of nitrates generates an increase of the local pH at the electrode surface, leading to catalyst precipitation as LDHs (Fig. 2). Nickel nitrate (>99%), cobalt nitrate (>98%), iron nitrate (>99%), and sodium hydroxide were purchased from Sigma–Aldrich (Germany). The deposition was carried out in a single compartment three-electrode cell (Amel, Italy), connected to a potentiostat Multi Autolab/M204 (Metrohm Italiana Srl, Italy).

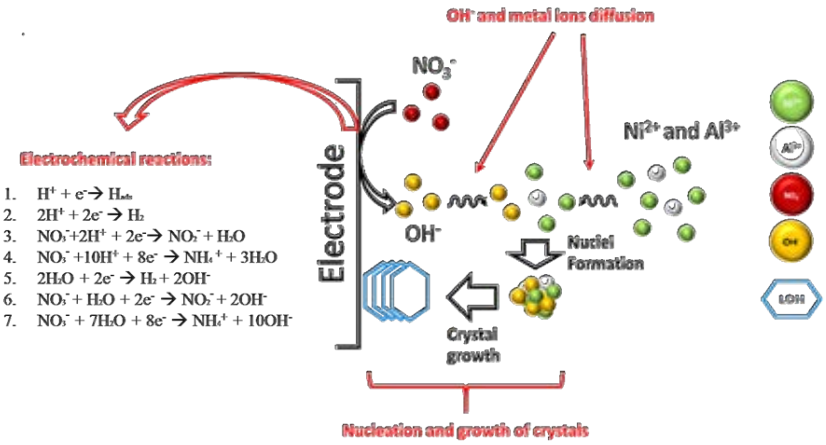

Fig. 2. Main steps involved in the potentiodynamic electrodeposition of LDH catalysts [3].

Characterization techniques such as X-ray diffraction (XRD), scanning electron microscopy (SEM), and electrochemical impedance spectroscopy (EIS) provided insights into the material properties and their correlation with electrochemical performance. The catalytic performance was evaluated in AEM flow cell operation (X-Cell, RedoxFlow), with key metrics including overpotential, current density, and long-term stability (Fig.3). Gas production was analysed with gas chromatography (Focus Series, Thermo Fisher Scientific) and high-performance liquid chromatography (1260 Infinity, Agilent Technologies) was used to quantify the liquid fraction. The presence of metals in the electrolyte solution was assessed via inductively coupled plasma mass spectroscopy (4210-MP-AES, Agilent Technologies).

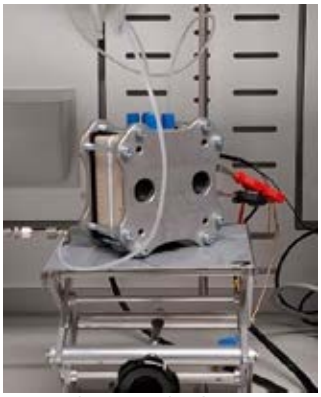

Fig. 3. AEM flow cell (X-Cell, RedoxFlow).

3. RESULTS AND DISCUSSION

3.1. Electrosynthesis of LDHs

The study provided an efficient and scalable solution for producing industrially viable electrodes for green hydrogen application. The physic-chemical characterization of the GDEs confirmed the accuracy of the synthetic method, providing stable and homogeneous catalyst deposition (Fig. 4). No catalyst leaching was observed after stress tests in both potentiostatic and potentiodynamic conditions. Catalyst composition was easily controlled by changing metals

concentration in the deposition solution, and a wide range of transition metals was successfully placed in the LDH structure to optimize the structural and electronic properties. A quantitative SEM-EDS analysis on carbon paper electrodes confirmed the metals ratio of the precursors' solution, indicating excellent tunability of the synthesis (Table 1).

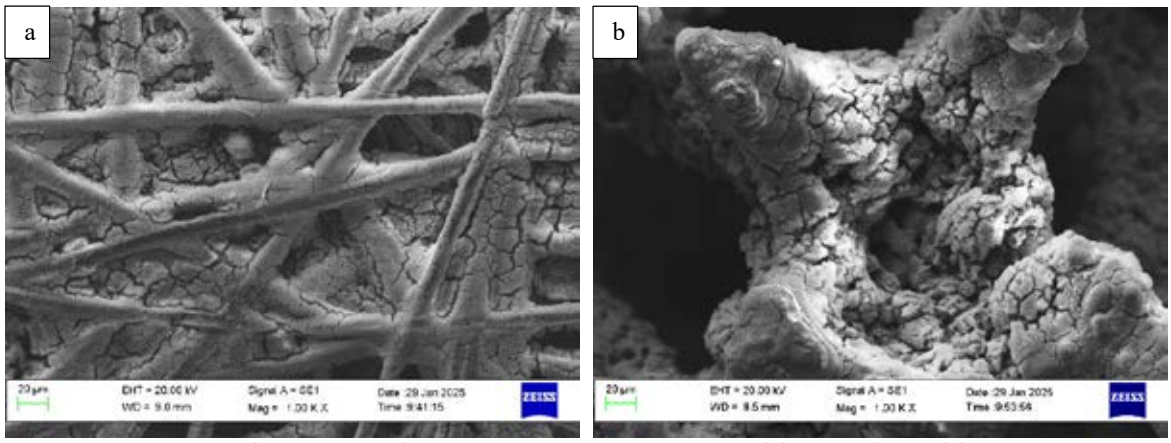

Fig. 4. SEM images of LDHs deposited on carbon paper (a) and Ni foams (b).

Table 1. Catalyst composition obtained via SEM-EDS analysis.

Catalyst	Ni atomic ratio (%Ni)
Ni75Fe25	75 ± 2
Ni75Al25	78 ± 3
Ni67Al33	68 ± 2

3.2. Optimization of electrodes performance

The tailored electrocatalysts achieved excellent performance in terms of overpotential and reaction kinetics, minimizing the energy consumption of the process. Ni foams GDEs achieved current densities up to ten times higher than carbon paper electrodes, due to higher conductivity and capillary effect of the support, which led to a higher electrochemically active surface area (ECSA). The catalyst Ni75Fe25 LDH exhibited high OER activity, with an onset potential of 0.335 V vs SCE and Tafel slope of 70 mV dec^{-1} (Fig. 5). Among the dopants, Co resulted in enhancing the electrocatalytic performance. The presence of Co in Ni/Fe LDH structure lowered the OER onset potential, due to synergistic effects between Co and Fe that increased the electrical conductivity of the material.

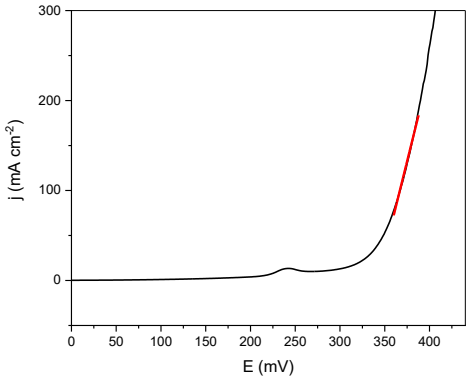

Fig. 5. Linear sweep voltammetry (LSV) of Ni75Fe25 LDH on Ni foam recorded in 1.0 M NaOH.

4. CONCLUSIONS

The research provided an industrially viable solution for producing GDEs for AEM water electrolysers. The synthetic protocol adopted allowed stable, homogeneous, and controlled deposition of Ni-based LDHs on both carbon paper electrodes and Ni foams. In particular, Co-doped Ni/Fe LDHs supported on Ni foams turned out to be the most performing OER catalysts, showing low cell overpotential, good reaction kinetics, and long-term stability.

ABSTRACT
Reversible Solid Oxide Fuel Cells (R-SOFCs) are a promising green energy technology, efficiently operates in fuel cell and electrolysis modes. Dual functionality reduces operational complexity and system integration costs while enhancing affordability. However, degradation issues may hinder the lifetime and durability of such systems. This makes an in-depth scientific evaluation of their complex performance crucial for future advancements. In literature, there is limited work that methodically investigates main degradation parameters: operating in Solid Oxide Electrolysis Cell mode SOEC/duration in Solid Oxide Fuell Cell mode SOFC; daily switches; power in SOEC/power in SOFC. This study evaluates the performance of two cells (each 10 cm²) of Ni-YSZ|YSZ|LSM, effective area of 9x9 cm² (81 cm²) operated periodically at 750 °C in reversing mode at 0.3 A/cm². The first cell operates for 15 h in SOFC (2 h measurements), while cell 2 operates 15 h in SOEC and 7 h in SOFC. We investigate optimal switching frequency and power levels that could help predict failure modes and improve operational strategies to minimize degradation. The cell behavior was analyzed using electrochemical impedance spectroscopy (EIS) and IV curve measurements under load to determine polarization resistance. Result shows how operating conditions significantly impact cell performance, power ratios, efficiency, stability, and performance.

Keywords: Reversible solid oxide fuel cells, degradation, durability, EIS, performance

1. INTRODUCTION

Fuel cell technology is a clean and effective way to produce energy, by electrochemical means using hydrogen and oxygen, byproducts producing only water and electricity. It reduces fossil fuel reliance, helps to combat climate change, [1] and advances towards reducing greenhouse gas emissions. Fuel cells operate using an electrochemical system within a conductive electrolyte that directly converts the chemical energy of fuels into electricity without intermediate conversions [2]. Fuel cells are essential for the global shift toward green energy and reducing carbon emissions as the world moves toward renewable energy. Solid Oxide Cells (SOC) are the most efficient electrochemical technology for power generation. SOCs can operate in dual mode - fuel cell mode and electrolysis mode, which enables high utilization of fuels and promising energy management. SOCs are the prominent electrochemical energy conversion and storage devices that are used at a high-temperature range (600 – 1000 °C). When a Solid Oxide cell is operated in Electrolysis Mode (SOEC), then electrical energy is converted into a chemical form of hydrogen (H_2) and syngas (CO + H_2) with high-temperature steam and CO_2 co-electrolysis. Produced H_2 and syngas could be reused and stored for further processing. Whereas the SOFC mode is used to regenerate electricity by the use of stored fuels. This technology is reversible and can work in a switching operational mode, known as reversible solid oxide cells (R-SOC). SOC typically requires two separate devices for both modes, however, RSOCs eliminate these distinct two units by a single cell combining within a facilitating SOFC and SOEC functions.
R-SOCs is an advanced technology that can operate in dual modes, making promising applications in a versatile energy storage solution [4]. Reversible operations give stability to cells and decrease electrode degradation alternating between SOFC and SOEC modes [5]. This helps to reduce the time spent under high-stress conditions, redistribute thermal and electrochemical stresses across both electrodes, preventing localized degradation and enhancing material longevity.
This versatility enhances renewable energy integration and storage, stabilizing cells and reducing electrode degradation. However, degradation due to sintering and poisoning still remains a significant challenge, impacting performance, lifespan, and cost of a cell. [6].
Reversible solid oxide fuel cells (RSOFCs) are classified based on electrolyte material, cell geometry, mechanical support, operating temperature, and fuel flexibility [7]. Electrolyte materials include phosphoric acid, yttria-stabilized zirconia, and gadolinium-doped ceria. The cell designs include planar and tubular, while support types encompass electrolyte, cathode, anode, and substrate-supported cells. RSOFCs operate at low (400-600°C), intermediate (600-800°C), and high temperatures (800-1000°C) and can utilize various fuels. Current-Voltage (I–V) curves are obtained using a potentiostat/galvanostatic system. Electrochemical impedance spectroscopy is used to determine irreversible degradation, measuring the internal resistance, and allowing the estimation of potential degradation through polarization resistance analysis across operating cycles. EIS distinguishes ohmic, activation, and concentration losses that assess cell's performance[8]. At the end of each operational cycle, EIS is performed across SOFC and SOEC. The I-V curve

shows cell's voltage output at specific current densities, collected using a potentiostat. Accurate measurements are required for steady-state conditions [9], with one curve recorded each day for fuel cell and electrolysis operations in each test. From the analyzed literature that gap is left, and we try to fill it.

2. Experimental Procedures

2.1 Materials and methods

This was performed using a test bench developed by the Korean Institute of Science and Technology (KIST). The setup includes flow meters, a gas-tight furnace, and humidification for anodic gases. CHINO Corporation supplied the SOC cell housing, featuring ceramic compartments, type K thermocouples, and current collectors made of nickel and silver, respectively, along with sensors and high-temperature seals. The experiment on two SolydEra's Ni-YSZ|YSZ|LSM anode-supported cells, with dimensions of (10x10 cm² sides, 81 cm² active area), operated at 750 °C are performed.
The electronic load utilizes a reversible power supply, ITECH IT-M3902C-32-80. The Zahner ZENIUM X potentiostat conducts EIS by linking its terminals to the fuel and air electrodes of the test cell. EIS occurs twice daily for two experimental campaigns, with measurements taken after SOFC (15 hours) and SOEC (7 hours) operations at specified intervals, ensuring a thorough analysis of each operational cycle. The ceramic housing can tolerate current increases of 0.3 A/min. The anode uses a 50% H2 and 50% steam mix, while air flows at 2000 ml/min for 80% utilization.

2.2 Chemical characterization

For the first and second experimental campaigns, cell degradation and performance were characterized through in-situ electrochemical testing using I-V polarization curves during operation. During data acquisition for the polarization curves, the current increased allowing at a rate of 0.27 A/min from zero to -0.3 A/cm². Then, the current dropped to zero. The ramp-up phase of the current was considered for the analysis of polarization curves in both fuel cell and electrolysis modes. Data acquisition occurred at 1 Hz, generating 5401 points for the fuel cell polarization curve. In electrolysis mode, the current ramped down from zero to -0.3 A/cm².
Two experimental campaigns, the first cell lasting in 10 days, produced 10 (I-V) polarization curves for SOFC and SOEC modes while second cell data operated for 7 days. EIS was conducted in galvanostatic mode, maintaining a constant current while measuring voltage across frequencies from 10 mHz to 100 kHz. After configuring parameters for the Nyquist diagram, a stepped current input was applied, distinguishing between measurements after fuel cell and electrolysis operations. The amplitude was set to 1, and the measured periods were set to 1. After setting parameters, input a stepped current. Distinguish between EIS after fuel cell and electrolysis mode cycles.

- In the first case, the system is supplied with a positive stepped current input, where each step is 0.1 A, starting at 0 and increasing to a maximum of 1 A.
- In the second case, the system is supplied with a negative stepped current input, starting at 0 and decreasing to -1 A, with each step equal to -0.1 A.

Table 1 summarizes the parameters used in the two experimental campaigns:

Table 1. Description of the experimental campaign

Test No.	Current density SOFC [A/cm2]	Current density SOEC [A/cm2]	SOFC time [h]	SOEC time [h]	Intraday cycles	Duration per cycle [h]	Cycles	Campaign duration [h]	Campaign duration [days]
1	0.3	0.3	15	7	1	24	10	240	10
2	0.3	0.3	7	15	1	24	10	240	10

3. RESULTS AND DISCUSSION

First test cell operates approximately twice as long in SOFC, whereas in the second campaign, the opposite is true. I-V polarization curves and EIS, graphing voltage over time to reveal detailed trends for both cells. Fig. 1 I-V curves for both fuel cell mode and electrolysis mode operation. Polarization curves reveal cell degradation through contrasting voltage trends over time indicating that the cell is undergoing degradation. To quantitatively assess degradation, calculate the percentage difference in maximum voltage during electrolysis at the first cycle, midpoint (fifth cycle), and final work cycles, also applying this to minimum voltage in fuel cell operation.

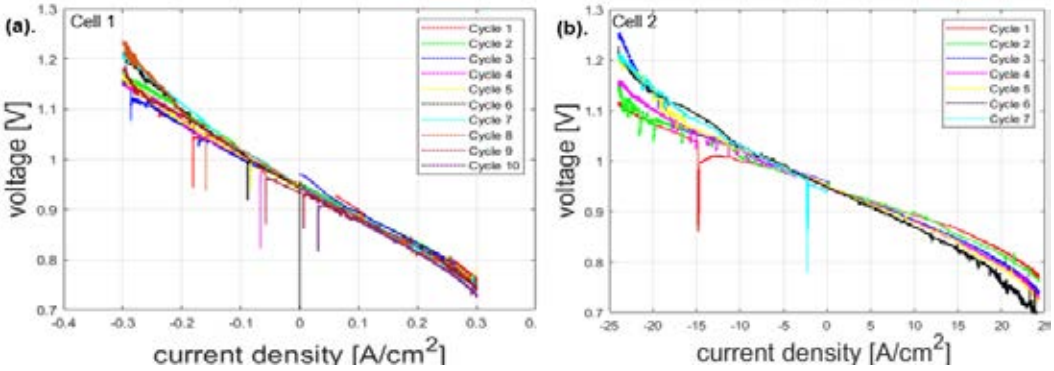

Fig. 1. I-V polarization curves (a) Cell 1 (b) Cell 2

Table 2 shows the percentage difference in voltage for both operating modes across the different work cycles.

Table 2. Percentage variation in cell voltage as the cycles increase (Cell 1 & Cell 2)

	Cell 1		**Cell 2**	
	%cycle1-cycle5	**%cycle1-cycle9**	**%cycle1-cycle4**	**%cycle1-cycle7**
V_{min}FC	-1,2%	-4,9%	-5,4%	-10,7%
V_{max}EL	0,8%	7,7%	4,1%	9,8%

The table indicates significant voltage variation for SOFC and SOEC with increased operating hours, with cell 1 & Cell 2 showing greater variation compared to cell 1 during the second campaign. Fig. 2 displays the trend of the imaginary part of the impedance as a function of the real part for the work cycles for Cell 1 & Cell 2 underwent during the campaign.

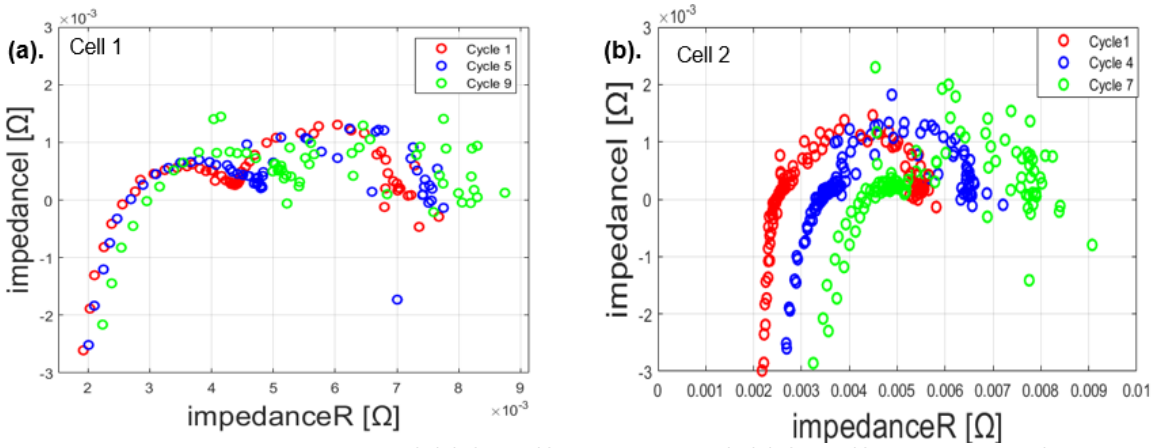

Fig. 2. Impedance spectra EIS (a) Cell 1 (Cycles 1, 5, and 9), (b) Cell 2 (Cycles 1, 4, and 7)

To improve data interpretation, the impedance spectrum is analyzed for Cell 1 (Cycles 1, 5, and 9), and Cell 2 (Cycles 1, 4, and 7), facilitating comprehension and studying impedance trends throughout the campaign. Removing data points enhances graph interpretation; impedance spectra shift with more cycles, indicating increased internal resistance and semicircle diameter growth.

Comparing the EIS graphs of cells 1 and 2 reveals that cell 2 exhibits a more uniform trend. As operating cycles and working hours increase, cell 2's internal resistance steadily rises, evident in its clear graph. In contrast, cell 1 shows fluctuations in resistance, especially in early cycles, leading to a less coherent EIS graph, where increased cycles do not consistently correlate with resistance increase. Both cells undergo electrochemical impedance spectroscopy for performance evaluation.

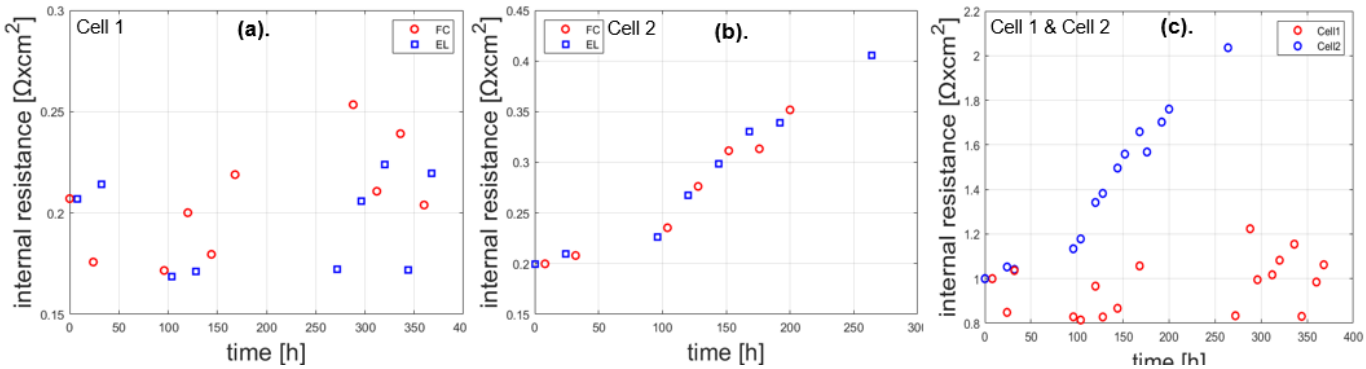

Fig. 4. (a) Internal resistance of Cell1 (b) Internal resistance of Cell 2 (c). Internal resistance of Cell1& Cell 2

In Fig. 4 (a), the value of internal resistance is calculated using the Nyquist plot. In the impedance curve at low frequency region, the real part of the impedance is defined by internal resistance of the cell. Cell 1 shows a rise during electrolysis while recovery in fuel cell mode, and potential degradation with increased operational hours over time. (b) In Cell 2 the resistance graph indicates degradation with increased resistance during electrolysis, while the SOFC exhibits variable lower resistance, that's confirming greater degradation in SOEC compared to SOFC mode. (c) This graph summarizes the earlier observations regarding the resistance fluctuations for Cell 1 throughout the campaign, with final values slightly above initial measurements. In contrast, Cell 2 shows consistent growth, culminating in significantly higher resistance. The distinct outcomes stem from different operating times, underscoring the literature's emphasis on usage duration as crucial for SOC performance. As mentioned for Cell 1, the goal is to quantify the increase in internal resistance during the second experimental campaign. To achieve this, the table presents the percentage differences between the initial resistance value and two resistance values at the end of two intermediate cycles (cycle 4 and cycle 6) and finally, between the initial value and the value of one of the final cycles (cycle 8).

Table 3. Percentage variation of internal resistance values for Cell 1 & Cell 2

Cell 1	**IR Min value[Ω/cm^2]**	**IR max value[Ω/cm^2]**	**IR Final value[Ω/cm^2]**
IR First Value [Ω/cm^2]	-18.4 %	23.3 %	5.9 %
Cell 2	**IR Cycle 4[Ω/cm^2]**	**IR Cycle 6[Ω/cm^2]**	**IR Cycle [Ω/cm^2]**
IR Cycle 1 Value [Ω/cm^2]	34.1 %	22.3 %	103.6 %

This table clearly summarizes what was mentioned earlier; it is evident how, for cell 1, the resistance values fluctuate throughout the entire campaign, with both increases and decreases in values compared to the corresponding value measured in the previous cycle. Moreover, the final cycle value is only slightly higher than the initial cycle value. For cell 2, the trend between cycles shows continuous growth, reaching the final cycle with a resistance value significantly higher than the value at cycle 1.

4. CONCLUSIONS

R-SOC is a very useful technology in the future, but it still needs technological advancement in terms of stability, modularity, and durability. These findings allowed for evaluating voltage values during SOFC and SOEC operations to ascertain which cell exhibited greater degradation. These plots reveal cell degradation over time, showing recovery or at least experiencing a lower amount of degradation after fuel cell mode compared to electrolysis. It can therefore be observed that prolonged use of the SOC in electrolysis mode, as in the second campaign, leads to significantly greater degradation of the cell compared to prolonged use in SOFC, as with cell 1. In particular, it must be stated that more extensive use of SOEC not only leads to greater degradation but can even result in irreversible cell degradation. It needs systematic study towards analysing various degradation parameters improving the reliability and lifetime of RSOCs.

ABSTRACT

The efficient storage and utilization of hydrogen energy are crucial for the advancement of clean energy technologies. Sodium borohydride ($NaBH_4$), a promising hydrogen carrier, has gained attention for its potential in hydrogen generation through hydrolysis. This study provides a comprehensive overview of the research landscape concerning g-C_3N_4-based catalysts for hydrogen production, focusing on trends and developments from 2009 to December 2024. Through the systematic evaluation of publication volumes, thematic shifts, and the evolution of key keywords, the study offers valuable insights into the field's emerging priorities. Additionally, the analysis identifies leading countries and institutions driving global research efforts, highlighting significant contributions to g-C_3N_4 catalyst development. The study also uncovers a notable research gap related to the application of $NaBH_4$ in hydrogen production, with only 47 publications published on this topic up to December 2024. This finding emphasises the necessity for additional exploration and research in this field to bridge the existing gap and optimise hydrogen production technologies.

Keywords: g-C3N4 Catalyst, NaBH4 Hydrolysis, Hydrogen, Bibliometric Analysis

1. INTRODUCTION

In today's world, the energy crisis has become a significant global problem caused by various factors such as rapid population growth, rising living standards, depletion of limited energy and water resources, and the emission of greenhouse gases [1]. This crisis has led to an increasing interest in clean, affordable, and sustainable alternative energy sources. The limited reserves of fossil fuels and their adverse environmental impacts indicate the necessity for the development and widespread adoption of sustainable alternative energy sources. In this context, the urgent global imperative is for the development and deployment of new energy sources that are abundant, environmentally compatible, and efficient. Hydrogen energy is recognized as one of the most promising alternatives due to its high calorific value, non-polluting combustion products, and renewability [2]. In recent years, various high-capacity hydrogen storage materials, such as sodium borohydride ($NaBH_4$), lithium borohydride ($LiBH_4$), and ammonium borane (NH_3BH_3), have attracted the attention of researchers. Among these, $NaBH_4$ stands out for its safe structure and high hydrogen storage capacity. It can store hydrogen at a weight percentage of 10.8% and efficiently releases large amounts of pure hydrogen through hydrolysis in an alkaline solution [3]. To enhance the hydrolysis process, researchers have focused on developing efficient and durable catalysts using both noble metals (e.g., Ru, Pt, Pd,) and non-noble metals (e.g., Co, Ni). Although noble metals have superior performance, their high cost and limited availability limit their widespread industrial use. In contrast, non-noble metal catalysts attract attention due to their low cost and abundance. The limitations of noble metals have encouraged the search for alternative options, leading to the widespread use of non-noble metals in catalysts [4]. While single-component non-noble metals often lack sufficient performance and durability, doping them with other elements to form binary, ternary, or multicomponent alloys (e.g., Co-B, Ni-B, Co-Ni-B) significantly enhances their effectiveness and stability. However, these catalysts face challenges, such as deactivation due to polyborate formation during the hydrolysis reaction [5]. Addressing this issue requires the use of suitable catalyst supports that facilitate polyborate desorption, prevent metal agglomeration, and increase surface area. To optimize metal catalysts further, reducing metals to nanoparticle sizes maximizes the surface-to-volume ratio. However, the high surface energy associated with nanoparticles often leads to aggregation, which reduces catalytic activity. Support materials, such as oxides, carbon-based materials, mesoporous materials, zeolites, and nickel foam, help prevent aggregation, enhance surface area, and improve catalytic activity by optimizing the distribution of active sites and reaction kinetics. Recently, among the support materials, multilayer graphite carbon nitride (g-C_3N_4) has become an important research topic in applications such as catalysts and energy storage due to its unique electronic structure, superior chemical properties and high thermal stability [6]. g-C3N4 acts as an electron transporter for metal ions due to the free electron pairs on the nitrogen atoms in its structure. It has become a popular catalyst in recent years because it is inexpensive to produce and can be easily synthesized in a single step using affordable materials like cyanamide, urea, thiourea, and melamine [7]. The present study systematically conducts a bibliometric analysis with a view to highlighting the significance of g-C_3N_4 as a support material in enhancing the activity of catalysts for hydrogen production via $NaBH_4$ hydrolysis. Furthermore, the study provides a comprehensive overview of the current state of research in the hydrogen production, offering valuable insights derived from statistical data and analyses. In addition to providing a thorough review of existing trends in research, it also identifies potential future directions for research and development.

2. MATERIALS AND METHODS

Bibliometrics, first defined by Pritchard in 1969 as “the application of mathematical and statistical approaches to books and other forms of communication,” has since become a cornerstone of research evaluation [8]. Bibliometric analysis is a highly effective tool that can be used to identify critical insights from a highly extensive body of literature. It enables researchers to explore the evolution, emerging trends, research boundaries, and current topics of interest within a chosen field. Moreover, it allows the examination of many relationships such as articles, citations, productivity of authors and emerging trends in keywords. These assessments often allow the identification of research gaps in the field through the visualization of network structure analysis [9]. This method has been widely applied across various disciplines, demonstrating its effectiveness in systematically mapping scientific knowledge and providing a data-driven foundation for strategic research planning [10–13].

2.2. Data Collection and Analysis

This study aims to systematically analyze the articles on renewable energy and hydrogen production in the Scopus database until December 2024. Scopus is the most comprehensive abstract and citation database in the peer-reviewed literature for information retrieval processes and approximately 3 million new articles are published each year [14]. The methodology employed in this study plays a crucial role in systematically identifying and analyzing relevant literature on hydrogen production using g-C_3N_4-based catalysts. The use of the TITLE-ABS-KEY search strategy, with carefully selected keywords such as "hydrogen evolution," "hydrogen generation," and "hydrogen production," AND “g-c3n4”, “g c3n4” and “graphitic carbon nitride”, ensures that only the most relevant and high-impact studies are included. After the title-based search, the document type was limited as “article” and the search results were filtered on the condition that the language of the article was English. The data extracted from the Scopus database in CSV format were meticulously analyzed using the Biblioshiny package in R software [15], a recognized tool in bibliometric research. This approach, covering documents from 2009 to December 2024, enables a systematic exploration of citation patterns, trends, and key scholarly contributions within the field.

3. RESULTS AND DISCUSSION

According to data from the Scopus database for the period 2009- December 2024, the productivity and collaboration dynamics of academic publications were analyzed. In this period, with a remarkable average annual growth rate of 45.63%, a total of 3,696 articles were sourced from 332 different publications. On average, each article received 62.09 citations, reflecting the significant impact of this body of work. Moreover, a total of 150,376 references were cited across these articles, demonstrating the extensive literature coverage within the field. In terms of author collaborations, 6081 authors contributed during this period and only 9 authors produced single-authored articles. An average of 6.5 co-authors collaborated per document and the international co-authorship rate in this period was 23.38%. The analysis of the distribution of publications shown in Fig. 1a shows that China leads in scientific output with a significantly higher number of published articles compared to other countries. This data demonstrates the significant impact of Chinese research on the global scientific environment. Especially Asian countries have an important place in this ranking. Countries such as China, India and South Korea stand out in terms of the number of scientific research and publications, while European countries and the USA are ranked further behind. Fig. 1b clearly shows that Asian institutions, especially universities in China, have made the largest contribution in this field. Jiangsu University stands out as the largest contributor with 833 publications. It is followed by Xi'an Jiaotong University, University of Science and Technology of China and Zhengzhou University.

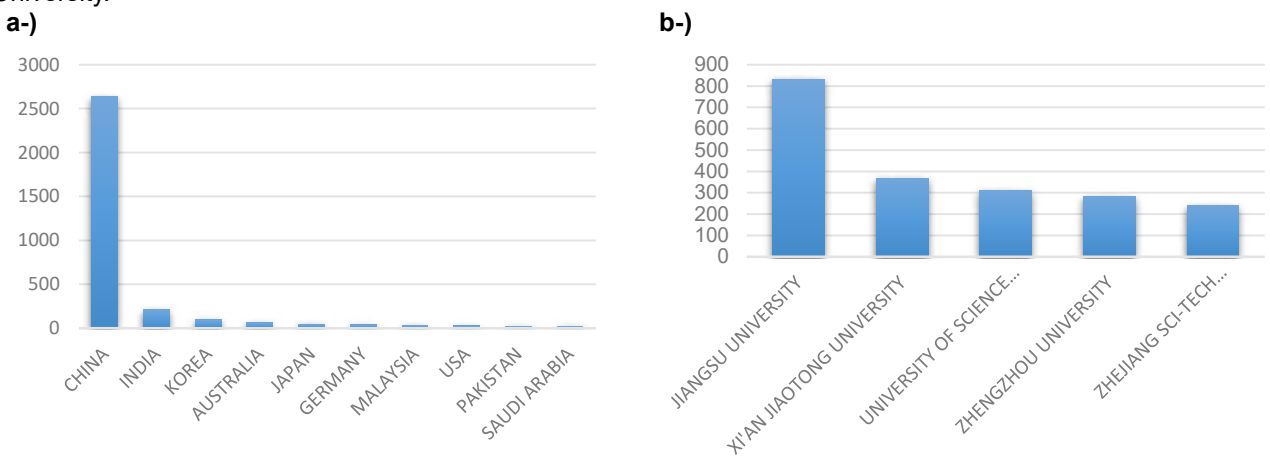

Fig. 1. (a) Distribution of Publications by Country. (b) Academic Publication Performance by University

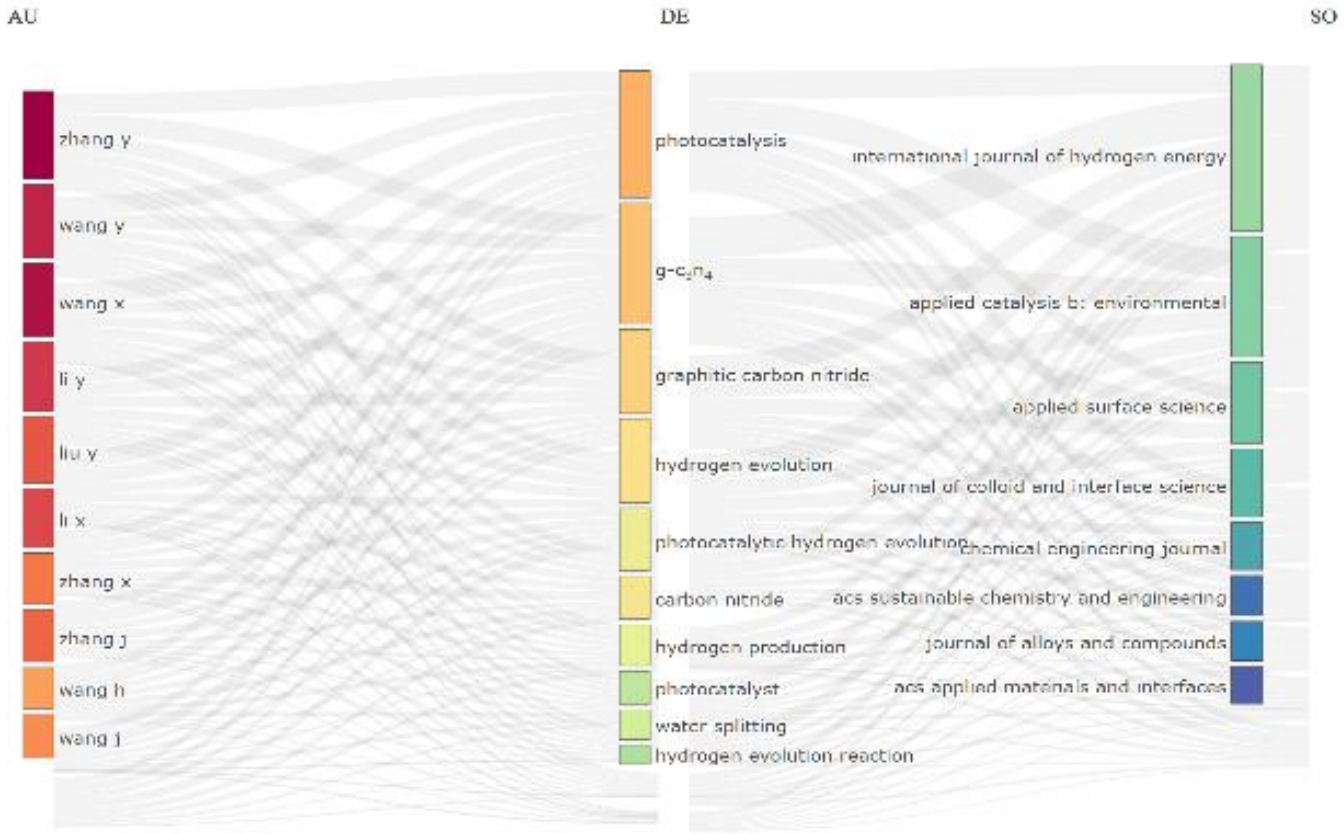
Fig. 2a visualizes the interactions between authors, keywords and sources in scientific research areas. The diagram provides a data-guided overview of the relationships between authors, keywords and journals. This visual representation allows us to analyze research trends, identify developing areas and understand the larger context of scientific publications. Zhang Y, Wang Y, Wang X, Li Y, Liu Y, are the most frequently cited authors in the diagram. These authors have generally worked on key topics in the field of renewable energy, photocatalysis, hydrogen production and water separation. These keywords reveal that sustainable energy technologies are at the center of the studies and important scientific contributions have been made, especially for hydrogen production. The majority of the articles published by these authors appear in prestigious scientific journals. The main journals featured in the diagram include International Journal of Hydrogen Energy, Applied Catalysis B: Environmental, Journal of Colloid and Interface Science, Chemical Engineering Journal and ACS Applied Materials and Interfaces. These journals present important work on interdisciplinary and application-oriented topics such as hydrogen energy and photocatalysis. The variation of keywords preferred by authors reveals the main scientific focus in this research area and offers a view of the potential for future research. The network analysis, as shown in Fig. 2b, presented visually represents key words and the relationships between them in scientific research areas such as hydrogen production and photocatalytic activity. The different colored groups in the diagram show the connections around specific research topics. The red group concentrates on critical research areas like hydrogen production and photocatalytic activity, particularly in the areas of light absorption and photocatalytic hydrogen evolution. These topics are central to the development of hydrogen production. The green group is investigating the use of carbon nitrides in light-based reactions and highlighting their potential for photocatalytic processes. This research highlights the importance of carbon-based materials in hydrogen production. Lastly, the blue group covers more specific topics such as photocatalysis and electron microscopy, which are crucial in the development of hydrogen production. Overall, these groups represent key areas of research in the field of hydrogen production solutions.



(a)

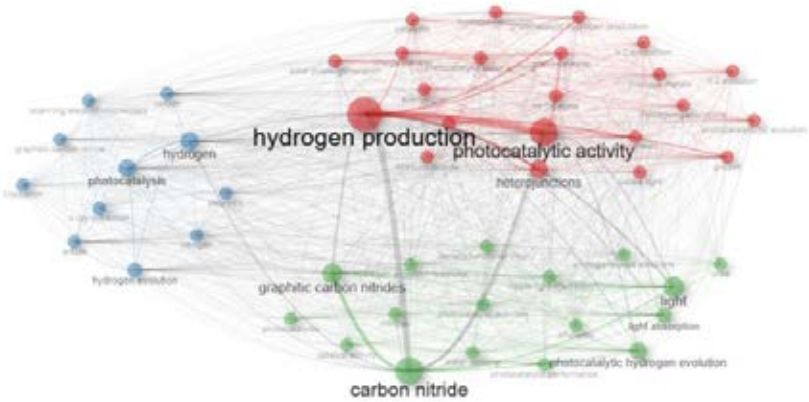


Fig. 2. (a) Sankey diagram and (b) Network Analysis

The thematic analysis presented in the graph is divided into four main categories based on the degree of development (intensity) and centrality (importance) of keywords in scientific research areas such as hydrogen production and photocatalysis. In this graph, the area in the upper right part of the graph means that it is both at the center of the relevant issue and will play an active role in future studies. In the lower right corner, it is again at the center of the related issue, but the expressions here have completed their development and no further innovations can be made in these areas. In the upper left corner are meanings that are not at the center of the related topic but are likely to be developed in future studies. The expressions in the lower left corner indicate either that they have completed their development in that field and will not be at the center of the subject in future studies, or that the relevant subject is developing but has not yet been included in the studies in large numbers. Thematic diagrams are used to help identify areas that have been studied in the past and are potentially to be studied in the future.

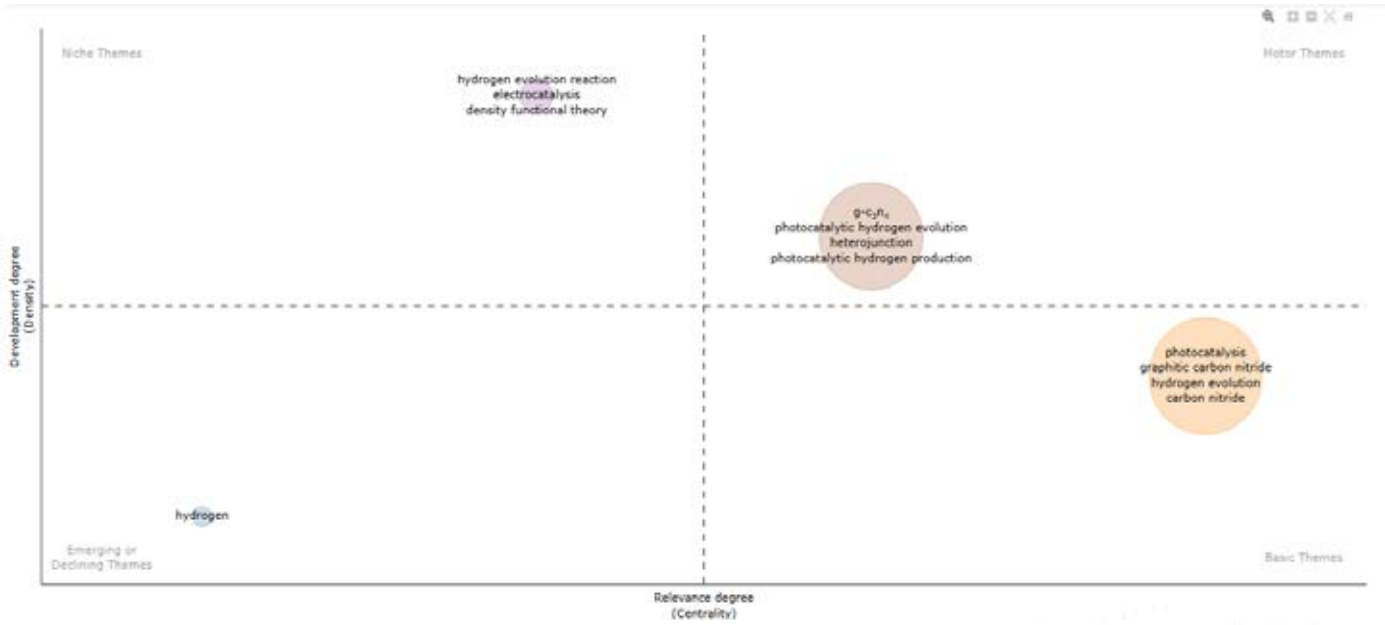

Fig. 3. Thematic Analysis

4. CONCLUSIONS

This bibliometric analysis provides a comprehensive overview of the current research landscape use of g-C_3N_4 based catalysts in hydrogen production, highlighting key trends and developments from 2009 to December 2024. By systematically analyzing publication volumes, thematic shifts, and the evolution of top keywords, this study offers valuable insights into the emerging focal points within the field. Furthermore, it identifies leading countries and prominent institutions that are shaping the direction of research, underscoring the global efforts in advancing g-C_3N_4 based catalysts developments. The study reveals a notable gap in research concerning the application of $NaBH_4$ in hydrogen production, with only 47 publications to date, emphasizing the need for further investigation in this critical area. This insight underscores the importance of expanding research efforts to bridge this gap, ultimately contributing to the continued

progress and optimization of hydrogen production technologies.

AN OPTIMIZATION MODEL FOR HEAVY-DUTY FLEET TRANSITION USING HYDROGEN FUEL-CELL VEHICLES

[1]*Fidan Eser*, [1*]*Sule Itir Satoglu*
[1] Istanbul Technical University Management Faculty, Industrial Engineering Department, ITU Isletme Fakultesi Macka, 34369 Istanbul, TURKIYE

ABSTRACT
Alternative fuels are proposed as a solution to reduce carbon emissions in the transportation sector. Hydrogen is an attractive alternative for heavy-duty transportation due to its quick refueling time and longer range compared to electric vehicles when used in fuel cells. However, no single method has been proposed for hydrogen production, storage, and transportation decisions simultaneously. Therefore, in this study, an optimization model is proposed to decide the number, sizes, and technologies of the hydrogen production facilities as well as the number and sizes of the storage facilities, over a planning horizon. Hence, the hydrogen demand of the grids is intended to be satisfied. The objective of the model is to minimize total investment costs of the facilities. As the hydrogen production and storage facilities are built, the fuel-cell vehicles of heavy-duty transport can be started to be used. Hence, decarbonization of the logistics activities can be achieved. The model was illustrated with a synthetic example.

Keywords: Fleet transition, heavy-duty fleet, fuel-cell, hydrogen supply chain

1. INTRODUCTION

The increasing global population has raised the demand for energy, and the dominant role of fossil fuels in energy supply has led to serious environmental problems. Industrialization, population growth, and human activities have significantly increased greenhouse gases in the atmosphere. Among the greenhouse gases responsible for climate change, CO_2 holds the largest share at 80%. The primary source of CO_2 emissions is fossil fuels. On a global scale, the energy sector is the largest emitter of greenhouse gases, highlighting the crucial role of energy policies in reducing emissions. The two sectors with the largest shares in energy-related emissions are industry (24.2%) and transportation (16.2%), with road transportation being the dominant mode within the transportation sector.

Electric vehicles have emerged as a prominent alternative to reduce greenhouse gas emissions. However, over time, it has become clear that relying solely on electric vehicles is not sufficient and introduces new challenges. The fact that the materials used in electric vehicle batteries are not readily available in every country, along with the logistical and economic challenges of their supply, has become an obstacle to the widespread adoption of this technology. Additionally, the environmental waste caused by used batteries is another significant issue. Therefore, instead of focusing on a single alternative fuel technology, evaluating a variety of energy solutions together seems to be a more sustainable and long-term strategy.

Alternative fuels are proposed as a solution to reduce carbon emissions in the transportation sector. In particular, hydrogen is an attractive alternative for heavy-duty transportation due to its quick refueling time and longer range compared to electric vehicles when used in fuel cells. However, no single method has been established for hydrogen production, storage, and transportation. The management of these processes and the identification of the most environmentally and economically viable options remain ongoing research topics.

The lack of a single method for hydrogen production, storage, and transportation has made it an important research question to determine which of the available alternatives is the most environmentally friendly and economically viable [1]. Analyses have evaluated 11 different hydrogen production technologies and 4 different storage and transport alternatives, considering their environmental impacts from multiple perspectives. The findings provide valuable insights for developing a sustainable hydrogen supply chain. Kotze et al. [2] analyzed the impact of green hydrogen usage in heavy-duty vehicles on investments in New Zealand using system dynamics modeling. Çabukoğlu et al. [3] examined the feasibility of hydrogen as an alternative in heavy-duty transportation in Switzerland and demonstrated that hydrogen is technically viable. Similarly, Erdoğan et al. [4] proposed the design of a hydrogen supply chain network for Turkey, which minimizes cost, security risks, and carbon emissions.

Additionally, facility location models are explored to balance the construction of refueling infrastructure with the widespread use of alternative fuel vehicles. The placement of refueling stations is a critical factor in the effective distribution of hydrogen. Kuby and Lim [5] used the Flow-Refueling Location Model (FRLM) to determine the optimal locations for hydrogen refueling stations. Furthermore, the planning and management of the hydrogen supply chain will not be limited to technical and economic factors alone; it will also encompass regulatory frameworks, incentive mechanisms, and carbon pricing strategies. Regulations and government support will be decisive in the development of hydrogen infrastructure. Many countries in Europe and Asia have developed policies to promote the hydrogen economy, and Turkey must also develop similar strategies.

Although there is a significant amount of research on hydrogen, studies that illustrate the step-by-step transformation to hydrogen are limited and insufficient. This gap in the literature hinders the development of strategies and policies to

support the transition to hydrogen-based solutions. This study aims to address this gap by focusing on a systematic and phased approach to hydrogen transition, providing a comprehensive framework that can guide future implementations and facilitate a more effective shift toward a sustainable hydrogen economy. Specifically, this study will focus on the mathematical modeling and design of a hydrogen supply chain for heavy-duty transportation. By considering hydrogen production technologies, transportation methods, storage alternatives, and the process of delivering hydrogen to the end-user, the aim will be to minimize costs and reduce environmental impacts. The design of the hydrogen supply chain is a critical component of the transition to sustainable energy, and optimizing this supply chain will play a key role in accelerating the green transformation of the energy sector.

2. MATERIALS AND METHODS

This study presents a model-based decision support system for the transition of heavy-duty vehicle fleets to hydrogen fuel-cell vehicles. The formulation builds on Almansoori and Shah's multi-period hydrogen supply chain model [6] and is tailored to our scope with a few targeted revisions. The model considers various hydrogen production technologies and the associated processes. Specifically, the region is divided into grids, with the assumption that each grid has a specific demand. Grid-level demand is determined based on the number of registered heavy-duty vehicles and their forecasted counts. The model focuses on critical decisions regarding whether to establish hydrogen production and storage facilities, and if so, where and at what capacity they should be located, in order to meet the demand in each grid. Additionally, the system determines the most suitable method for storing the produced hydrogen. The solution to the model is obtained using the Gurobi optimization software. The goal of this research is to implement the developed mathematical model on a micro scale within a real-world heavy-duty transportation company, providing a practical solution for the transition to hydrogen-powered vehicle fleets.

2.1. The Optimization Model

In this sub-section, we present our optimization model. The indices of the model are as follows: *g*: grid, *t*: period, *i*: physical form of hydrogen (liquid, gas), *j*: facility size, *p*: production technology (1: Steam methane reforming, 2: Coal gasification, 3: Biomass gasification, 4: Water electrolysis), *l*: transportation mode (tanker, railway), *s*: storage facility type (liquid, gas), *e*: energy source (natural gas, coal, biomass, renewable energy, nuclear energy). The parameters of the problem are summarized in Table 1. The parameters pertain to the demand of the grids in each year, the minimum and maximum capacity of each production facility type of each size to produce each hydrogen product type, the minimum and maximum product inventory holding capacity of the storage facilities, and the cost and capacity parameters related to the transport modes and flow rates.

Table 1. The parameters of the mathematical model.

Parameters
D_{gti}: Total demand for product i of grid g in period t
$PCap_{pji}^{min}$: Minimum production capacity of production facility p in size j to produce product i
$PCap_{pji}^{max}$: Maximum production capacity of production facility p in size j to produce product i
$SCap_{sji}^{min}$: Minimum product holding capacity of storage facility *s* of size j for product i
$SCap_{sji}^{max}$: Maximum product holding capacity of storage facility *s* of size j for product *i*
Q_{il}^{min}: Minimum flow rate of product i by transportation mode *l*
Q_{il}^{max}: Maximum flow rate of product i by transportation mode *l*
β: Storage factor (to take into account uncertainties in supply and demand, facility outages)
$AD_{gg'}$: Average distance between grids g and g'
SP_l: Average speed of transportation mode *l*
LUT_{il}: Hydrogen loading and unloading time in transportation mode *l* for product *i*
TMA_{il}: Availability of transportation mode *l* for product *i*
$TCap_{il}$: Capacity of transportation mode *l* for product *i*
IE_{ge}: Amount of energy *e* available in grid *g* (for t=1)
EP_{egt}: Amount of energy *e* produced in grid *g* in period *t*
γ_{epji}: Consumption of energy source *e* by production facility *p* with size j to produce product i
HCC_{pijt}: Investment cost of production facility p in size j to produce product i in period t
SCC_{sijt}: Investment cost of storage facility *s* of size j for product i in period t

The optimization model is presented below. The objective function minimizes the total hydrogen supply chain costs including the total hydrogen production and storage facilities initial investment and hydrogen fuel transportation costs through all years. The constraints pertain to the demand satisfaction constraints of the grids, production plants' construction constraints to satisfy the demand of the grids, the transportation constraints to satisfy the demand of the grids by transporting the required hydrogen fuel among the grids, and storage constraints for the hydrogen storage facilities to be built beside the production facilities. Besides, the constraints of the production and storage units force them to be kept open after construction, and the energy constraints that stipulates satisfaction of the grids' hydrogen energy demand.

Objective function

$$\text{Minimize } TAC$$

Subject to:

$$TAC = \sum_{t} \frac{TAC_t}{(1+r)^t} \tag{1}$$

$$HFCC_t = \sum_{p,i,j,g} HCC_{pijt} IP_{pijgt} \ ; \forall t \tag{2}$$

$$SFCC_t = \sum_{s,i,j,g} SCC_{pijt} IS_{sijgt} \quad ; \forall t \tag{3}$$

$$TAC_t = HFCC_t + SFCC_t \quad ; \quad \forall t \tag{4}$$

Demand Constraints

$$D^L_{gti} + D^I_{gti} = D_{gti} \quad \forall i, g, t \tag{5}$$

$$HP^T_{gti} \geq D^L_{gti} \quad \forall i, g, t \tag{6}$$

$$D^I_{gti} = \sum_{l} Q_{ilg'gt} \quad \forall i, g, t; g \neq g' \tag{7}$$

Production plants' constraints

$$PCap^{min}_{pij} NHP_{pijgt} \leq HPR_{pijgt} \leq PCap^{max}_{pij} NHP_{pijgt} \quad \forall p, i, j, g, t \tag{8}$$

$$PCap^{min}_{pij} NHP_{pijgt} \leq HPR_{pijgt} \leq PCap^{max}_{pij} NHP_{pijgt} \quad \forall p, i, j, g, t \tag{9}$$

$$HP^T_{gti} = D_{gti} + \sum_{l,g'} (Q_{ilgg't} - Q_{ilg'gt}) \quad \forall\, i, g, t; g \neq g' \tag{10}$$

$$HP^T_{gti} = \sum_{p,j} HPR_{pijgt} \quad \forall\, i, g, t \tag{11}$$

Transportation constraints

$$Q^{min}_{il} X_{ilgg't} \leq Q_{ilgg't} \leq Q^{max}_{il} X_{ilgg't} \quad \forall\, i, l, g, t; g \neq g' \tag{12}$$

$$Y_{igt} \geq X_{ilgg't} \quad \forall\, i, l, g, t; g \neq g' \tag{13}$$

$$Z_{igt} \geq X_{ilg'gt} \quad \forall\, i, l, g, t; g \neq g' \tag{14}$$

$$Y_{igt} + Z_{igt} \leq 1 \quad \forall\, i, g, t \tag{15}$$

Storage

$$HS^T_{gti} = \beta D_{gti} \quad \forall\, i, g, t \tag{16}$$

$$HS^T_{gti} = \textstyle\sum_{s,j} HS_{sijgt} \quad \forall\, i, g, t \tag{17}$$

3. APPLICATION RESULTS AND DISCUSSION

The model is solved for a synthetic dataset with five grids, five periods, two product forms (*gas and liquid*), three facility sizes, four production technologies (*1: Steam methane reforming, 2: Coal gasification, 3: Biomass gasification, 4: Water electrolysis*), two transportation modes (*1: tanker, 2: railway*), two storage modes (*1: gas, 2: liquid*), and four energy resources (*1: natural gas, 2: coal, 3: biogas, 4: renewable energy*).

The model determines the number and sizes of production and storage facilities to be built in each year and in each grid. Since the results have several details, a representative set of results for the Grid-1 for the five years is presented in Fig. 1. For the five-year period, the numbers of production and storage facilities built in each year and their types are presented here. For year-1, four production facilities were decided to be built, such that one of them will employ steam methane reforming technology (*p=1*) to produce liquid hydrogen, other two facilities will employ coal gasification (*p=2*) to produce liquid (*i=1*) and gas (*i=2*) hydrogen, and the other facility will empoy water electrolysis (*p=4*) to produce liquid hydrogen (*i=1*). Besides, in the first year, in Grid-1, two storage facilities will be built to store liquid (*i*=1) and gaseous hydrogen (*i=2*). In the following years, as the hydrogen demand of the Grid-1 is expected to increase, more production and storage facilities are planned to be built. In Fig. 1, only the number of the facilities to be built in years 3-5 is shown. Similar results were obtained for the other four grids, for the five-year planning horizon.

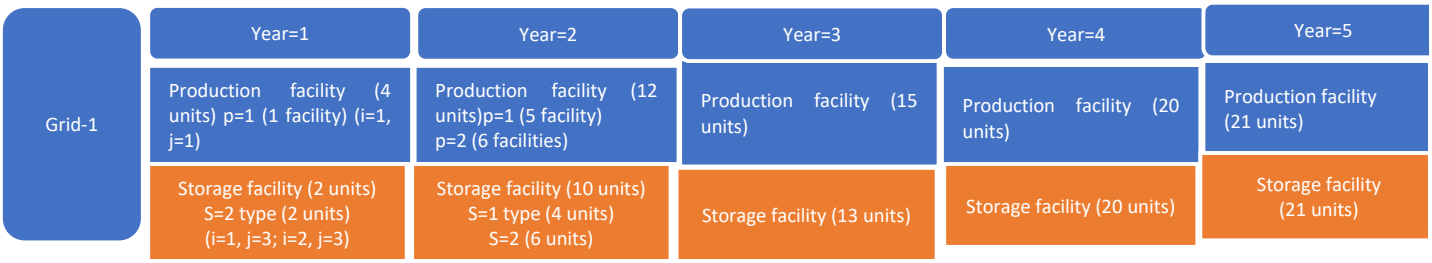

Fig. 1. Results of the model for Grid-1 for all years.

4. CONCLUSIONS

In this study, a mathematical model is proposed to decide the number, sizes, and technologies of the hydrogen production facilities, as well as the number and sizes of the satorage facilities, over a planning horizon. Hence, the hydrogen demand is intended to be satisfied. The objective of the model is to minimize total investment and operational costs of the facilities and material handling costs. As the hydrogen production and storage facilities are built, the fuel-cell vehicles of heavy-duty transport can be started to be used. Hence, decarbonization of the logistics activities can be achieved.

The model is illustrated with a synthetic example. In future studies, it will be solved for a real case example of an industrial zone located in Turkiye, where heavy-duty transportation is dense. As another potential future study, industrial use of the hydrogen in industrial zones based on the established hydrogen supply chain can be planned, and the saved carbon dioxide emissions can be computed.

ABSTRACT
Geothermal energy, which is one of the important renewable energy sources of energy conversion, is an energy production method that provides continuity with circular heat transfer by separating the hot fluid obtained from geothermal reservoirs into liquid and steam phases and re-injecting the waste liquid phase underground. Depending on the temperature of the fluid, energy production is carried out worldwide with different technologies (flash, binary ORC cycle or integrated systems).
Geothermal wells, which are drilled from deep in the earth's crust to reach the surface conditions, are generally distributed in the geothermal field due to geological and structural factors and are located at long distances from the geothermal power plant. Inhibitor dosing pump systems, which are critical equipment for uninterrupted flow production in geothermal wells and providing remote control and communication between the power plant power control center and different locations throughout the field, and, require energy as long as the power plant is operating. In case of short-term power outages, diesel generators are used to meet the energy load, which requires additional equipment and fuel.
This study aims to examine the use of sodium borohydride-based fuel cell systems, a clean alternative to wellhead generators that produce energy from fossil fuels during failure conditions, and to reveal their contribution to energy conversion. Fuel cells are off-grid systems that convert the chemical energy of the fuel directly into electrical energy with high efficiency. Polymer electrolyte membrane fuel cells (PEMFC) are a type of fuel cell that has the potential to be used in a wide power range. In this study, the use of high-purity hydrogen, required for a 10kW PEMFC during a 1–3-day failure condition, will be investigated by producing it from sodium borohydride. Issues such as the safe and long-term storage of sodium borohydride in solid form, its suitability for hydrogen production when needed, the controllability of the reaction, the environmental impact of by-products, and the potential use of Turkey's boron resources—which account for more than 70% of global reserves—in high-value-added applications will be evaluated.

Keywords: Geothermal, Sodium borohydride, Remote Area, PEMFC

1. INTRODUCTION

Kizildere geothermal field is a multifunctional integrated production site located on the border of Denizli and Aydın with a total electricity generation capacity of 260 MWe, providing resources for city heating, high-volume greenhouse heating, thermal tourism, and pure liquid CO2 production. The first power plant was established as single flash cycle in 1984 and the capacity expeanding studies continued between 2008-2018 with thriple flash and combined binary cycle in the field [1].
In order to produce geothermal energy, the hot geothermal fluid deep in the earth's crust is usually pumped to the surface by geothermal wells located scattered in the geothermal field due to geological and structural factors (e.g., Fig. 1). Power plant communication between different locations throughout the field, inhibitor dosing pump systems, which are critical equipment for uninterrupted flow production in geothermal wells, require energy as long as the power plant is operating. During planned maintenance at the power plant and in case of failure at the power plant, the energy supplied to the well areas is cut off. In case of short-term power outages, diesel generators are used to meet the energy load, which creates additional equipment and fuel needs.
In this study, the use of PEMFC is proposed to meet the emergency energy needs in remote areas far from power plant facilities. In comparison to fossil fuels, sodium borohydride fuel cells are a cleaner source of energy and it is intended to use the boron mineral, 70% of the world reserves of which are located in Turkey, in energy needs.

2. MATERIALS AND METHODS

In cases where geothermal power plants are connected to the grid, they meet all their internal consumption including well zones. In case of emergency in the geothermal power plant, power outages occur and the systems in the power plant stop working. This does not apply to the wells that produce artesian production and the wells continue to produce

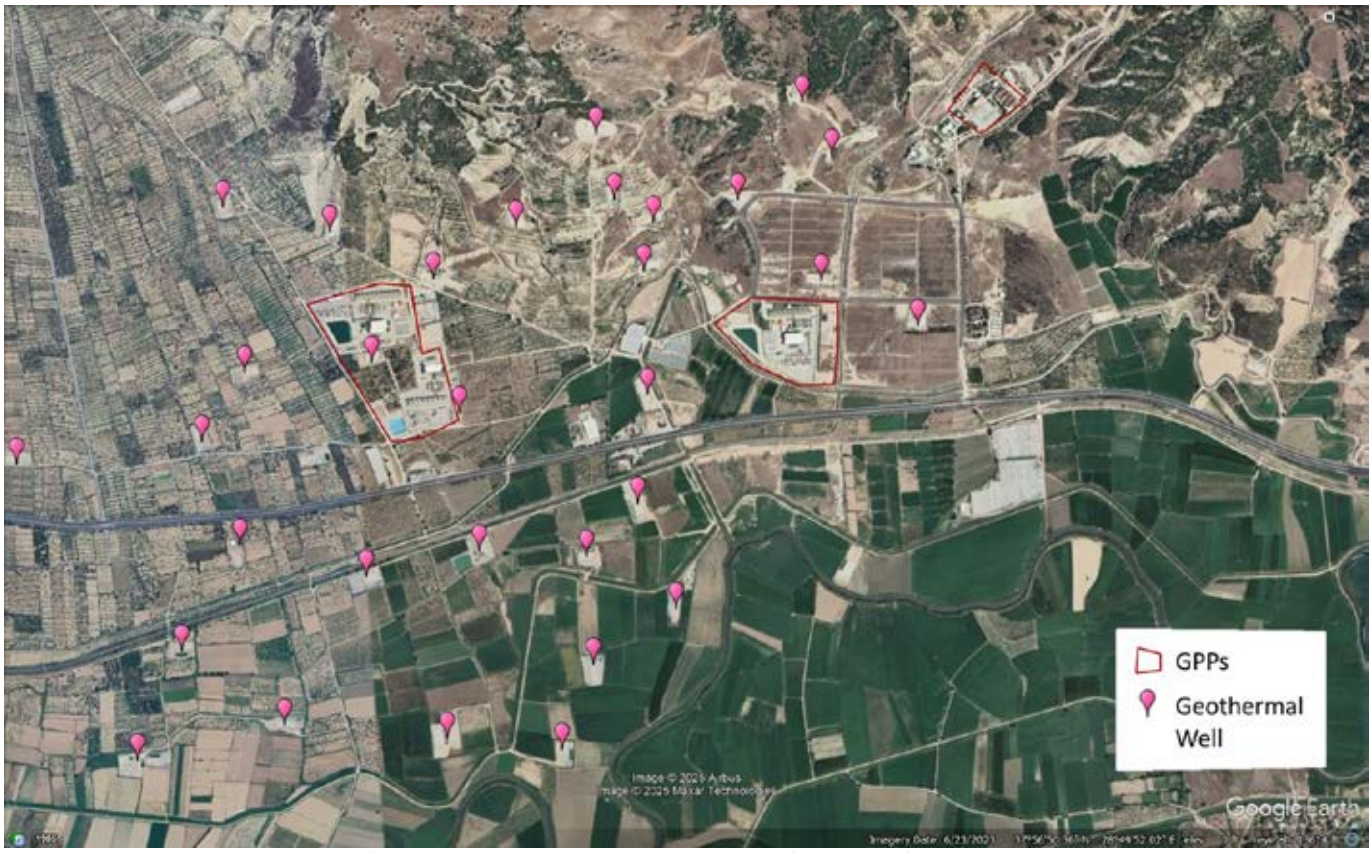

Fig. 1. GPPs and the production well locations of Kızıldere Geothermal Field.

fluid. Considering parameters such as well depth, fluid temperature and reservoir pressure, geothermal production wells, which are very difficult to be reactivated when shut down, are required to continue production even when the power plant is not in operation. these wells discharge their fluids into emergency pools. In order to control the geothermal wells, the communication between the control room and the wells and therefore the energy should not be interrupted. Inhibitor dosing systems are another system affected by power failure in the well area. Inhibitor dosing systems are the risk of precipitation in the well as a result of physicochemical reactions of geothermal fluid containing dissolved minerals. In order to prevent precipitation, capillary tubings reaching kilometres in length are lowered into the wells and inhibitors are injected into the well through them. In the event of a power failure, if the inhibitor dosing system stops, the inhibitors in the capillary tubing burn and disable the tubing, resulting in precipitation in the well. This leads to costly operational requirements at the well site and in order to prevent this situation from developing, generators are located at the well sites.

It is common use to utilise generators in emergency power outages in industry and residences. At Kızıldere geothermal field well sites, diesel generators are also preferred. A total of 7A current is drawn in the well area. Each well needs a 5 kW 3-phase generator in case of emergency. 16 kW diesel generators are activated in emergency conditions at the well sites. Considering that each litre of diesel fuels creates 2.68 kg of CO_2 emissions each time it burns, therefore each generator has the capacity to create 107.2 kg of emissions. Only the number of production wells in Kizildere Geothermal Field is more than 50. For this reason, diesel generators produce a considerable amount of emissions in case of power outages. In order to prevent carbon emission, it is purposed to use $NaBH_4$ PEMFC, which is sustainable and relatively cleaner, instead of fossil fuelled generators.

$NaBH_4$ (Sodium borohydride) has been investigated as a potential hydrogen source for PEMFCs due to its high hydrogen content and ability to release hydrogen when reacting with water by various researchers [2],[3],[4]. $NaBH_4$ can release hydrogen gas through hydrolysis. $NaBH_4$ stored in solid state does not release hydrogen directly at room temperature. Controlled hydrolysis of $NaBH_4$, with the reaction rate and efficiency increased by catalysts, is a common method to supply hydrogen to PEMFC's anode side. The reaction can be controlled to release hydrogen at a rate suitable for the demand of the fuel cell. The general hydrolysis reaction is:

$$NaBH_4 + 2H_2O \rightarrow NaBO_2 + 4H_2$$

Generated hydrogen from $NaBH_4$, is sent to the anode part of the PEM fuel cell, creating an electrochemical reaction. At

the anode, hydrogen molecules are split into protons and electrons with a catalyst. On the other hand, at the cathode, oxygen molecules combine with the protons and electrons transferred from the anode to form water.

$2H_2 \rightarrow 4H^+ + 4e^-$ anode

$O_2+4H^++4e^- \rightarrow 2H_2O$ cathode

$2H_2 + O_2 \rightarrow 2H_2O$ total

Once the $NaBH_4$ has been consumed, it will be necessary to refill the fuel compartment with fresh $NaBH_4$ and remove the $NaBO_2$ produced by the reaction.

3. RESULTS AND DISCUSSION

If the energy requirement is considered as 10 kW for a well, it is calculated that 80 kg of solid $NaBH_4$ can meet the daily energy requirement of a well in Kızıldere geothermal field.

$NaBH_4$ is a source with adjustable reaction conditions and a high volumetric energy density that can be stored and transported more easily than hydrogen gas, which requires high-pressure tanks. These properties make it a potential option for portable or mobile fuel cell applications, but the by-products generated during hydrogen production present some challenges such as efficiency, cost and scalability. In any case $NaBH_4$ based PEMFC, which are still open to improvement, can be an alternative that can be used in emergencies with the development of cost, fast start-up and efficiency.

4. CONCLUSIONS

The Kizildere geothermal field wells have an average energy requirement of 10 kW, so 16 kW diesel generators are activated in emergency conditions at the well sites. Considering that each litre of diesel fuels creates 2.68 kg of CO_2 emissions each time it burns, therefore each generator has the capacity to create 107.2 kg of emissions. Only the number of production wells in Kizildere Geothermal Field is more than 50. For this reason, diesel generators produce a considerable amount of emissions in case of power outages. In order to prevent carbon emission, it is recommended to use $NaBH_4$ PEMFC, which is sustainable and relatively safer, instead of fossil fuelled generators.

ABSTRACT

Recent research on intermediate temperature solid oxide fuel cells (IT-SOFC) address on issues about developing more efficient cathode structures. The purpose is to relay ionic conduction through the cathode as fast as possible. Materials based on LSC (La, Sr, Co oxides) with both $(La,Sr)CoO_3$ (LSC113) and $(La,Sr)_2CoO_4$ (LSC214) stoichiometry are chosen in this study. In the literature, several coating and fabrication processes were used to combine these materials to form composite cathode structures. In this study, electrospray deposition (ESD) method is used to coat polymeric precursor solutions prepared with these material compositions onto gadolinia-doped cerium oxide (GDC) electrolyte material. Layered coating approach were tested to form composite coating structures and compared different compositions. The approach involved coating thin LSC113 and LSC214 layers one on top of the other. Electrochemical Impedance Spectroscopy (EIS) measurements were done with the symmetrically coated samples. Promising EIS measurements were taken and the work is ongoing.

Keywords: Electrospray deposition, solid oxide fuel cell, LSC113, LSC214, cathode layer

1. INTRODUCTION

Fuel cells, are environmentally friendly energy production technologies that are named according to the type of the electrolyte material used. Solid Oxide Fuel Cells (SOFC) can convert chemical energy into electrical energy silently and efficiently. Only heat and water are formed as by-products. However, high operating temperatures (>800°C) lead to problems such as corrosion, reduced durability, long start-up times and high maintenance costs. To overcome these problems, operating temperatures need to be reduced to the intermediate-temperature range (500-700°C), but this causes a decrease in ionic and electronic conductivities and thus a decrease in energy production efficiency. The selection of materials is very important to increase efficiency in the intermediate temperature range. The ionic conductivity of the electrode layers, especially the cathode layer, is increased by using Mixed Ionic-Electronic Conductor (MIEC) materials. LaSrCo-based perovskite oxides have been shown to have promising electrochemical properties among MIEC materials for IT-SOFCs.

Cathode layers are coated on the electrolyte layer with various methods such as PLD, screen printing, solid-state reaction, etc [1–4]. In this study, the Electrospray Deposition (ESD) method, which is a low-cost and faster method compared to other techniques, was used. In the literature, the ESD method has not yet been used for LaSrCo-based compounds. ESD allows the atomization of liquids with the help of electrical forces. The liquid used is a solution containing the components of the cathode layer such as La, Sr and Co in stoichiometric ratios. Upon impact with the targeted heated electrolyte pellet the solution is rapidly vaporized and metal ions form an amorphous oxide attached to the surface. Coatings with the desired composition and structures can be created by controlling the ESD parameters. In this way, different coating structures such as reticular, dense, etc. structures can be obtained on the electrolyte surface by optimizing the ESD parameters for different experimental plans [5–7]. Recently, Tayfur Ozturk et al. have studied the coating of LSC-based cathode materials onto the electrolyte by the sputtering coating method [8]. In these studies, LSC113 was combined with LSC214 in certain proportions and used to form composite cathode layers.

In this study, LaSrCo oxide solutions were prepared in specific A-site stoichiometries such as $(La_{0.5}Sr_{0.5})CoO_3$, $(La_{0.8}Sr_{0.2})CoO_3$, $(La_{0.5}Sr_{0.5})_2CoO_4$ and $(La_{0.8}Sr_{0.2})_2CoO_4$ and were symmetrically coated onto gadolinia doped ceria (GDC) pellets used as electrolyte. Electrochemical impedance spectroscopy (EIS) measurements were performed with symmetrically coated samples.

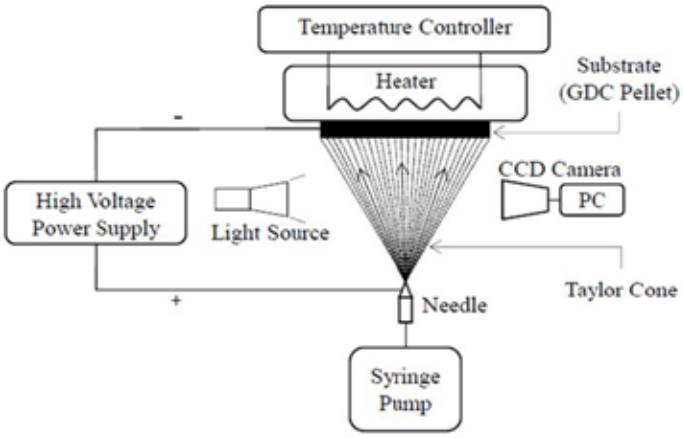

Fig. 1. Schematic of electrospray deposition (ESD) method [7]

2. MATERIALS AND METHODS

$(La_{0.5}Sr_{0.5})CoO_3$, $(La_{0.8}Sr_{0.2})CoO_3$, $(La_{0.5}Sr_{0.5})_2CoO_4$ and $(La_{0.8}Sr_{0.2})_2CoO_4$ solutions were prepared from precursor solutions in the stoichiometric proportions which were selected based on the literature in order to make electrochemical performance comparisons of the resulting cathode layers. For these solutions, Lanthanum (III) nitrate hexahydrate (ALFA-AESAR >99.99%), cobalt (II) nitrate hexahydrate (ALFA-AESAR >97.7%) and strontium chloride hexahydrate (ALFA-AESAR >99%) precursor salts were used to prepare the solutions to be coated on dense GDC pellets by Electrospray Deposition (ESD) method. The composite cathode layers were formed by ESD with layered coating structure approach. This approach is explicable by coating different solutions one by one on GDC pellet. The electrolyte pellets were made from commercial GDC powder by pressing in a uniaxial hydraulic press at 180 MPa pressure followed by sintering to >95% density. Experimental ESD parameters were flow rate (2 ml/h), voltage (13 kV), solution concentration (0.02M), working distance (27 mm), temperature (350 °C) and coating duration (10 minutes). Finally, XRD analysis was used for determining phase compositions, SEM was used for microstructural analysis and EIS for electrochemical performance analysis. An in-house silver (Ag) paste and Ag wires were employed to facilitate efficient current collection. The wires were secured using a high-temperature ceramic adhesive (Ceramabond). Electrochemical impedance spectroscopy (EIS) measurements were conducted with an Autolab (Metrohm, Switzerland) instrument over a temperature range of 500–700 °C in stagnant air (Protherm Tube Furnace). The EIS analyses utilized an excitation voltage of 15 mV and covered a frequency range of 10^{-2} to 10^{5} Hz.

3. RESULTS AND DISCUSSION

Cathode layers with $(La_{0.5}Sr_{0.5})CoO_3$, $(La_{0.8}Sr_{0.2})CoO_3$, $(La_{0.5}Sr_{0.5})_2CoO_4$ and $(La_{0.8}Sr_{0.2})_2CoO_4$ compositions were deposited onto the electrolyte using ESD. It was crucial to evaluate the chemical and phase compositions of the cathode layers after deposition. Precursor solutions were individually heated in a glass beaker at 250 °C to evaporate the solvents, simulating the final cathode composition. Energy-dispersive X-ray spectroscopy (EDX) were performed on these powder samples to determine the elemental composition of the cathode layers after coating process. The results closely matched the intended stoichiometric ratios as listed in Table 1 below. This was done so because coatings sraped off from the pellet surface were too-rich in GDC and XRD analysis peaks for LSC were overshadowed by GDC peaks.

Table 1. Stoichiometric ratios of precursor solutions

Sample	Stoichiometric Ratios	
	Intended	Calculated
1	$(La_{0.5}Sr_{0.5})CoO_3$	$(La_{0.49}Sr_{0.51})CoO_3$
2	$(La_{0.8}Sr_{0.2})CoO_3$	$(La_{0.77}Sr_{0.23})CoO_3$
3	$(La_{0.5}Sr_{0.5})_2CoO_4$	$(La_{0.51}Sr_{0.49})_2CoO_4$
4	$(La_{0.8}Sr_{0.2})_2CoO_4$	$(La_{0.79}Sr_{0.21})_2CoO_4$

Cross-sectional SEM image obtained from the fracture of coatings made using layered-structured coating approach by ESD method with $(La_{0.5}Sr_{0.5})CoO_3$ ve $(La_{0.5}Sr_{0.5})_2CoO_4$ is shown in Fig. 2. This sample shows partially dense coating structure. Nevertheless, the approach showed the availability for formation of desired reticular structures.

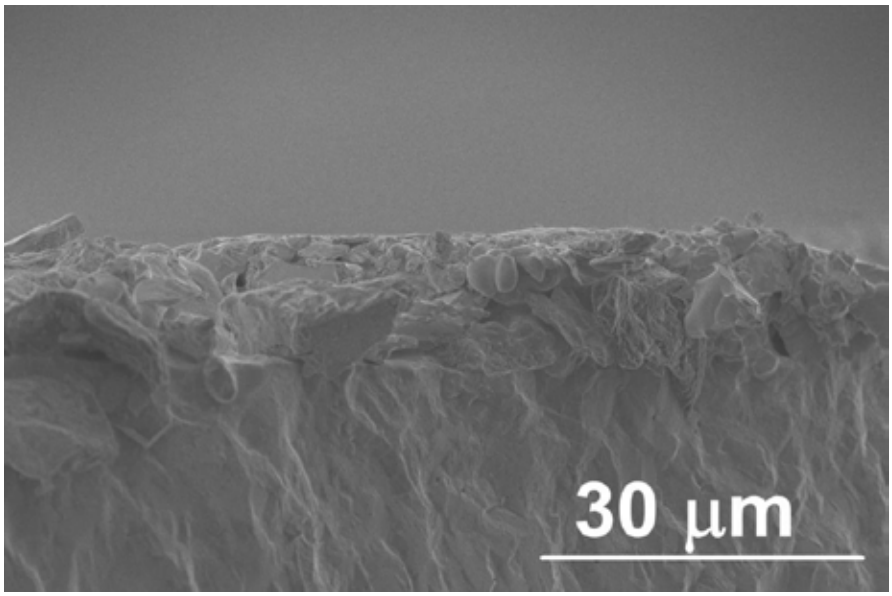

Fig. 2. SEM image of coating made using the layered-structure approach by ESD method with $(La_{0.5}Sr_{0.5})CoO_3$ and $(La_{0.5}Sr_{0.5})_2CoO_4$ solution.

4. CONCLUSIONS

The prepared precursor solutions were successfully coated on dense GDC electrolyte pellets. EDX analysis performed to check intended stoichiometric ratios. SEM observations revealed partially dense and desired reticular structures according to the composite constituents and coating conditions. Thus, the effects of layered-structured composite coatings were observed. Electrochemical impedance spectroscopy (EIS) measurements confirmed the effectiveness of ESD method on coatings on GDC electrolyte. Area specific resistance (ASR) measurements at 700°C showed better values than the benchmark of 0.15 Ω·cm² for IT-SOFC cathodes.

ABSTRACT
In this study, the performance of a regenerative fuel cell with a 9 cm² active area was experimentally investigated in both electrolyzer and fuel cell modes. The MEA consisted of 75% Platinum Black and 25% Iridium Black on the anode side, while Platinum Carbon was used on the cathode side. In the bipolar plate design, serpentine flow channels were used on the cathode side, whereas a titanium mesh structure was employed on the anode side.
The experiments were conducted using the L9 orthogonal array Taguchi experimental design. In electrolyzer mode; compression torque (5-7-10 N.m), temperature (40-60-80°C) and water flow rate (10-20-30 ml/min) were varied, and current density were measured. In fuel cell mode, compression torque and temperature were selected the same as in electrolyzer mode, while hydrogen flow rate (1.296, 1.62, 1.944 ml/min.) was varied, current density and power density were measured. The findings reveal the effects of compression torque, temperature, and flow rate variations on the performance of the regenerative fuel cell.
Keywords: Regenerative Fuel Cell, Hydrogen

1. INTRODUCTION

In recent years, energy production and storage technologies have been rapidly advancing with a focus on sustainability and environmental impact [1]. In this context, regenerative fuel cells (RFCs) have gained attention as innovative systems capable of both hydrogen production and electrical energy conversion [2]. RFCs operate in electrolyzer mode by splitting water into hydrogen and oxygen for energy storage, and in fuel cell mode, they utilize these gases to generate electricity, with water as the only byproduct [3]. This bidirectional working principle offers high efficiency and an environmentally friendly approach to energy storage and recovery.
Regenerative fuel cells are categorized into separated and unified systems. In separated systems, the electrolyzer and fuel cell are designed as independent modules, operating with an external hydrogen storage unit. The hydrogen produced in the electrolyzer is stored separately and later used by the fuel cell. In contrast, unified systems integrate both functionalities within a single cell, allowing it to operate in both electrolyzer and fuel cell modes[4]. Unified systems provide advantages in energy storage applications due to their compact design and lower costs. However, for efficient operation in both modes, it is essential to optimize the membrane, catalyst, and flow field design[5]. There are two design strategies for unified regenerative fuel cells: fixed electrode and fixed gas configurations. In a traditional fixed gas setup, the URFC consists of a hydrogen electrode (HOR/HER) and an oxygen electrode (ORR/OER). The primary advantage of this configuration is preventing hydrogen and oxygen mixing while also enabling rapid switching between electrolyzer (EL) and fuel cell (FC) modes. However, a major limitation of this design is that both kinetically and thermodynamically controlled OER and ORR reactions occur on the same side of the device, leading to efficiency losses [6]. In contrast, the fixed electrode approach operates with a continuous gas exchange mechanism, where HER/ORR occurs at the cathode and OER/HOR at the anode. This configuration enhances energy conversion efficiency, improves oxygen transport and ORR kinetics, and allows for lower material loading while enhancing OER kinetics. Additionally, operating with a single electrode in a continuous mode enables more efficient coordination of gas diffusion layers. However, the main drawback is that the wide potential range experienced by the electrodes increases material degradation, leading to a shorter lifespan compared to the fixed gas configuration.[7].
Although various studies in the literature have focused on different design approaches for regenerative fuel cells, the majority emphasize material innovations. In the study by Kim et al.[8] bifunctional Pt-Ir catalysts were synthesized via spray pyrolysis and optimized through thermal treatment for RFC applications. The physical structure of the catalysts was analyzed, and their electrochemical performance was evaluated. Results indicated that heat-treated Pt-Ir/rGO catalysts exhibited high ORR and OER activity along with enhanced stability, demonstrating the potential of Pt-Ir alloys as an efficient alternative for RFCs.
In another study by Regmi et al., a low-temperature unified regenerative fuel cell (URFC) design achieved 60% round-trip efficiency and 10,000 cycle durability. The fixed electrode (CE) and fixed gas (CG) configurations were compared, revealing that the CE configuration provided higher current density and efficiency. In the CE setup, HOR and OER occurred at the anode, while ORR and HER took place at the cathode. Accelerated stress tests confirmed that stable performance was maintained over 10,000 cycles.
Park at al.[9], focused on optimizing the membrane electrode assembly (MEA) for URFCs. The study investigated gas diffusion layers, ionomer content, ORR/OER catalysts, and catalyst loading on oxygen electrodes. Results indicated that

MEA parameters had the most significant impact on RFC performance in both fuel cell (FC) and water electrolysis (WE) modes. An optimized design achieved 49% round-trip efficiency at 500 mA/cm², comparable to values reported in the literature.
Yim et al. [10] optimized bifunctional electrocatalysts for PEM-based unified RFCs. The study synthesized and evaluated various Pt-based catalysts for oxygen electrodes. Cell temperature, catalyst loading, and electrode stability were analyzed to determine the optimal operating conditions. The findings demonstrated that Pt-Ir catalysts provided the highest efficiency and stability in both FC and EL modes, confirming their effectiveness as oxygen electrode materials for URFC systems.
In this study, a novel RFC design was introduced by replacing the conventional bipolar plate with a titanium mesh structure on the anode side. While traditional designs typically use bipolar plates on both the anode and cathode, this study aims to investigate the impact of using a titanium mesh on RFC performance in both electrolyzer and fuel cell modes. This approach has been minimally explored in the literature, and the influence of mesh structures on gas transfer at the membrane-electrode interface and bidirectional cell operation remains insufficiently studied. Therefore, this study aims to contribute to the field by analyzing the effects of replacing bipolar plates with a titanium mesh on RFC performance.
Additionally, to achieve systematic optimization, the study employs the L9 orthogonal array Taguchi experimental design. The effects of compression torque, temperature, and flow rate on cell performance were examined to determine optimal operating conditions. Experimental investigations were conducted by first testing the system in electrolyzer mode, followed by fuel cell mode, and repeating the same procedures for each compression torque value. The findings highlight the significant impact of using a titanium mesh instead of a bipolar plate on RFC performance, offering valuable insights for future studies in this area.

2. MATERIALS AND METHODS

2.1. Design of the Regenerative Fuel Cell

The active area of the regenerative fuel cell used in the experiments was set to 9 cm². The cell operates in a fixed electrode mode. The Membrane Electrode Assembly (MEA) consists of 75 wt.% Platinum Black and 25 wt.% Iridium Black on the anode side, while the cathode side contains Platinum-Carbon catalyst. In terms of bipolar plate design, a serpentine flow channel structure is utilized on the cathode side, whereas a titanium mesh structure is implemented on the anode side.

2.2. Experimental Design and Parameters

In this study, the L9 orthogonal array Taguchi experimental design was employed to investigate the effects of three key variables at three different levels:
Electrolyzer Mode Parameters:

- Compression Torque: 5, 7, 10 N.m
- Temperature: 40, 60, 80°C
- Water Flow Rate: 10, 20, 30 ml/min.

Fuel Cell Mode Parameters:

- Compression Torque: 5, 7, 10 N.m
- Temperature: 40, 60, 80°C
- Hydrogen Flow Rate: 1.296, 1.62, 1.944 ml/min.

The impact of each parameter on performance was analyzed based on the output data of the fuel cell.

Table 1. Electrolyzer Mode Taguchi Experimental Design

Experiment No	Torque (N.m)	Temperature (°C)	Water Flow Rate (ml/min.)
1	5	40	10
2	5	40	20
3	5	40	30
4	7	60	20
5	7	60	30
6	7	60	10
7	10	80	30
8	10	80	10
9	10	80	20

Table 2. Fuel Cell Mode Taguchi Experimental Design

Experiment No	Torque (N.m)	Temperature (°C)	H_2 Flow Rate (ml/min.)
1	5	40	1.296
2	5	40	1.62
3	5	40	1.944
4	7	60	1.944
5	7	60	1.296
6	7	60	1.62
7	10	80	1.62
8	10	80	1.944
9	10	80	1.296

3. RESULTS AND DISCUSSION

3.1. Performance in Electrolyzer Mode

As the temperature increased, a significant rise in current density was observed, as higher temperatures accelerate electrochemical reaction kinetics and enhance ion mobility within the membrane. At elevated temperatures, the activation energy required for electrode surface reactions decreases, reducing the overall internal resistance of the cell and leading to a more efficient current flow.

Additionally, an increase in compression torque contributed to a more stable current density by reducing the contact resistance between the electrodes. Higher compression torque levels improved the contact interface between the electrode and membrane, enhancing electrical conductivity and minimizing resistance losses at the contact points. As a result, at higher compression torque values, the cell performance and current density remained more stable and consistent.

On the other hand, a slight decrease in current density was observed with increasing water flow rate. While a higher water flow rate facilitates the removal of gas bubbles from the electrode surface, it can also lead to water accumulation on the electrode, restricting gas diffusion in reaction sites. This limitation can hinder the optimal progression of the reaction mechanism, causing a minor reduction in cell performance. However, this decrease remains relatively small and does not pose a significant obstacle to the overall system efficiency.

3.2. Performance in Fuel Cell Mode

As the temperature increased, both current density and power density showed a significant improvement. This enhancement can be attributed to the acceleration of electrochemical reaction kinetics at higher temperatures, which reduces the activation energy required for electrode reactions. Additionally, increased temperature enhances ion mobility within the membrane, leading to a reduction in internal resistance and improved proton conductivity. These factors collectively result in a more efficient electron transfer process, allowing the cell to operate at higher performance levels. Furthermore, the improved gas diffusion at elevated temperatures enhances mass transport, ensuring a more effective utilization of the reactant gases at the electrode surfaces, thereby maximizing the overall energy conversion efficiency.

Conversely, as the compression torque increased, both current density and power density exhibited a decline. Higher compression torque, while beneficial up to a certain limit by improving contact between the membrane and electrodes, can also lead to excessive mechanical stress on the cell components. This excessive pressure can compress the gas diffusion layers (GDLs), reducing their porosity and impeding effective gas transport. Consequently, the limited gas supply to the catalyst sites results in mass transport losses, negatively impacting the overall reaction rates. Furthermore, excessive torque can introduce structural deformations in the membrane-electrode assembly (MEA), potentially increasing internal ohmic resistance, leading to reduced current and power output.

Although hydrogen flow rate had a less significant impact compared to temperature and compression torque, the highest performance was achieved at a hydrogen flow rate of 1.296 ml/min. Maintaining an optimal hydrogen flow rate is crucial for ensuring sufficient reactant supply to the catalyst sites, enabling efficient electrochemical reactions. Insufficient hydrogen flow can lead to reactant starvation, causing mass transport limitations and reduced reaction rates. Conversely, excessively high hydrogen flow may result in unreacted hydrogen bypassing the catalyst layer, leading to inefficient gas utilization and lower energy conversion efficiency. The optimal performance observed at 1.296 ml/min suggests that this specific hydrogen flow rate provides the best balance between reactant availability and reaction efficiency, ultimately enhancing the overall performance of the fuel cell.

4. CONCLUSIONS

In this study, the performance of a regenerative fuel cell was experimentally investigated under different parameters in both electrolyzer and fuel cell modes. The optimum performance, affecting both electrolyzer and fuel cell operations, was

achieved at 7 Nm compression torque and 80°C temperature. Additionally, in electrolyzer mode, the best performance was observed at the lowest water flow rate of 10 ml/min, while in fuel cell mode, the highest performance was recorded at the lowest hydrogen flow rate of 1.296 ml/min.

Experimental results indicate that temperature is the most influential parameter on the performance of the regenerative fuel cell. An increase in temperature enhances electrochemical reaction kinetics, significantly improving efficiency in both electrolyzer and fuel cell modes. Compression torque is also a critical factor in determining cell performance; however, its impact is more limited compared to temperature. Increasing torque up to a certain level improves electrode contact by reducing contact resistance, thus enhancing conductivity. However, excessive compression torque negatively affects gas diffusion, leading to performance losses.

In contrast, the effects of water and hydrogen flow rates were significantly lower compared to temperature and torque. In electrolyzer mode, decreasing the water flow rate resulted in higher performance, with the best efficiency observed at the lowest water flow rate of 10 ml/min. In fuel cell mode, the highest performance was achieved at the lowest hydrogen flow rate of 1.296 ml/min. Excessive hydrogen supply led to unreacted hydrogen exiting the system, reducing overall efficiency.

Overall, temperature was identified as the most influential parameter on the performance of the regenerative fuel cell, while compression torque had a moderate effect, and water and hydrogen flow rates had the least impact compared to the other parameters.

To further improve the performance of regenerative fuel cells, several key aspects should be explored in future studies. Testing different catalyst combinations can help enhance the efficiency and durability of cell components by optimizing electrocatalytic activity and stability. Additionally, conducting long-term durability tests is essential to assess the system's stability over extended operational periods, ensuring reliable performance under varying conditions. Furthermore, performing comparative analyses of different flow field designs can provide valuable insights into optimizing mass transport and gas distribution within the cell, ultimately improving overall efficiency. These factors will be crucial for future research aimed at enhancing the performance and longevity of regenerative fuel cells.

In conclusion, the efficiency of regenerative fuel cells can be enhanced by selecting the right operating parameters, making these systems promising solutions for sustainable energy applications.

ABSTRACT
The study is centered on the design and development of a cost-effective 3-cell Proton Exchange Membrane Fuel Cell (PEMFC) prototype, delivering a power output of 150 W. The focus is on optimizing the fuel cell design by using Nafion 212 membranes, platinum-based catalysts, and serpentine flow channels to enhance efficiency and durability. On the analysis, attention was paid to key performance factors such as temperature, pressure and reactant flow. Simulations and experimental evaluations conducted using MATLAB and SolidWorks verified the system's reliability. The obtained results demonstrate the potential of PEMFCs for handling energy shortages as well as reducing greenhouse gas emissions, with further enhancements thought to support scalability for higher power applications.

Keywords: Hydrogen energy, Proton exchange membrane fuel cells, Emission reduction, Renewable energy.

1. INTRODUCTION

Proton Exchange Membrane Fuel Cells (PEMFCs) are increasingly recognized as a key clean energy technology with broad applications in portable power systems and transportation [1]. Monitoring and optimizing the performance of PEMFCs is critical for their reliable and efficient operation, particularly under varying conditions [2]. Unlike conventional systems, this project introduces a customized 3-cell PEMFC stack design with serpentine flow channels and optimized Nafion 212 membranes to address energy efficiency, durability, and portability challenges [3]. Aspects such as balancing efficiency, stability and scalability, can often represent limitations on traditional PEMFC designs, specially concerning real-world applications [4,5]. This study offers a novel approach by integrating advanced modeling techniques and experimental validation to enhance the performance and practicality of PEMFC systems. By focusing on reactant flow optimization, system thermal stability, and precise voltage-current response analysis, this study sets a benchmark for portable PEMFC systems in remote or energy-deficient areas. As part of the methodology, simulation tools such as MATLAB and SolidWorks were employed with experimental analysis to validate the system's efficiency. Key innovations include the use of advanced platinum catalysts for minimizing activation losses and a tailored design to improve reactant distribution and water management [6]. These improvements contribute to the practical application of PEMFCs by reducing material costs, extending operational stability, and ensuring compatibility with real-world energy demands. This study draws attention to the potential of PEMFCs and their capacity to face global energy challenges while providing an efficient, cost-effective, and scalable solution for portable energy applications. Furthermore, the aim is to contribute to the vast adoption of hydrogen-based clean energy technologies by advancing the performance standards of PEMFC systems.

2. PERFORMANCE AND DESIGN ADVANCEMENTS OF THE PEMFC PROTOTYPE

The performance and design process of a 3-cell Proton Exchange Membrane Fuel Cell (PEMFC) prototype, tailored for portable energy applications, reached significant upgrading through this study. By integrating Nafion 212 membranes, platinum-based catalysts, and serpentine flow channels, the system demonstrated a stable power output of 150 W and an efficiency of approximately 50%, outperforming previous designs. Advanced simulations using MATLAB and SolidWorks optimized the reactant distribution and water management, while experimental validation under real-world conditions confirmed the system’s reliability and durability. Improvements on power output, efficiency and operational stability are featured on Table 1.

Table 1. Comparative analysis of PEMFC performance metrics

Parameters	Previous Studies	This Study
Power Output	100–120 W	150 W
Efficiency	40–45%	~50%
Operating Temperature	50–70°C	60–80°C
Flow Channel Design	Parallel/single-path	Serpentine
Stability Duration	6–8 hours	10 hours

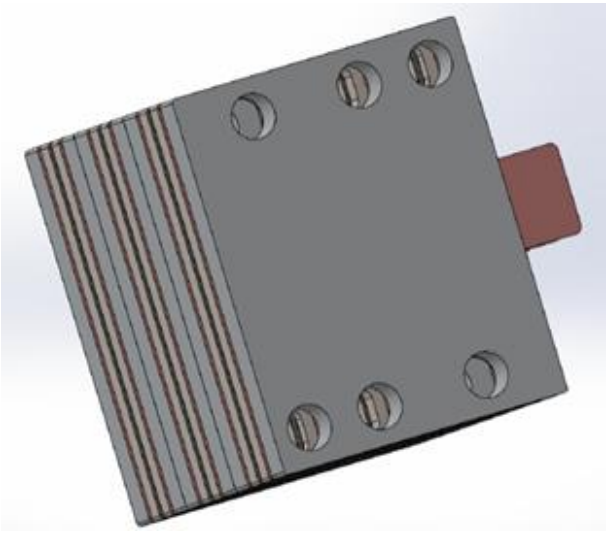

Fig. 1. 3D design of fuel cell stack

The 3D design of the PEMFC stack was developed using SolidWorks to ensure precise optimization of the system's geometry and flow dynamics. To enhance reactant distribution and water management, serpentine flow channels were specifically designed, minimizing concentration losses and ensuring uniform current density through the active area. This detailed design plays a crucial role in achieving the system's high efficiency and stability, making it suitable for real-world applications in portable energy solutions [7]. The visual representation provides an overview of the stack structure and flow channel configuration.

3. PERFORMANCE OPTIMIZATION OF PEMFC

Advanced optimization techniques and MATLAB modeling was applied in this study to enhance the performance of Proton Exchange Membrane Fuel Cells (PEMFCs). Key improvements included minimizing polarization losses and identifying optimal parameters under different operating conditions. The Multi-Verse Optimizer (MVO) algorithm was implemented and compared against other methods like SSA, PSO, SCA, and MFO [8,9], showing superior performance with reduced error and convergence time. Matlab simulink model of fuel cell is depicted in Fig.2.

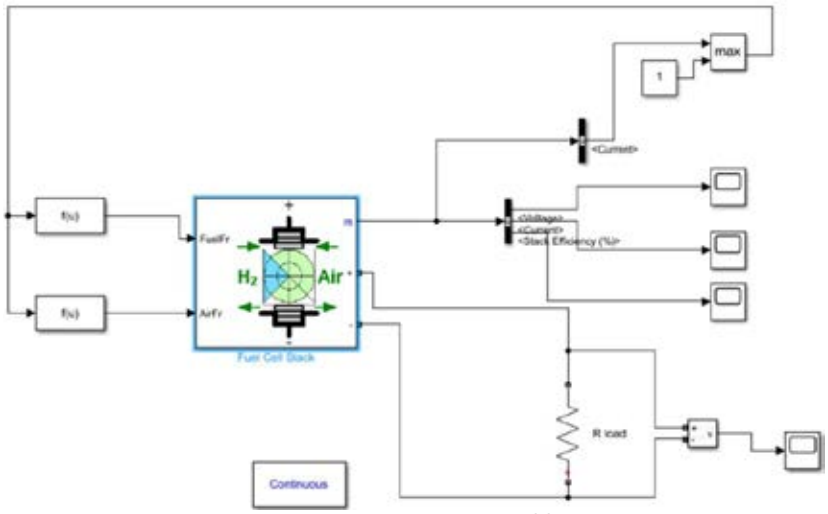

Fig. 2. Matlab simulink model of fuel cell

The attached figures and tables provide a consistent and detailed representation of the performance optimization process for PEMFCs. The result is a logical flow of evidence supporting the effectiveness of the Multi-Verse Optimizer (MVO) [10]. Fig. 3 (a) and (b) highlight the comparative performance of various optimization algorithms under two distinct operating conditions. Fig. 3. (a) focuses on SSA, SCA, MFO, PSO, and MVO under the first condition, showcasing how MVO minimizes polarization losses and stabilizes voltage more effectively than other methods. In contrast Fig. 3. (b) compares HABC (Hybrid Artificial Bee Colony) [11], HADE (Hybrid Adaptive Differential Evolution) algorithms [12], and MVO under the second condition, further validating MVO's consistent superiority in enhancing PEMFC performance.

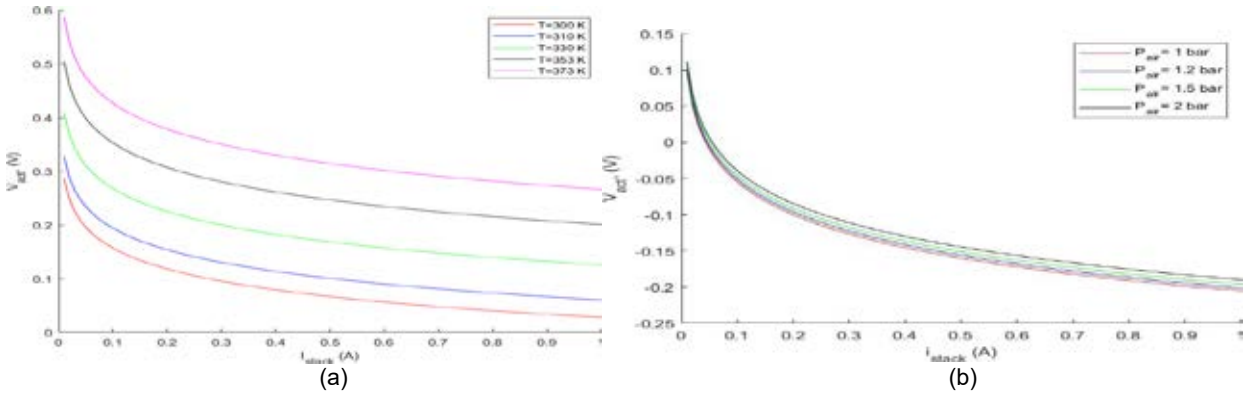
Fig. 3. Polarization curves obtained via some different algorithms (a) conditions #1, (b) conditions #2



(a) (b)

Fig. 4. PEM fuel cells' polarization curves for (a) different temprature conditions, (b) different pressure conditions

To furtherly examine the operational parameters, Fig. 4 (a) presents V-I polarization curves under five different temperature conditions, demonstrating the critical role of temperature in improving reactant distribution and reducing concentration losses. These enhancements lead to better system efficiency and highlight the importance of precise thermal management. Complementing this, Fig. 4 (b) examines the effect of varying pressure, with V-I polarization curves under four pressure conditions. The results reveal that increasing pressure significantly reduces ohmic and concentration losses, thus boosting overall system performance. Tables 2 and 3 provide the technical foundation and experimental setup for these findings. Table 2 summarizes the PEMFC stack's specifications, such as the number of cells, active cell area, Nafion membrane thickness, and rated power. These parameters form the backbone for accurate modeling and optimization efforts. Table 3 details the operating conditions, including pressure, temperature, relative humidity, voltage, and reactants, ensuring consistent and reliable testing protocols. The figures and tables provided can illustrate a clear narrative of how MVO outperforms traditional optimization methods like PSO and SCA. This is achieved through an effective reduction of losses, an enhanced reactant distribution and by stabilizing system efficiency, proving the MVO to be a powerful tool in advancing PEMFC performance. These visual and tabular results not only validate the study's approach but also underscore the practical potential of PEMFCs as a scalable and sustainable solution for clean energy applications.

Table 2. Technical data

Stack parameter	Value
Number of cells in a stack, cells	42
Active cell area (c m ^{2})	27
Nafion membrane thickness 1	127μm
Maximum current density Jmax (A c m$_{-2}$)	0.86
Rated power(W)	250

Table 3. Operating conditions

Parameters	Value
Pa (bar)	1-3
Pc (bar)	1-5
Stack temperature T (K)	343,15 - 353,15
Relative humidity in anode RHa	1
Relative humidity in cathode RHc	1
Voltage (V)	24
Maximum Current (A)	100
Reactants	H2 and Air

4. CONCLUSIONS

In this study, a 3-cell Proton Exchange Membrane Fuel Cell (PEMFC) prototype tailored for portable energy applications was successfully developed. By leveraging optimized Nafion 212 membranes and platinum-based catalysts, the system achieved a stable power output of 150 W under standard conditions. The system's efficiency and durability were enhanced through the measurement of key performance parameters, including pressure, temperature, and reactant flow, were carefully analyzed to enhance the system's efficiency and durability. The integration of advanced modeling tools, including MATLAB and SolidWorks, allowed for precise optimization of the PEMFC design. Notably, the serpentine flow channel configuration improved reactant distribution and water management, minimizing losses and ensuring stable operation over extended periods. The system demonstrated an electrical efficiency of approximately 50%, highlighting its potential for portable and remote energy solutions. Future research can focus on scaling the PEMFC design to accommodate higher power requirements, further reducing material costs, and exploring alternative catalyst compositions to enhance overall performance. These advancements would position PEMFCs as a practical and sustainable energy solution capable of addressing global energy challenges and reducing greenhouse gas emissions. This study draws attention to the critical role of innovation in the development of reliable, efficient, and scalable clean energy technologies.

ABSTRACT
This study presents a methodology for steady-state CFD simulations to analyze key combustion parameters, including flame temperature, velocity fields, and pollutant formation (CO_2, CO, and NO_x). The proposed approach provides researchers and engineers with an accessible framework for simulating complex fuel systems, facilitating improved system design and optimization. To assess its accuracy and practical applicability, the methodology is currently being tested in a real case study with unique characteristics. The simulation provides a comprehensive analysis of multiple combustion parameters. As examples, results show that blending hydrogen with methane increases the adiabatic flame temperature by 0.2% and 0.5% for hydrogen blends of 10% and 20% (by volume), respectively, and by 8.9% for pure hydrogen. The maximum CO_2 molar fraction decreases by 2.6% and 6.1% for 10% and 20% hydrogen blends, respectively, and is entirely eliminated with 100% hydrogen combustion. Additionally, temperature and pollutant concentrations were analyzed at the combustion chamber outlet. While some trends observed in the flame zone were confirmed, others exhibited different behaviors due to mixing, heat loss, and chemical kinetics along the flow path. These findings highlight the potential of hydrogen-enriched combustion for reducing pollutant emissions while emphasizing the importance of detailed spatial analysis in combustion studies.

Keywords: Computational Fluid Dynamics, Combustion, Methane-Hydrogen Blending.

1. INTRODUCTION

The ongoing global transition toward sustainable energy sources necessitates a deep understanding of alternative fuel systems to mitigate environmental concerns and promote cleaner energy solutions. Among these alternatives, hydrogen combustion stands out as a promising candidate due to its lower carbon footprint and potential as a renewable energy source. However, transitioning entirely to hydrogen presents several challenges, including infrastructure limitations, safety concerns, and economic viability. A practical intermediate solution is the use of hydrogen-enriched natural gas blends, which can reduce greenhouse gas emissions while ensuring compatibility with existing energy systems. By integrating hydrogen into the current natural gas network, this approach enables a gradual transition toward hydrogen-based energy without requiring immediate large-scale infrastructure changes.

Blending hydrogen with natural gas influences combustion characteristics, affecting flame stability, temperature distribution, pollutant formation, and overall system efficiency. While hydrogen-enriched combustion reduces CO_2 emissions due to the absence of carbon in hydrogen fuel, it can also impact NO_x emissions and alter flame behavior. Understanding these effects is critical for optimizing combustion performance and ensuring safe, efficient operation in industrial and power generation applications.

Computational Fluid Dynamics (CFD) simulations provide a powerful tool for analyzing the complex fluid dynamics and combustion behavior of hydrogen-natural gas blends. CFD allows researchers and engineers to model key parameters such as temperature distribution, velocity fields, and pollutant formation, offering valuable insights that can inform the design and optimization of combustion systems. Previous studies have demonstrated the effectiveness of CFD in predicting combustion performance, but further research is needed to validate simulation methodologies and assess their accuracy in real-world applications.

2. SYSTEM DESCRIPTION AND METHODOLOGY

2.1. Case Study Overview

This study focuses on an industrial drying process installed in a Portuguese industry, which utilizes a vertical drying oven with a recirculating combustion system. The system is designed to provide controlled heat for the drying process, optimizing energy efficiency while ensuring effective moisture removal from the processed materials. The drying oven is equipped with a burner coupled to a combustion chamber, where fuel is burned to generate heat. A portion of the combustion gases is reinjected into the chamber to improve thermal efficiency and reduce overall emissions.

At the combustion chamber outlet, a fan plays a crucial role in extracting air and combustion products, distributing the hot gases through ducts that supply heat to the drying process. This fan also facilitates the recirculation of air from within the drying oven back into the combustion chamber, further enhancing heat utilization. Any remaining air and exhaust gases are released through the system's chimney. This process is illustrated in Figure 1.

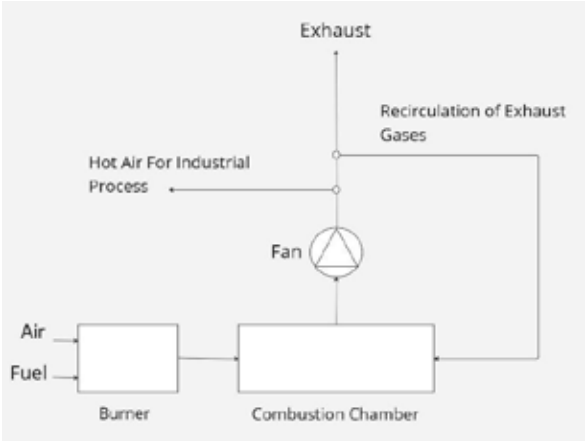

Fig. 1. System working principle

The numerical simulations carried out aim to determine the combustion characteristics inside the combustion chamber, whose geometry is presented in Figure 2, while also considering the burner's injection system. For this purpose, it was necessary to study each component of this system.

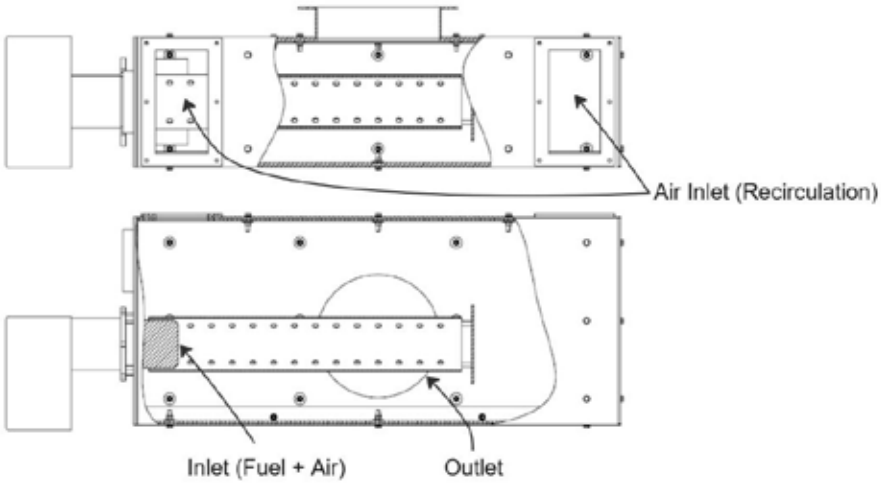

Fig. 2. Geometry of the combustion chamber

One of the key components to be studied is the burner's injection system, which consists of 8 injectors, hereafter referred to as primary injectors, that supply gas in the direction of the flow, and 6 injectors that supply gas in directions perpendicular to the flow, hereafter referred to as secondary injectors (see Figure 3). On one of the faces, there are also 4 openings for the passage of air into the zone where the fuel is injected perpendicular to the flow. This injection system also includes a turbulator, aimed at promoting the homogenization of the air-fuel mixture before it reaches the ignition electrode.

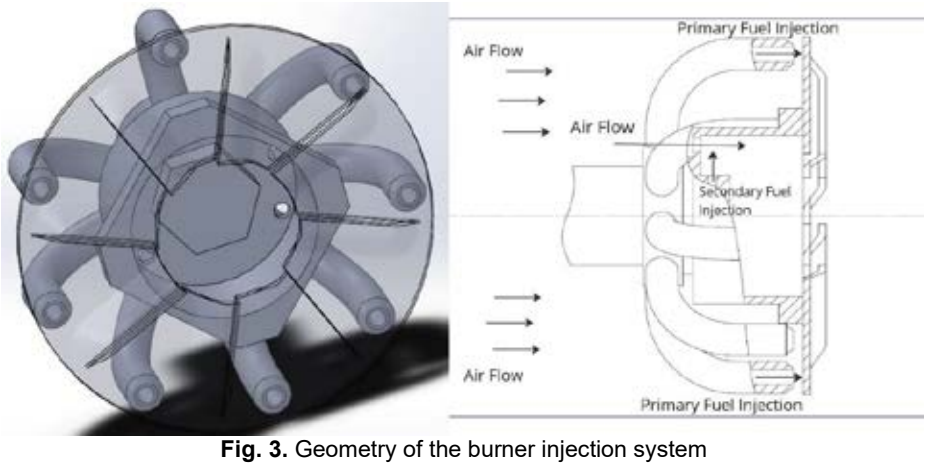

Fig. 3. Geometry of the burner injection system

2.2. Methodology

To support the CFD analysis of combustion in the chamber, a tool was developed to calculate the total fuel and air flow rates in the burner based on its operating power, the molar composition of the fuel, and the excess air percentage. Additionally, preliminary CFD simulations were conducted to examine the fuel flow within this specific injection system, aiming to determine the flow distribution at each injector outlet.

All CFD models in this study were developed using ANSYS Fluent [1]. For conducting combustion CFD simulations in this case study, the species transport model was employed. This model enables the simulation of mixing and chemical species transport by solving conservation equations that describe convection, diffusion, and reaction sources for each species involved in the process [2].

The combustion reactions were modeled using the Finite-Rate/Eddy Dissipation model, which is widely used in CFD combustion simulations as it accounts for both finite-rate chemical kinetics and turbulence effects. By combining finite-rate chemical reactions with turbulent mixing effects, this approach provides an accurate representation of combustion in turbulent flows.

Chemical modeling increases computational complexity as the number of species and reactions involved grows. To reduce the computational effort in numerical modeling, a reduced mechanism was proposed in [3] to describe the combustion of CH_4 and H_2, considering a significantly lower number of chemical species and reactions compared to the two previously identified detailed mechanisms. This kinetic mechanism is also capable of predicting NO_x (NO and NO_2) formation.

3. RESULTS AND DISCUSSION

In this section, a selection of results obtained from the simulations is presented, focusing on key parameters such as combustion characteristics, temperature distributions, and pollutant formation. Figure 4 illustrates an example of a temperature contour for the base scenario (combustion of 100% CH_4), generated using the ParaView postprocessing tool [4]. Although the temperature distribution in the flame region changes with fuel composition, the overall pattern remains quite similar across all scenarios.

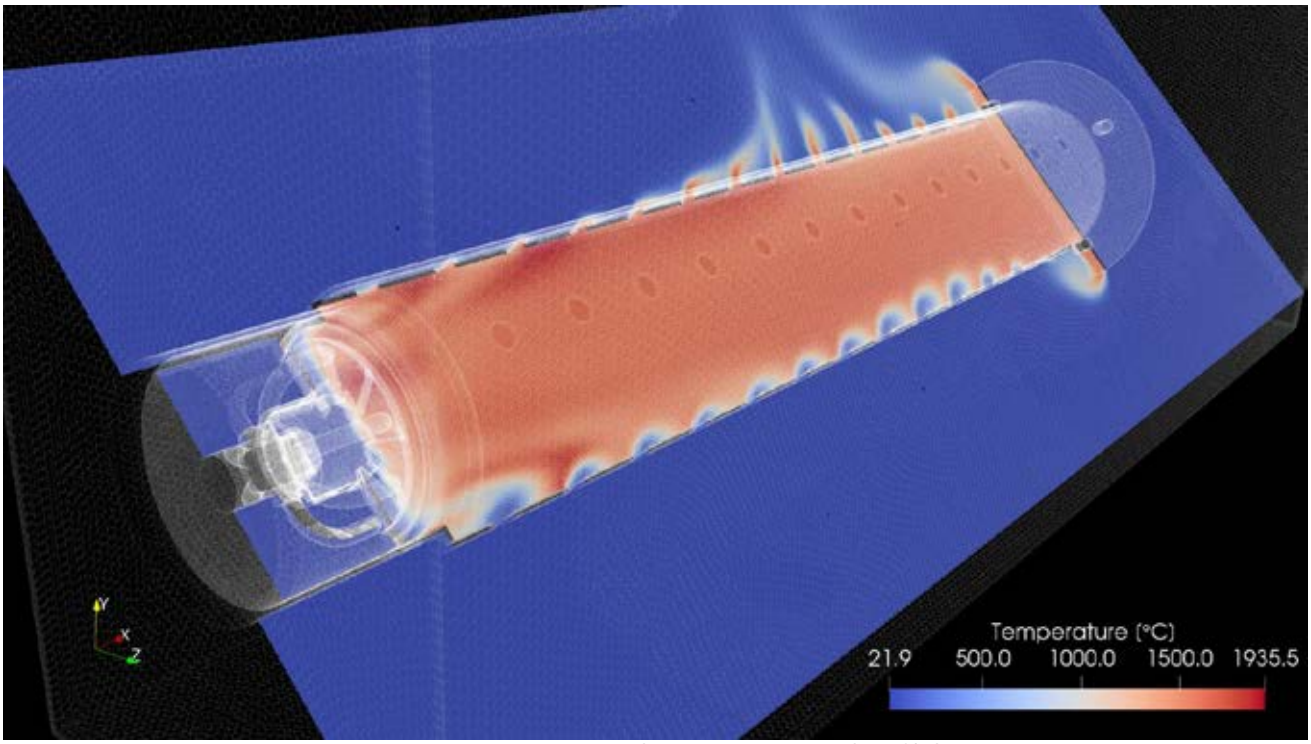

Fig. 4. Temperature contour for the combustion of 100% CH_4

To analyze the detailed temperature, pollutant, and H_2O formation values, selected maximum values obtained in the flame region are presented in Figure 5.

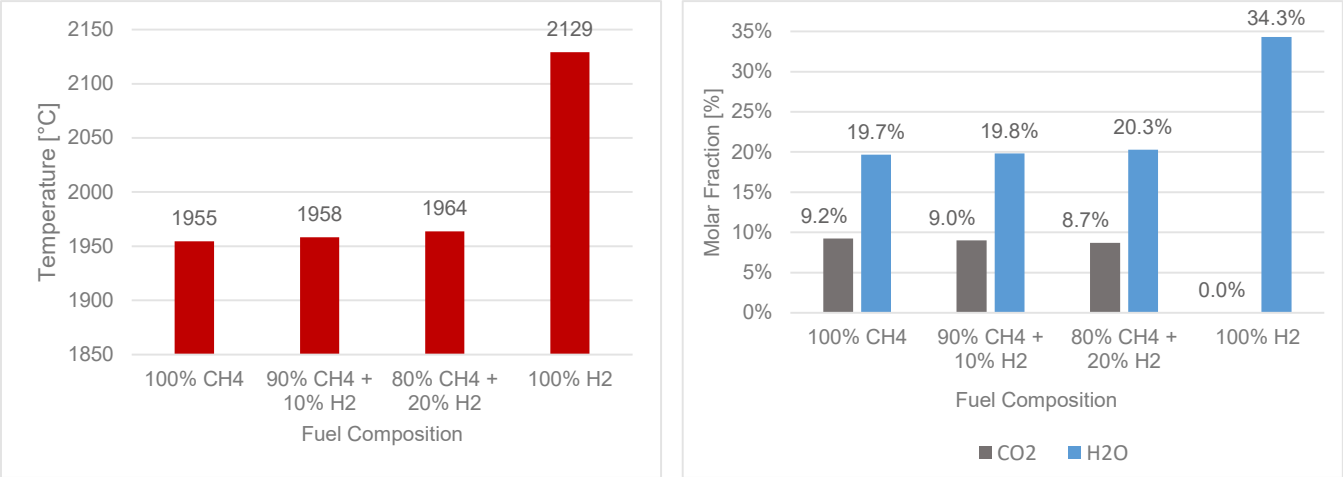

Fig. 5. Maximum temperature, CO_2 and H_2O mole fractions in the flame region

According to the results shown, the maximum flame temperature, increases with the higher percentage of H_2 in the fuel. For the air excess in this study (30%) and assuming excellent fuel-air mixture uniformity, lower maximum temperature values were expected. However, due to the non-uniform fuel distribution before the reaction zone, there are regions where the fuel-air mixture is richer (near stoichiometry), leading to higher combustion temperatures in those regions. The maximum increase in this parameter, compared to 100% CH_4, is approximately 9%.
The maximum CO_2 value in the flame decreases with the increasing percentage of hydrogen in the fuel, reaching zero for 100% H_2 combustion, as expected. Additionally, the maximum H_2O value increases with the higher percentage of hydrogen, showing a maximum increase of about 74% compared to 100% CH_4.
The results presented represent only a small portion of the study. This research includes a detailed analysis of the temperature field, velocity field, pollutant mole fraction fields, and water mole fraction fields. The maximum values obtained for each fuel composition were analyzed, along with the study of these quantities at the chamber outlet and for three different recirculation flow rates. The impact of pollutant mass fractions at the outlet enabled a decarbonization analysis. Additionally, profiles of these quantities along the flame region were plotted.

4. CONCLUSIONS

According to all the results obtained from the CFD study for this case, it can be concluded that blending up to 20% hydrogen with CH_4 can reduce CO_2 formation by up to 7.5%. The addition of hydrogen to the fuel increases the flame temperature, but the outlet temperature remains unchanged. Even in the case of 100% hydrogen combustion, the outlet temperature can be similar to that obtained with 100% CH_4 combustion or even slightly lower. Possible reasons for this behavior may be related to the thermal capacity and composition of the combustion gases. It was also observed that hydrogen blending increases NO_x formation in the flame region, although the values at the outlet remain similar.
To further validate the numerical modeling methodology, experimental studies will be conducted. Additionally, the development of auxiliary tools to provide accurate inputs for the CFD model was crucial in ensuring reliable simulations and meaningful conclusions.

ABSTRACT

The paper presents the results of studies on the evolution of phase transformations in the Mg-7%Ni-3%Ce system under successive exposure to mechanical fusion (MF) and spark plasma sintering (SPS), with a focus on structural changes after the SPS stage. During the MS stage, the gradual formation of phases from the initial components to the intermetallic compounds Mg_2Ni and $CeMg_3$ was observed, accompanied by the transformation of the magnesium crystal lattice and an increase in structural defects. Notably, the SPS process played a key role in stabilizing the material structure. During sintering, phase transformations were completed, leading to the formation of a dense, multicomponent microstructure with a uniform distribution of intermetallic compounds. SPS facilitated grain growth and densification, as well as the elimination of defects accumulated during the MF stage. The average crystallite size after sintering ranged from 20 to 70 nm, depending on the processing conditions. Thus, the combined application of MF and SPS allows for controlled management of the phase composition and microstructure of the material, ensuring the development of stable hydrogen-absorbing alloys with improved properties.

Keywords: mechanical fusion, spark plasma sintering, phase transformations, intermetallic compounds.

1. INTRODUCTION

Magnesium-based (Mg) metal hydride materials have attracted significant attention due to their high hydrogen storage capacity (up to 7.6 wt.%), availability, and environmental safety [1-4]. However, their practical application is limited by the high thermodynamic stability of the hydride phase, which requires elevated temperatures for effective sorption kinetics, as well as low resistance to atmospheric contaminants, leading to the degradation of sorption properties [5-9]. Methods for improving the hydrogen sorption kinetics of Mg-based materials include alloying with transition metals [10], nanostructuring of Mg via mechanical synthesis in ball mills [11–13], and severe plastic deformation [14-16]. The incorporation of transition metals (e.g., Ni) and rare earth elements (RE) promotes the formation of intermetallic phases such as Mg_2Ni, $Mg_{12}Ni_6$, and CeNi, which exhibit enhanced hydrogen sorption and desorption kinetics [17]. Additionally, RE elements stabilize the fine-grained structure and reduce the hydrogen desorption temperature through the formation of new intermetallic phases, such as $REH_{2.73}$ [18-20]. The combination of mechanical fusion (MF) and spark plasma sintering (SPS) offers promising opportunities for alloy consolidation. However, research in this field remains insufficient, necessitating a deeper investigation into the effects of MF and SPS on the structure, phase state, and properties of these alloys.

During SPS, structure stabilization, defect elimination, material densification, and uniform distribution of intermetallic compounds occur. A key advantage of SPS is its ability to prevent excessive oxidation, which may be observed at high ball-to-powder mass ratios (BPR) during MF. Furthermore, SPS facilitates the formation of a dense microstructure with low porosity and minimal residual stresses, which positively affects the mechanical and functional properties of the material [21]. The novelty of this study lies in the investigation of the phase transformation evolution in the Mg-7%Ni-3%Ce system under successive application of MF and SPS, with an emphasis on structural changes after SPS. For the first time, the influence of sintering conditions on the formation of the CeNi phase, which was absent after MF but appeared as a result of SPS at 500–560 °C, has been studied. The obtained results demonstrate the possibility of targeted control over phase evolution and improvement of hydrogen-absorbing properties through the combined application of MS and SPS.

2. MATERIALS AND METHODS

As the starting materials, high-purity metal powders were used: magnesium powder (GOST 6001-79, grade MPF-3, purity 99%, particle size 120–180 μm), metallic cerium (purity 99.99%, particle size 70 μm), and nickel carbonyl powder (grade PNK-UT3, purity 99.99%, particle size 20 μm) (supplier: Suoyi, China).

Based on the analysis of technical literature, the Mg-7%Ni-3%Ce composition was mixed in optimally predetermined proportions and then successively processed in a Retsch PM100 planetary mill under the parameters specified in Table 1.

Table 1.

Sample composition	Ball-to-powder ratio (BPR)	Milling time (h)	Rotation speed (rpm)
Mg-7%Ni-3%Ce	10:1,20:1,30:1	5 and 10	350 and 450

SPS was carried out at 500–560 °C under a pressure of 1 MPa for 5 minutes. Phase composition analysis was performed using X-ray diffraction (XRD) on an EMPYREAN (Panalytical) diffractometer with Cu-Kα radiation in the range of 20–90° 2θ (step size 0.013° 2θ). The experimental parameters were as follows: 45 kV, 40 mA, divergence slit 1°, incident beam mask 15, and exposure time 30.6 s. Data processing was conducted using the HighScore software with the Crystallography PDF-4 AXIOM database.

To complement the XRD data and calculate crystallite sizes, scanning electron microscopy (SEM) was performed using a Hitachi TM4000plus. The studies included topographic and compositional contrast, energy-dispersive spectroscopy (EDS), and particle size measurements. Morphological and elemental analysis was conducted on four randomly selected areas of each sample.

3. RESULTS AND DISCUSSION

XRD analysis confirmed that MF induces significant phase changes in the Mg-Ni-Ce system. At a BPR of 30:1 and a milling duration of 10 hours, a significant decrease in the intensity of Mg peaks was observed in Fig. 1a, indicating an increase in structural defects. After SPS (Fig. 1c), the high degree of crystallinity of these phases was confirmed by the presence of sharp and well-defined peaks in the diffraction patterns. Structural changes related to the percentage content of alloying elements in the samples are also evident.

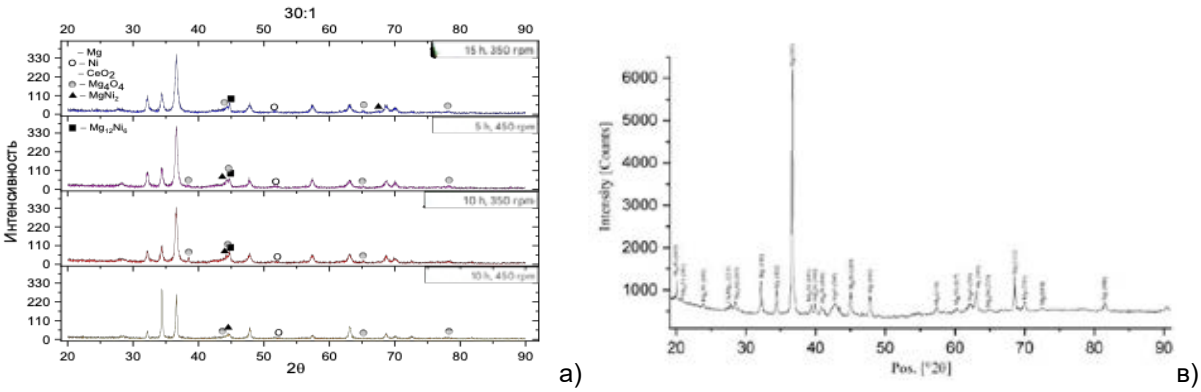

Fig. 1. a) Diffraction patterns of the studied PS of the Mg-7%Ni-3%Ce system after MS, grinding ball ratio – 30:1 c) Diffraction pattern of the Mg-7%Ni-3%Ce sample after SPS.

After IPS, the CeNi phase appeared, which was absent after MF. At a temperature of 500-560 °C, a uniform distribution of components occurred, which prevented the formation of large oxide phases.

4. CONCLUSIONS

Thus, the study of phase transformations in the Mg-7%Ni-3%Ce system during mechanical fusion (MF) and spark plasma sintering (SPS) showed that their sequential application allows for effective control of the phase composition and structure of the material. X-ray phase analysis and scanning electron microscopy confirmed that an increase in the ball-to-powder mass ratio, mechanical treatment duration, and rotation speed accelerates the formation of intermetallic compounds Mg_2Ni and CeNi, which catalyze hydrogen sorption processes. Further work on dispersion and sorption/desorption is planned.

ABSTRACT
Dibenzyl toluene is an organic compound that can store hydrogen via chemical bonding of hydrogen having a storage capacity of 9 mol_{H2}/mol_{DBT} to form perhydro-dibenzyl toluene. When required, the stored hydrogen can be retrieved by supplying thermal energy, however, for a continuous hydrogen supply as required by fuel cell applications, the degree of dehydrogenation can go well below 30% making the process highly inefficient as well as uneconomic. This study introduces the use of in-line distillation within the dehydrogenation process to enhance the degree of dehydrogenation to a minimum of 80%. This will highly increase the process efficiency while reducing the cost incurred for hydrogen release.

Keywords: LOHC, perhydro-dibenzyl toluene, degree of dehydrogenation, hydrogen, fractional distillation

1. INTRODUCTION

High-temperature heat waves are striking across the globe and one of the fundamental reasons is the global warming [1], [2]. To overcome this issue, the highest priority is being given to renewable energy resources. However, the renewable energy resources have high fluctuations with seasonal variations and other weather conditions. The fluctuations in the energy from these renewable energies can be stored as hydrogen gas. This concept of storing seasonal fluctuation energy in the form of hydrogen in form of chemical hydrides and using it for transportation purposes dates back to early 1980's [3], [4], [5], [6]. However, its realization at that time was not aggressively pursued due to economic issues. The price of renewable energy is considerably higher than the conventional energy generation via fossil fuel [3]. As a result of these techno-economic issues at that era, the concept of hydrogen storage from renewable energies was not a pressing issue. Research continued in this area but at a sluggish rate. One such published work during this time is done by S. Yolcular and Ö. Olgun where the hydrogen storage is classified as chemical hydrides [7]. Recently, due to the visible outcome of global warming, energy production from renewable energy resources became the focal issue throughout the globe with renewable energy production growth increasing exponentially since 2009 with 12.2% increase recorded for the year 2018 [8]. Due to this, the concept hydrogen storage was re-introduced in 2011 by D. Teichmann, W. Arlt, P. Wasserscheid, and R. Freymann classified as Liquid Organic Hydrogen Carrier (LOHC) [9]. Their research group have made significant commendable advances in this topic with a few notable ones given in [9], [10], [11], [12].
Various methods can be used for the storage of hydrogen including compression, liquefaction, adsorption, chemical/metal hydrides. Compression of hydrogen requires a high pressure of 100-400 bar and exhibits a low volumetric and gravimetric storage density [9], [13], [14]. Liquefaction of hydrogen is a well-established industrialized process. However, it is an energy-intensive process due to an extremely low boiling point of -253 °C at 1 bar pressure and moreover, it does not cool down during the throttling process [13]. Hydrogen can also be stored via adsorption on an adsorbent surface, but it is only implemented lab-scale and is highly expensive with very less hydrogen storage capacity [13]. Hydrogen is also stored in the form of metal hydrides by forming chemical bonds with the metal which results in a high energy density but results in a high energy demand for dehydrogenation with very sluggish kinetics [13]. Another way of hydrogen storage is by chemically bonding the hydrogen with light elements to form chemical hydrides which are generally liquid at ambient conditions. However, most of the suggested chemical hydrides for hydrogen storage including methanol, ammonia, and formic acid are synthesized via methane gas [13].
LOHC materials are similar to chemical hydrides with an additional quality to endure a fully cyclic hydrogenation and dehydrogenation and retain their original structure [10], [13]. Due to this definition, methanol and formic acid are not considered to be LOHC material despite being organic and liquid at ambient conditions [13]. Bourane et al. have considered LOHC materials to be a subset of chemical hydrides [14]. LOHC materials store hydrogen by chemically bonding the hydrogen atoms to either of the double-bonds between carbon atoms of aromatic compounds. Dehydrogenation of LOHC+ materials results in pure hydrogen at the output which is highly suitable for fuel-cell applications.
One of the methods to obtain hydrogen gas is to produce it via surplus energy from various fluctuating renewable energy resources. The hydrogen produced can be stored and/or transported as chemical energy in the form of hydrogenated Liquid Organic Hydrogen Carrier (LOHC) [11], [15]. The hydrogenated LOHC referred to as LOHC+ can be stored,

transported, and it is economically more viable over long-distance transportation [16]. The dehydrogenation of LOHC+ is an endothermic process requiring 53~65 kJ/mol_{H_2} depending on the LOHC material used.

Brückner et al. proposed the use of heat transfer fluids; Marlotherm(s); as LOHC materials. They tested the dehydrogenation of H12-MLH at 270 °C and H18-DBT at 290~310 °C in presence of platinum on alumina catalyst and culminated these LOHC materials to be better than the previously reported materials discussed as NEC, TOL, and NPT [17]. Their mixtures appear to be more attractive LOHC material for hydrogen storage [18]. Among al the different LOHC materials, dibenzyl toluene (DBT) is an optimal selection due to high storage capacity, availability and finally its recovery after dehydrogenation [19]. The dehydrogenation reaction kinetics is very slow and keeps declining as the degree of dehydrogenation increases. For a small-scale plug flow reactor, the reaction kinetics obtained experimentally by S. Park et al. is given in Eq. (1) [20].

$$r = 5.4 \times 10^{11} e^{\frac{-171.72}{RT}} C_{H18-DBT}^{2.395 \pm 0.045} \quad (1)$$

With this reactor the only 30% degree of dehydrogenation (DoD) was achieved with an elapse of almost 5 hours. The reactor kinetics are highly improved using a rotating bed reactor studied by J. Lee et al. [21]. Despite the signification improvement in reaction kinetics, almost double that of previous study, the maximum DoD achieved was 50%. In this study, a new process design to maximize the degree of dehydrogenation by increasing the H18-DBT concentration at the reactor inlet via distillation column is proposed. The distillation column will be utilized to separate the two miscible hydrogenated and dehydrogenated forms of DBT according to the boiling points. It is further improvised to utilize dual distillation columns to investigate the possibility of further improvements.

2. MATERIALS AND METHODS

2.1. Material Properties

Three materials have been defined, hydrogen, H18-DBT, and H0-DBT. Due to the complexity of the problem, the reaction intermediate, H12-DBT and H6-DBT, are not considered in this study. The properties of DBT are evaluated using the thermodynamic data engine (TDE) and is validated as given in [19]. The LOHC materials have varying properties when hydrogenated which also serves to measure the degree of hydrogenation/dehydrogenation. For this analysis the most important property is the binary mixture liquid/vapor transition temperature at different mole ratio of H18/H0-DBT and is shown in Fig. 1.a.

2.2. Process Design and Simulation

Three different processes are modeled to simulate the dehydrogenation process as shown in Fig. 1. The first process is the conventional process where the flow passes through the dehydrogenation reactor and hydrogen is obtained. The second is the proposed process utilizing the distillation column to keep highest concentration of H18-DBT at the reactor as the H0-DBT is continuously removed from the product mixtures via the distillation column. The third process serves as an extension to the proposed concept in which two distillation columns are used in series to highly enhance the concentration of the dehydrogenated DBT at the outlet increasing the H18-DBT concentration at the reactor. The corresponding parameters for the simulation are compiled in Table I.

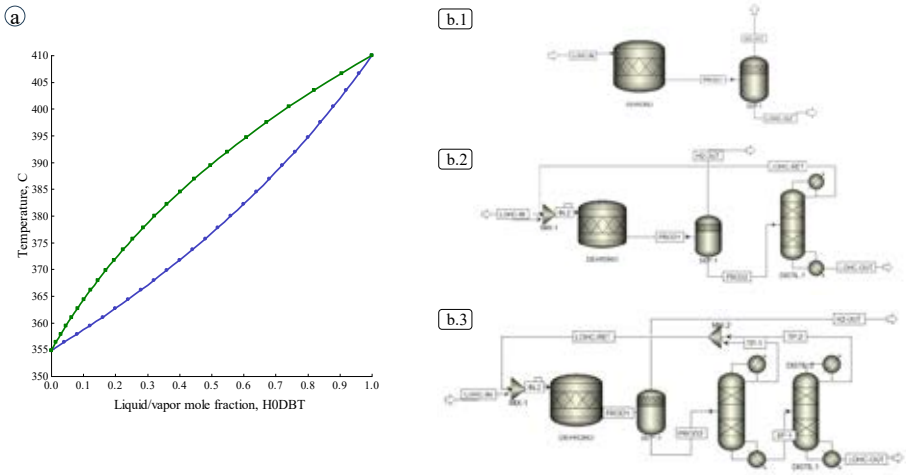

Fig. 1 a. Liquid/Vapor transition temperatures between mixtures of H18/H0-DBT for varying mole fractions of H0–DBT, b. Process Layout used for simulation of different systems, a. conventional, b. with single distillation column, and c. with dual distillation column.

Table 1. Simulation Parameters used for analysis

Variable	Value	Units
Dehydrogenation Reactor		
Temperature	290	°C
Pressure	1	bar
Reaction Yield	30	%
Single Distillation Column		
No. of stages	20	
Feed stage	12	
Feflux ratio	1	
Distillate-feed ratio	0.8	
Condenser pressure	1	bar
Reboiler Pressure	1.1	bar
Dual Distillation Column		
No. of stages	12	
Feed stage	2	
Feflux ratio	1	
Distillate-feed ratio	0.9	
Condenser pressure	1	bar
Reboiler Pressure	1.1	bar

3. RESULTS AND DISCUSSION

The different configurations are simulated and compared with the conventional system for hydrogen release rate when supplied with a continuous LOHC supply at a rate of 10 mol/hr. The hydrogen release obtained is shown in Fig. 2.

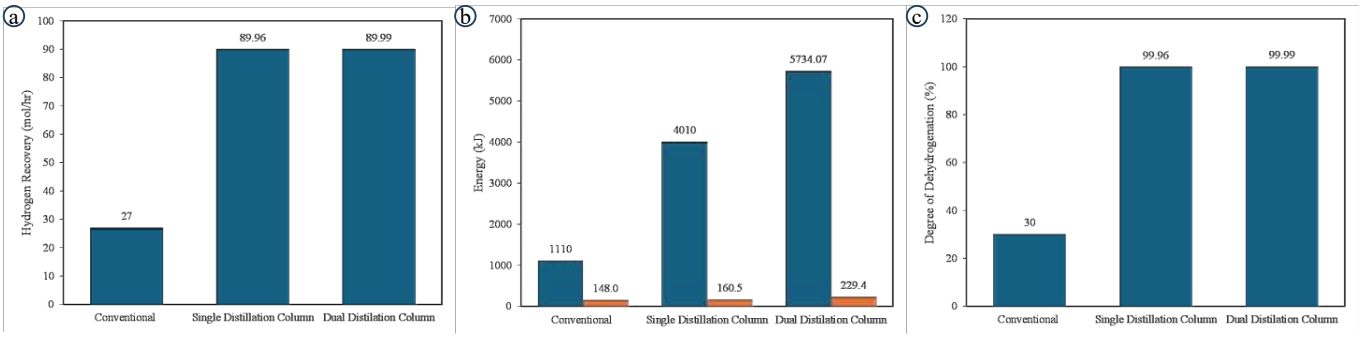

Figure 2. a. Hydrogen recovery achieved via dehydrogenation of DBT for the different process, b. Total energy and the specific energy required for different process to release hydrogen, c. Degree of dehydrogenation achieved for different process layouts using a constant reactor yield of 30%.

By adding distillation process in-line with the dehydrogenation reactor highly enhances the maximum hydrogen release rate from 27 mol/hr to 89.96 mol/hr. However, an insignificant increase is obtained using a dual distillation column. Likewise, the energy requirement also increase as the heat of reaction is the same but the total amount of hydrogen produced increases. Moreover, the distillation column also requires energy for the reboiler making this process more energy intensive increasing the energy required per unit mole of hydrogen from 148 kJ/mol to 160.5 kJ/mol as shown in Fig. 6. Following the trend, the dual distillation increases the energy requirement even higher up to 229.4 kJ/mol.

The degree of dehydrogenation increases tremendously by employing a distillation column as shown in Fig.7. using the conventional method, that is, a batch type system, a maximum of 30% dehydrogenation occurs since the reaction yield is set at 30% however, by employing a distillation column, the degree of dehydrogenation goes beyond 99%. This is probably due to the recirculation of H18-DBT back to the dehydrogenation reactor.

4. CONCLUSIONS

A new process to employ in-line distillation column with the dehydrogenation reactor is proposed. Employing a single distillation column highly enhances the hydrogen produced as well as the degree of dehydrogenation with a cost of an increased energy demand of 20 kJ/mol. Using a dual distillation column gives more adverse effects and hence is not viable.

This study is continued further with the following improvements:

- Reaction intermediates will be considered.

- Investigate the various parameters of the distillation column for optimal hydrogen recovery.
- Process optimization to achieve maximum degree of dehydrogenation for minimum energy consumption.
- The reaction kinetics be incorporated to accommodate the changes in input concentration.

ABSTRACT
Integrating metal hydride-based hydrogen storage tanks with PEM fuel cells offers a transformative solution for sustainable energy applications, particularly in underwater environments. Metal hydrides are recognized for their high volumetric hydrogen storage capacity, safety, and structural stability under varying pressure conditions. This study aims to integrate and optimize such systems by addressing critical challenges in hydrogen desorption processes, particularly in the endothermic desorption phase. The hydrogen storage system is integrated with PEM fuel cells to ensure a continuous energy supply in underwater conditions. A system architecture showing a flow diagram, visualizing energy and mass flows while incorporating thermal and water management strategies to maximize system reliability and efficiency.
Keywords: Metal hydride; Hydrogen storage; PEM fuel cell; Underwater hydrogen energy system

1. INTRODUCTION

A central challenge in hydrogen-based energy systems is hydrogen storage, which is crucial in enabling efficient and safe utilization. Among various storage methods—such as compressed gas, cryogenic liquid, and solid-state storage—metal hydrides have gained significant attention due to their high volumetric hydrogen density, reversibility, and ability to operate at relatively moderate pressures and temperatures. For underwater hydrogen energy systems applications [1], metal hydride-based storage systems offer significant advantages, such as safety, structural stability under pressure, and integration with thermal management systems. While metal hydrides provide an effective storage medium, optimizing their thermodynamic and reaction kinetics performance is essential to ensure efficient hydrogen desorption and a reliable supply to PEM fuel cells at operational temperatures.

Integrating metal hydride storage tanks with PEM fuel cells presents a promising approach to address these challenges. PEM fuel cells are known for their high efficiency, rapid response time, and ability to generate clean electricity, making them ideal power sources for underwater systems. However, the endothermic nature of the hydrogen desorption process necessitates effective thermal management to sustain continuous operation.

It is known that numerous studies have been conducted on hydrogen storage in metal hydride-based hydrogen storage systems, with the majority concentrating on hydrogen absorption reactions [2]. However, numerical investigations focusing on the hydrogen desorption process remain comparatively scarce. Therefore, the primary goal is to optimize thermodynamics, desorption kinetics, and thermal management of metal hydride-based hydrogen storage systems. This study focuses on integrating and optimizing a metal hydride-based hydrogen storage system with a PEM fuel cell to enhance system performance in underwater environments. A key aspect of this research is addressing thermal and water management strategies to ensure a stable and efficient hydrogen supply. To illustrate the system design and functionality, a flow diagram is presented, mapping energy and mass flows within the integrated system.

2. DESORPTION CALCULATIONS OF METAL HYDRIDE-BASED HYDROGEN STORAGE SYSTEMS

Hydrogen storage in metal hydrides (such as $LaNi_5$) is governed by the reversible absorption and desorption of hydrogen molecules. The fundamental reaction is shown by Eq. (1):

$$M + \frac{x}{2} H_2 \leftrightarrows MH_x \tag{1}$$

Hydrogen absorption and desorption in metal hydrides is a reversible process that allows for efficient hydrogen storage and release. The absorption reaction occurs when a metal or metal alloy reacts with hydrogen to form a metal hydride, releasing heat in an exothermic process.

The hydrogen desorption rate is estimated using the following equation Eq. (2) [3]:

$$n_d = C_d exp\left(\frac{-E_d}{RT_{MH}}\right)\left(\frac{P_g - P_{eq}}{P_{eq}}\right)(\rho^s - \rho^0) \tag{2}$$

where n_d is the rate of H_2 desorption in kg/m^3.s, C_d is desorption rate constant in 1/s, E_d is activation energy for desorption reaction in J/mol, R is the universal gas constant in J/mol.K, T_{MH} is the temperature of the metal hydride tank in °C or K, P_g is the pressure of the metal hydride tank in bar, P_{eq} is the equilibrium pressure at temperature T, ρ^s is the density of saturated metal hydride material in kg/m^3 and ρ^0 is the initial density of metal hydride material in kg/m^3.

The equilibrium pressure, P_{eq}, is related to the changes in enthalpy ΔH and entropy ΔS, which are functions of temperature and can be estimated by the van't Hoff equation, i.e., Eq. (3):

$$ln(P_{eq}) = \frac{\Delta H}{RT} - \frac{\Delta S}{R} \quad (3)$$

Once the rate of desorption is found, the heat required during the endothermic reaction of hydrogen desorption is calculated by Eq. (4) [4]:

$$Q_{des} = \dot{m}_{H_2}\Delta H_{des} + m_{MH}c_{P_{MH}}\frac{dT_{MH}}{dt} + m_{H_2}c_{P_{H2}}\frac{dT_{H_2}}{dt} \quad (4)$$

where Q_{des} is the required heat for desorption in W, $\dot{m}_{H_2}$ is the mass flow rate of hydrogen released from a metal hydride tank in g/s, m_{MH} is the mass of metal hydride material in g or kg, $c_{P_{MH}}$ is the heat capacity of metal hydride material in J/kg.K, T_{MH} is the temperature of the metal hydride tank in °C or K, m_{H_2} is the mass of hydrogen in g or kg, $c_{P_{H2}}$ is the heat capacity of hydrogen in J/kg.K and T_{H_2} is the temperature of hydrogen in °C or K.

2.1. Design Considerations and Hydrogen Consumption Analysis of a PEM Fuel Cell Stack

Before performing these calculations, the mass flow rate of hydrogen released from the metal hydride-based storage system must be determined. This requires selecting a PEM fuel cell system's power output, design parameters, and operating conditions to estimate hydrogen demand. A PEM fuel cell stack with a power output of 60 kW is chosen for an underwater application. It is selected that the system will operate for 10 hours. The design parameters and results of different cases of the PEMFC stack are listed in Table 1.

Table 1. Design Parameters and Results of Different Cases

Parameters	CASE 1	CASE 2	CASE 3	CASE 4	CASE 5
Net Power Output of a PEMFC Stack (kW)	60	60	60	60	60
Voltage Output of a PEMFC Stack (V)	100	125	150	100	100
Current Output of a PEMFC Stack (A)	600	480	400	600	600
Cell Voltage (V/cell)	0.60	0.60	0.60	0.55	0.50
Current Density (A/cm^2)	1.5	1.2	1	1.5	1.5
Stoichiometry of Hydrogen	1.05	1.05	1.05	1.05	1.05
Stoichiometry of Oxygen	1.2	1.2	1.2	1.2	1.2
Operation Duration (hr)	10	10	10	10	10
Stack Temperature (°C)	70	70	70	70	70
Ambient Temperature (°C)	25	25	25	25	25
Results	**CASE 1**	**CASE 2**	**CASE 3**	**CASE 4**	**CASE 5**
Heat duty of desorption (kW)	123.8	123.9	123.8	125.6	127.28
Number of cells	167	209	250	182	200
The mass flowrate of hydrogen (g/s)	1.06	1.06	1.06	1.16	1.27
The heat generated in Fuel Cell (kW)	84.7	84.9	84.4	97.7	113.4

Considering these design bases, one can calculate the amount of hydrogen required by the PEM fuel cell stack using Eq. (4):

$$\dot{m}_{H_2} = S_{H_2} \times \frac{I_{stack}N_{cell}}{2F} \times MW_{H_2} \quad (4)$$

Where $\dot{m}_{H_2}$ is the flowrate of hydrogen supplied to the PEMFC stack in g/s, S_{H_2} is the stoichiometry of hydrogen, I_{stack} is the current of PEMFC stacks in A, N_{cell} is the number of cells of PEMFC stacks, F is the Faraday constant in C, MW_{H_2} is the molecular weight of hydrogen in g/mol.

Moreover, the number of cells in each stack is calculated using Eq. (5):

$$N_{cell} = \frac{Total\ voltage\ output}{Cell\ voltage} \quad (5)$$

Case 1 is chosen as the primary case for evaluation. As a result, the fuel cell stack is calculated to contain 167 cells. Using Eq. (4), the hydrogen mass flow rate required for the stack is determined to be 1.06 g/s. The other cases were designed while keeping the active area of the fuel cell at 400 cm^2 because of the electrode manufacturing technology [5].

3. SYSTEM ARCHITECTURE OF THE INTEGRATED METAL HYDRIDE AND PEM FUEL CELL STACK

Fig. 1 presents a flow diagram of the proposed system architecture to provide a clear understanding. This illustration offers an in-depth view of the interaction between the metal hydride-based hydrogen storage tank and the PEM fuel cell stack.

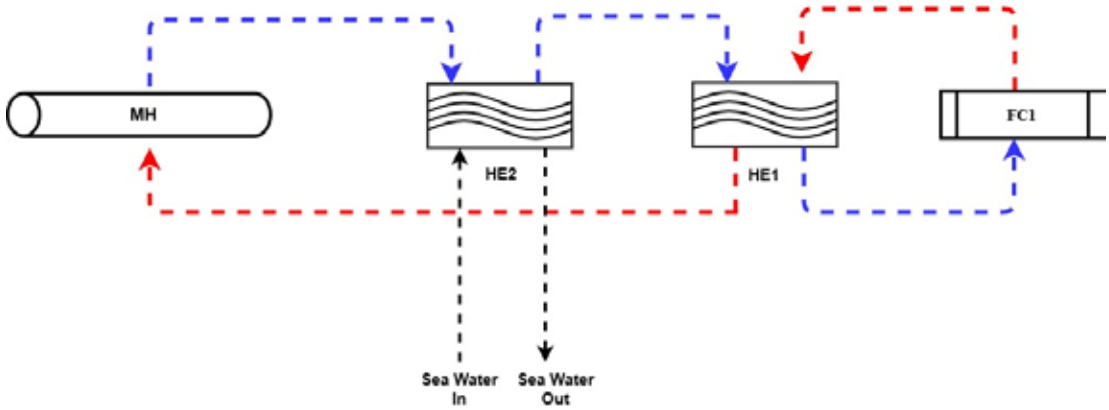

Fig. 1. System architecture of PEM fuel cell stack with metal hydride

The heat management system in this system is designed to maintain thermal balance during hydrogen desorption and fuel cell operation. The system includes a metal hydride tank (MH) for storing and supplying hydrogen. A PEM fuel cell stack (FC), delivering 60 kW, generates electricity by electrochemical reaction. Heat is required to release hydrogen from the metal hydride tank during hydrogen desorption. This heat is provided by a hot water circulation system, depicted by the red dashed lines in the diagram. Hot water flows through the MH tank, transferring thermal energy to the hydride material to facilitate hydrogen release. After absorbing heat from the MH tank, the water cools down and is recirculated back to HE2. The system integrates seawater cooling to manage waste heat effectively. Seawater flows through HE2, which uses the seawater to cool or heat the water circulating in the system. This closed-loop circulation ensures a continuous heat supply to the MH tank during desorption. Proper heat management in the MH tank is critical for maintaining the efficiency of hydrogen release and preventing thermal stress on the system components.

Once desorbed, the hydrogen flows to the PEM fuel cell stack (FC), generating electricity. The fuel cell produces waste heat as a byproduct of the electrochemical reaction. This heat is managed by the same hot water loop, which removes excess heat from the fuel cell stack to prevent overheating. The heated water from the fuel cell stack is directed to heat exchanger HE1, which is cooled before recirculating.

4. CONCLUSIONS

The hydrogen desorption process in a metal hydride-based storage system is criticalin enabling efficient hydrogen utilization for power generation, particularly when integrated with PEM fuel cells The desorption process is inherently endothermic, requiring a carefully designed heat management system to provide the necessary thermal energy while maintaining optimal operational conditions across all system components. The discussion so far has encompassed the system's architecture, thermodynamic calculations for desorption, and the role of the heat management infrastructure.
Moreover, the hydrogen desorption system architecture integrates thermodynamic principles, advanced material properties, and efficient heat management to facilitate the reliable delivery of hydrogen to PEM fuel cells. The design demonstrates a sustainable and scalable solution for hydrogen-based energy systems, with the potential for further optimization to meet varying operational demands and environmental conditions. The foundation is laid for improving hydrogen energy systems' overall efficiency, sustainability, and practicality through the combined understanding of system architecture and desorption calculations.

ABSTRACT
Ethylenediamine bisborane (EDAB) possesses a relatively high hydrogen storage capacity, and the hydrogen can be liberated via hydrolysis using a suitable catalyst. In this work, Palladium (Pd) was deposited on nickel foam (Pd/Ni foam) for EDAB hydrolysis to produce hydrogen. For hydrolysis of EDAB solution approximately 5-6 equivalent moles of hydrogen is generated and lower apparent activation energy of 30.88 kJ·mol-1 were achieved. Moreover, 79.3 % HGR was still maintained for Pd/foam Ni after five cycles, which disclosed the good cycle stability. The enhanced catalytic performance might be due to the smaller particle size, supplying more active sites.

Keywords: EDAB, Catalytic hydrolysis,nickel foam

1. INTRODUCTION

Today, energy consumption has increased with the development of technology and the human population. Most of the energy needs are met from fossil fuels. Considering the environmental effects of fossil fuels, it is necessary to turn to renewable energy sources. Hydrogen, the most abundant chemical element in the universe, is one of the renewable energy sources and has the potential to meet global energy needs in an environmentally friendly way. Hydrogen (H_2,) which is not found in pure form in nature, is abundant in water, natural fuels containing carbon,hydrogen,nitrogen (C-H-N) (such as coal, natural gas, etc.), and many chemical raw materials. In addition to hydrogen production, it must be stored in materials that can release hydrogen safely and efficiently when needed to adapt it to our daily life. In addition, suitable storage materials must be used for hydrogen energy in fuel cell systems, which are considered to be the future technology. Today, H_2, which is produced for energy production, is stored by two methods: physical and chemical storage. Compressed form storage, a commonly used type of physical storage, contains significant risks, especially in the transportation and portable device sectors, due to security. For this reason, chemical storage materials that contain 7% and above H_2 by mass and can quickly release H_2 under suitable conditions have recently come to the fore. In particular, amine and alkyl amine boranes such as metal borohydride (such as Hydrazine borane, $NaBH_4$, $LiBH_4$, $Ca(BH_4)_2$), ammonia borane (NH_3BH_3) and ethylenediamine bisborane ($C2H_4(NH_2)_2(BH_3)_2$), which are boron-containing storage materials, have high mass [1,2]. They are very popular research areas with their hydrogen storage capacities.
Conventional catalysts include homogeneous catalysts such as acid and metal-based homogeneous catalysts; heterogeneous catalysts such as noble metals, transition metals, metal-free catalysts, metal-organic frameworks (MOFs), and so on[3]. At present, metal Ni-based catalysts are attracting attention due to their relatively low price and intense activity [4]. The hydrogen production reaction of EDAB hydrolysis is shown in Equation (1)

$$BH_3NH_2CH_2CH_2NH_2BH_3(aq) + 4H_2O \rightarrow BO_2NH_3CH_2CH_2NH_3BO_2(aq) + 5H_2(g) \text{ or } 6H_2(g) \quad (1)$$

The combination of the non-precious metal Ni with Pd can greatly improve the catalytic activity of cobalt, so more researchers have devoted their attention to the preparation and research of Ni-based catalysts. Okay et al. and Büşra et al. [5,6] prepared a novel noble metal Pd /TiO2, catalyst for catalytic hydrolysis of EDAB and its hydrogen production was found as 5 equivalent mole of hydrogen at 313 K. Murathan et al. [7,8] reported a range of Pd-Ni-Zr-B-O with different contents, including (40%Ni, 60% Zr by mass) and Pd-Ni-Zr-B-O (5% Pd, 38% Ni and 57% Zr by mass). All of these nickel series exhibit excellent hydrogen evolution reactivity. Karataş (2024) et al. [9] prepared Pd/GO-SO4 catalyst by chemical deposition. The concentration, deposition time and temperature EDAB had obvious effects on the catalytic activity. The hydrogen production was found as 6 equivalent mole of hydrogen. Therefore, it can be indicated that the development of highly active Pd /Ni catalysts has important research and practical value. To date, a large number of supported Pd-Ni catalysts in powder form have been prepared. However, powdered catalysts have some drawbacks such as being difficult to separate and easy to reunite. In the past few years, in order to solve the disadvantages of powdered catalysts, a lot of studies have been conducted to exploit the bulk supported catalysts. In this study, the chemical deposition route was adopted to manufacture Pd-Ni catalysts using nickel foam as a support (Pd/foam Ni). In the experiment, the depositional pH value was investigated for obtaining the optimal conditions. Different characterization methods were used to characterize the catalyst. The hydrolysis reaction kinetics, apparent activation energy and durability of the catalyst were also tested. The result showed that the Pd/foam Ni was an effective catalyst toward EDAB

hydrolysis.
This study aims to conduct dehydrogenation by catalytic vapor phase and low-temperature hydrolysis of ethylenediamine bisborane (EDAB), a compound in which hydrogen is chemically stored. The catalytic vapor phase experiments were carried out in a tubular-packed reactor. Nickel foam is used as catalyst support, and nickel/carbon foam electrochemical precipitation/coating is used. Low-temperature experiments will be carried out in a batch reactor with the same catalysts. As a result of experimental studies in which temperature, concentration, and amount of catalysis were chosen as experimental parameters, 5 equivalent mol of H_2 was produced at 80°C, where the hydrolysis reaction followed Langmuir-Hinshelwood kinetics, and the activation energy was 33.61 $kJ.mol^{-1}$. In addition, it was concluded that 7 equivalent moles of H_2 were produced at 300°C and 9.5 equivalent moles at 450°C in vapor phase dehydrogenation experiments.

2. EXPERIMENTAL

2.1. Synthesis of Nickel/Carbon Foam (Ni/C-Foam)

In the experimental studies, the carbon powder used to prepare nickel foam, which was determined as the support material, was supplied commercially. Nickel foam was synthesized under laboratory conditions by creating an electrochemical experimental system.
Polyurethane sponge/foam was selected as the first support layer where Nickel would be electrochemically deposited. Polyurethane foam was first kept in dilute 0.1 M HNO3. Then, it was cleaned by passing through pure water. The cleaned foam was made conductive so that the coating process could be carried out. A carbon-based conductive solid-liquid suspension mixture was prepared to provide conductivity[10]. This mixture was prepared with graphite powder and organic solvent. The cleaned polyurethane foams were dipped into the prepared mixture and kept for one day. Afterward, it was removed from the mixture and allowed to dry at room temperature, and the polyurethane foam was coated with a black graphite layer, thus providing conductivity.
A nickel-containing electrolyte solution was prepared so that Nickel could be electrochemically coated onto the conductive foam. This solution was prepared in accordance with the literature and 200 ml of electrolyte solution was prepared as nickel sulfate hexahydrate, nickel chloride hexahydrate, and boric acid in the ratio of 5:1:0.5 [11]. A nickel plate (30x20x50 mm in size) was connected to the anode (+) end of the power supply, and the conductive polyurethane foam to be coated was connected to the cathode (-) end and immersed in the prepared electrolytic solution. A voltage of 1.5 volts was applied with the power supply, and the coating process was completed. The light gray polyurethane and nickel foam formed by coating on carbon surfaces were removed from the bath, washed with pure water at least three times, and then dried. The dried Ni/C-foam raw structure was placed in a quartz tube reactor and calcined at 500°C in an N_2 gas environment to ensure carbonization of the polyurethane in the structure.

2.2. Synthesis of Pd/C-Ni Foam Catalyst

Palladium coating on Ni/C-foam was carried out using two different methods: impregnation-reduction and electrochemical deposition of Palladium.

2.2.1 Coating of Palladium onto nickel surface by impregnation-reduction method

Palladium coating of Ni/C-foam was carried out by the wet impregnation method. 0.1M Na2PdCl4 solution was prepared for wet impregnation. Ni/C-foam was added to the prepared solution separately to impregnate 2% and 4% Pd by mass. It was decided that the impregnation process progressed with the lightening of the solution color and that it was completely covered based on the completely clear color of the solution.

2.2.2 Coating of Palladium onto nickel surface by electrochemical deposition method

A solution containing 1 mmol/L PdCl2 and 3 mmol/L NaCl was prepared for electrochemical plating of Palladium. The electrochemical precipitation of Palladium was carried out in a similar manner to the nickel foam preparation method. The plating system was created by connecting the nickel foams to the power supply's negative (-) cathode end and the platinized titanium, which is not dissolved in the solution, to the positive (+) anode end. Mechanical mixing was applied throughout the plating process. The plating process continued for 35 minutes, and the lightening of the solution color was evaluated as a physical indicator that the palladium concentration in the solution had decreased and accumulated on the nickel foams.

2.3. Catalytic Activity Test

Catalytic hydrolysis experiments were carried out in two different reactor systems. First, the batch reactor experimental system given in Figure 1. Pd/C-Ni foam catalyst experiments were carried out in two different amounts, 0.06g and 0.012g, and at 3 different temperatures (40, 60, 80°C).

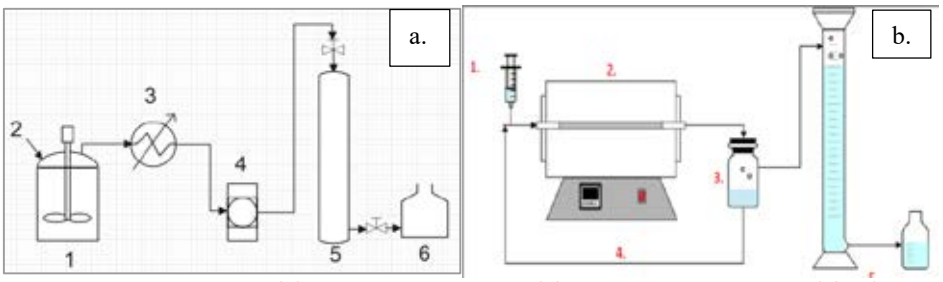

Fig. 1. a) Batch reactor experimental setup, (1) hot plate and reactor, (2) EDAB solution injector, (3) reflux condenser, (4) wash bottle, (5) gas burette, (6) reservoir b) Injector (1) Oven (2) Washing Bottle (3) reflux (4) wash bottle (5) gas burette,

The second stage experiments were carried out under continuous conditions, and vapor phase dehydrogenation experiments were carried out by placing a Pd/C-Ni foam catalyst in a 60 cm long Pyrex glass reactor with an inner diameter of 0.8 cm. In the experiment, 0.015 g EDAB was used in a 3 ml de-ionized water solution. This prepared solution was taken into the injector and fed to the packed reactor at the specified temperatures (300-450 ^{o}C). The feeding was completed in approximately 3-4 minutes.

3. RESULTS AND DISCUSSION

3.1. Pd/Ni Foam Characterization

SEM Analysis

In Figure 2(a) SEM images of the commercial Nickel foam used in the literature and (b) SEM images of the Ni-foam support materials prepared by electrochemical deposition method in a laboratory environment are given.

When the images in Figure 2(a) and (b) are viewed from a wide angle, it is seen that the porous foam structure is obtained with the synthesis (b) carried out in the laboratory environment. When examined at a larger magnification, it is seen that the surface morphology of the commercial Ni-foam is quite flat and smooth. Three different methods generally prepare commercial nickel foam. These are sputtering, electrochemical coating/deposition, and chemical vapor deposition (CVD).[12]. In commercially prepared nickel foams, high temperatures are reached (600-850°C) for sintering or reduction-sintering processes. For this reason, nickel metal lumps are welded together and form a tight, non-porous and flat layer (Figure 2(a). On the other hand, various nickel lump bumps and a more porous structure and possible carbon particles in between are seen on the surface of the Ni-foam synthesized by the electrochemical deposition method in the laboratory environment, which darkens the color of the foam obtained (Figure 2(b).

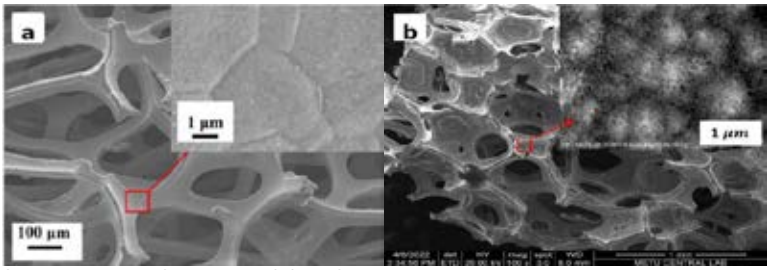

Fig. 2. (a) Commercial Ni-foam [13], (b) Ni-foam prepared by electrochemical deposition method

The EDS spectrum of nickel foam is given in Figure 3. According to this analysis, 10-12% carbon was found in the structure of the prepared nickel foam. It is thought that this carbon may have come from the carbon solution used during the nickel foam preparation process or from the polyurethane after the calcination process.

BET Analysis

The nitrogen adsorption-desorption isotherm curve of the prepared Pd/C-Ni foam catalyst is given in Figure 3.2. The prepared catalyst showed Type III isotherm behavior according to the IUPAC classification. The hysteresis interval started and ended at approximately P/P_0 = 0.05. The starting point of hysteresis indicates the starting point of capillary condensation[13]. Unlike the Pd/TiO_2 catalyst, the hysteresis onset P/P_0 value of the Pd/C-Ni foam catalyst is much lower. The surface area of the prepared catalyst was found to be 19 and 18 m^2/g according to the multi-point BET and BJH methods, respectively.

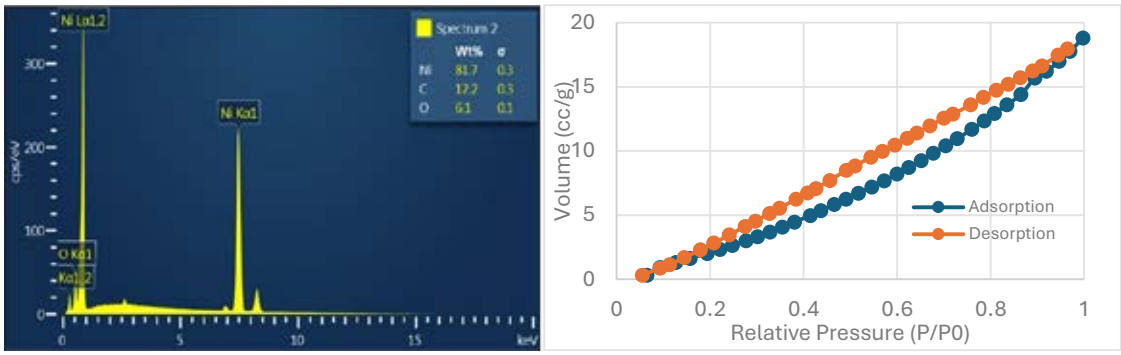

Fig. 3. Nickel foam EDS spectrum and N_2 (nitrogen) adsorption-desorption isotherm of Pd/C-Ni foam (electrochemical) catalysts

4. CONCLUSIONS

In summary, the Pd/C-Ni foam was successfully prepared via a simple electrochemical deposition method. Approximately 6 equivalent moles of hydrogen were produced in the EDAB hydrolysis with the Pd/C-Ni foam catalyst, and the E_a value was 30.88 kJ·mol^{-1}. The reason might be the relatively small particle size of the catalyst under this condition, which supplied a higher surface area for hydrogen transfer on the catalyst surface. In addition, the produced mole equivalent hydrogen amount for the hydrolysis of EDAB was still about 79.3% of the initial value after five cycles, indicating that the Pd/C-Ni foam catalyst had good cycling stability. The SEM and EDX analysis manifested that the increase in particle size and decrease in the amount of Pd after 5 cycles might be the main reason for the attenuation of catalytic activity.

ABSTRACT

In this study, bibliometric and text-mining analyses are conducted for the PEM electrolyzer to understand the general trends and provide insight into future works. First, the data was gathered from the Scopus webpage using 'PEM electrolyzer*' and its alternative combinations in January 2024, and 1631 articles were obtained. *Tidytext* and *stringr* libraries and Biblioshing environment were used in R Studio Language for the bibliometric analysis. In contrast, Colaboratory environment and *nltk, pandas,* and *numpy* libraries in Python programming language were used to conduct the text mining analysis. This study proves that the attention paid to PEM electrolyzers has increased dramatically, especially in the last decades. In addition, the research topics on which researchers focused changed during those years. At the beginning of the given period, 'polymeric membrane' was a popular research topic for eight years. Afterward, researchers focused on various research topics such as organic Rankine cycle, optimization, energy management, cathodes, etc. It is seen that besides cost and optimization analysis, the number of studies on the integration of PEM electrolyzers with other energy systems has increased recently.

Keywords: Hydrogen Production**,** PEM Electrolyzer, Text-Mining, Bibliometric analysis, Machine Learning

1. INTRODUCTION

Due to the changing lifestyle as a result of technological development, energy consumption is increasing continuously. Correspondingly, the increase of emissions and depletion of fossil fuels led researchers to seek alternative green energy sources. Hydrogen is one of the most promising green and sustainable energy sources when produced from renewable sources [1,2]. Water electrolysis, splitting water into oxygen and pure hydrogen, is one of the most promising hydrogen production methods. Among the various types of electrolyzers, such as Alkaline Water Electrolyzers (AWE), Solid Oxide Electrolysis Cells (SOEC), and Anion Exchange Membrane Water Electrolyzers (AEMWE), Proton Exchange Membrane (PEM) Electrolyzer is the most favorable method for the production of hydrogen with high purity because of its high efficiency and compact design [3,4]. In addition to high current density and minor carbon footprint due to oxygen production as a byproduct, PEM electrolyzers operate at low temperatures and high pressure, enabling quick response and easy storage of the byproducts [2,5–7]. The PEM electrolyzer enables water to oxidize by using electricity. In this way, the Oxygen Evolution Reaction (OER) occurs at the anode side, producing oxygen and protons. Produced oxygen is removed from the electrolyzer while protons pass through the membrane and electrons flow through an external circuit. At the cathode side, electrons reduce the protons to produce hydrogen and complete the Hydrogen Evolution Reaction (HER) [2,5,8]. Despite the advantages, operation under harsh conditions, such as high potential and acidic environments, requires the use of highly resistant catalytic materials such as noble metals, and these materials are limited and expensive, giving rise to high maintenance costs [4,8–10].

In order to be able to operate at high efficiency in the long term, alternative catalysts with low or no noble metal loadings are studied in the literature. In other words, the design of the electrode materials that operate efficiently under low over-potential and pH and high current densities in the long term is studied. In this regard, Machine Learning (ML) plays a significant role in the design of more effective materials and the improvement of design parameters [11]. Gunay et al. used varying statistical and machine-learning approaches, such as classification and a regression tree, to identify high-performance pathways and risks, and estimated the performance of the PEM electrolyzer. They concluded that polarization patterns can be forecasted without experiments with the aid of current information in the literature [11]. In addition to their previous study, Günay and Tapan used three different machine-learning techniques, local interpretable model-agnostic explanation (LIME), neutral network pattern recognition, and association rule mining (ARM), for the data of two different electrolyzers that are PEM and AEM. They observed that the LIME technique reveals the rules or pathways giving rise to high current densities and low polarization and power density. Also, key factors leading to high current density were identified by the ARM method, and the importance of catalytic material on the current density was revealed successfully with the neural network pattern [12]. In another study in the literature, Arsad et al. used bibliometric analysis to predict future trends and apply hydrogen electrolysis with the help of the most cited academic papers in the Scopus database [13]. In this study, we conducted detailed bibliometric and text-mining analyses for the PEM electrolyzers to project the research trends and the most important future research directions considered to have a high

impact on the development of the technology.

2. METHODS

This study aims to conduct a comprehensive examination of trend topics in PEM electrolyzers in the open literature by using bibliometric analysis and text mining. First, data analysis was done by searching keywords in the Scopus database (January 2024) using the term "PEM electrolyzer*" and 1631 published articles were obtained from 1998 to 2024. The title, keyword, and abstract of the articles were used, and the output was classified for its relevance with the PEM electrolyzers. The resources were documented following the articles' Authors, Author full names, Author IDs, Title, Year, Source Title, Volume, DOI number, Scopus website link for the article, Abstract, Author Keywords, Document type, and Source Name, after revision of each document meticulously, and all the information of the results gathered were exported as CVS document. In the text mining study, the information used for data visualization majorly consisted of author keywords, abstract, and DOI numbers. R studio environment was used to demonstrate various graphs in bibliometric analysis. Basic algorithms and libraries such as '*tidytext*' and '*stringer*' were used to clean repeated words from the text. '*Biblioshiny'* environment was used for the visualization of trends corresponding to research on PEM electrolyzers from 1998 onward. The Collaboratory environment, which provided tokenizing and filtering large amounts of data in Python programming language, was used to conduct detailed text-mining analysis for the abstract of the articles. Also, large datasets were tokenized and filtered using relevant Python libraries such as '*nltk', 'pandas'*, and '*numpy'.*

3. RESULTS AND DISCUSSION

The timeline/trend graph (Fig.1), constructed by the R programming language and 'Biblioshiny' environment, gives information about the frequency of occurrence of specific terms or keywords studied in the literature over a period of time. In the graph, the length of the line for each term represents the period along which the terms are studied or discussed in the literature, while the dots illustrate the most frequently appeared year, and the size of the dots represents the frequency of the term in a certain year.

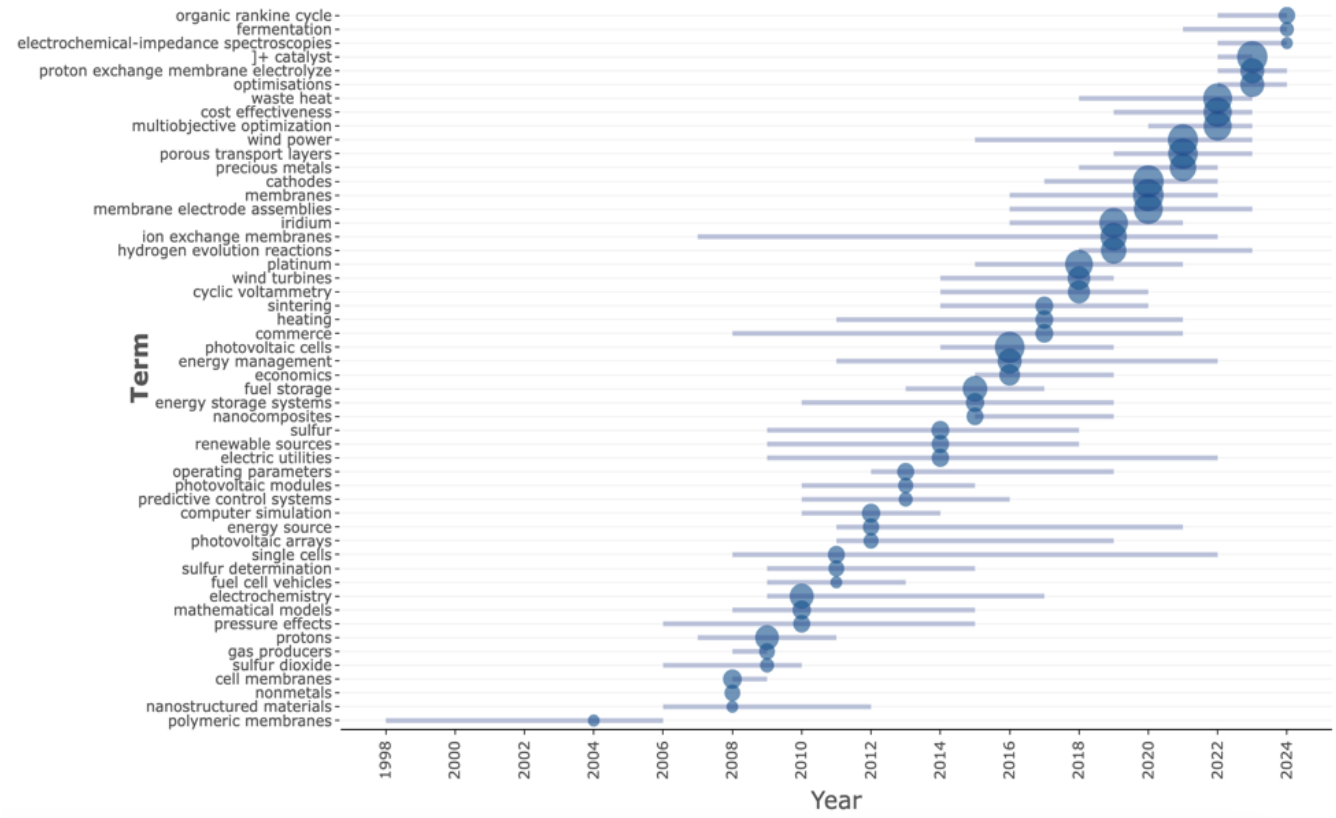

Fig. 1. Trend topics based on abstracts of scientific publications between 1998 and 2024.

In this regard, at the beginning of the period, between 1998 and 2006, polymeric membranes were the top research topic of PEM electrolyzers. On the other hand, for the last two years, "organic Rankine cycle," "fermentation," "electrochemical impedance spectroscopies," "catalyst," "proton exchange membrane electrolyzers," and "optimizations" were the most

commonly mentioned topics in literature. It is seen from this result that PEM electrolyzers can be integrated with different power systems. In the study conducted by Onwuemezie et al., renewable energy sources such as wind and solar energy with the PEM electrolyzer were used together with biohydrogen production [14]. Also, it is clear that the keyword “catalyst” had the highest frequency; in other words, “catalyst” was the most significant research topic among these keywords during those years. This is because one of the challenges of the PEM electrolyzer is the use of noble metals such as Pt, Ir, and Ru in the electrolyzer. These noble metals can operate efficiently under harsh conditions, but they are limited, which makes them more expensive [15,16]. Therefore, to use the PEM electrolyzers widely, researchers focused on decreasing the use of precious metals or designing alternative catalysts for noble metals with a longer lifetime [4,17,18]. The terms “single cell,” “ion exchange membrane,” and “energy management” were discussed over the longest period, while “nonmetals” occurred only in 2008.

Fig. 2. illustrates the most frequent 50 keywords mentioned in abstracts of publications about PEM electrolyzers from 1998 to 2024. It is seen that the most frequently aforementioned words are “cathodes,” “membranes,” ”catalyst,” “wind power,” “photovoltaic cell,” “porous transport layers,” “membrane electrode assemblies,” “waste heat,” and “iridium” with the 74, 73, 71, 69, 67, 65, 61, 61 and 59 absolute frequency respectively and 3% of entire data.

Fig. 2. Word frequency treemap of the word phrases in the specified domain.

4. CONCLUSIONS

This study conducted bibliometric and text-mining analyses for the PEM electrolyzer to demonstrate the trend topics and commonly discussed words about this field between 1998 and 2024. First, by using a keyword search, 1631 documents were extracted from the Scopus database. Then, the R Studio environment, Python programming language, and relevant libraries were used for the analysis. It was obtained from this analysis that the PEM electrolyzer has become a more popular research field in recent years, while the research topics have changed over the years. Topics of ‘ion exchange membrane’, ‘single cell’, and ‘energy management’ were discussed for the longest period in literature, while ‘nonmetals’ was mentioned only in 2008. Overall, this analysis can provide insight into the knowledge of PEM electrolyzers and guidance for future research areas.

ABSTRACT
This study examines adsorption and desorption values, which are among the most critical factors indicating the storability of hydrogen (H_2) in coal seams. Our work emphasizes the increasing prominence of hydrogen as a clean and sustainable energy source in response to global warming and rising energy demands. The reliable storage of hydrogen is considered one of the cornerstones of future energy systems. The research highlights that the micro and nano-pore structures of coal seams offer favorable properties for hydrogen storage. Notably, the high adsorption capacity of these pore structures enables the safe and efficient storage of hydrogen. Findings from literature reviews reveal the detailed effects of factors such as pressure and temperature on hydrogen storage capacity. Additionally, the comparison of hydrogen's adsorption/desorption behavior with other gases constitutes a significant dimension of this study. Investigating the hydrogen storage potential of coal seams is considered a crucial step toward energy security and sustainable energy management.
Keywords: adsorption, coal seams, desorption, hydrogen, underground storage

1. INTRODUCTION

The increase in the global population and rising living standards have led to higher energy demand, resulting in carbon dioxide (CO_2) emissions and global warming. In this context, zero-emission hydrogen energy has emerged as a significant alternative for addressing environmental issues [1]. The growing utilization of renewable energy sources has created the need for large-scale energy storage [2]. Hydrogen, as a clean energy source, has the potential to transform energy systems. However, developing effective and large-scale storage methods is essential for establishing a sustainable hydrogen economy. The high energy density and storability of hydrogen provide a flexible solution for ensuring energy security [3].

Underground gas storage methods have gained attention due to their low costs and minimal environmental impacts. Among these methods, geological formations such as salt caverns, depleted natural gas reservoirs, and coal seams hold significant potential for long-term hydrogen storage [4, 5, 6]. In particular, the micro- and nano-scale pore structures of coal seams are considered a viable option for hydrogen storage [7,8]. However, the mechanisms of hydrogen adsorption and desorption in coal seams are not yet fully understood. Investigating these mechanisms in detail is critical for accurately evaluating the storage potential of hydrogen.

In this study, adsorption/desorption, one of the most important factors for assessing hydrogen storage in coal seams, was examined based on findings from the literature.

2. MATERIALS AND METHODS

In literature, anthracite, bituminous and sub-bituminous coal samples were used in H_2 adsorption experiments. The micro/nanopore structures of these samples were analyzed. Adsorption and desorption processes were analyzed using the Langmuir isotherm model, with measurements conducted at a pressure range of 0.1–14.32 MPa and a temperature range of 303–318 K. BET and FTIR techniques were utilized for surface analysis.

Langmuir Model for Representing Experimental Hydrogen Adsorption Capacity in Coal: Adsorption models, including the linear Henry's law [9], the Freundlich model [10], the Langmuir model [11], the Brunauer-Emmett-Teller (BET) model [12], the Dubinin-Radushkevich (D-R) model [13], and the Dubinin-Astakhov (D-A) model, have been extensively studied to theoretically estimate the adsorption capacity of coal. Among these, the Langmuir model, which assumes that the amount adsorbed is limited by a threshold capacity at typical gas pressures [11], is widely used.

$$V = \frac{V_L p}{p + p_L} \tag{1}$$

Where p: pressure, V: the amount of gas adsorbed at typical gas pressure, V_L: the maximum adsorption capacity, p_L:the equilibrium pressure of the gas corresponding to half of V_L.

Eq. (1) describes adsorption by assuming that the adsorbate behaves as an ideal gas under isothermal conditions and exhibits monolayer coverage behavior on the solid adsorbent. Additionally, the surface coverage ratio can be represented as follows:

$$\theta = \frac{p}{p + p_L} \tag{2}$$

Where θ: represents the surface coverage ratio. Based on the equations, Eq. (1) and Eq. (2), the sorption behavior of

hydrogen on coal has been evaluated.

3. RESULTS AND DISCUSSION

Studies on hydrogen adsorption, a critical parameter for underground hydrogen storage systems in coal seams, and the influencing factors are relatively scarce worldwide. The findings from these studies are explained below.

Iglauer et al. [7] measured H_2 adsorption on a typical bituminous coal sample and demonstrated that significant amounts of H_2 could be stored even at moderate pressures using this approach. They observed that H_2 adsorption increased significantly with increasing pressure (Fig. 1). Initially, this increase was rapid, but the adsorption curve plateaued at approximately 4 MPa. At low pressure (0.1 MPa), only a small amount of H_2 was adsorbed (0.005 mol/kg coal). At 3.38 MPa, 0.23709 mol H_2/kg coal was adsorbed (both measured at 303 K). Hydrogen adsorption increased by a factor of 47.418 as the pressure rose from 0.1 MPa to 3.38 MPa. At 11.74 MPa (303 K), 0.54686 mol H_2/kg was adsorbed, while at 14.3207 MPa (318 K), this value reached 0.60183 mol H_2/kg. Compared to the initial condition (0.1 MPa), the amount of adsorbed H_2 increased by a factor of 120 at 14.3207 MPa. Additionally, changes in temperature (from 303 K to 333 K) had only a slight effect on the adsorption profile (slightly smaller amounts of H_2 were recorded at higher temperatures). They concluded that significant amounts of H_2 could be stored in deep coal seams dominated by high pressures and temperatures (Fig. 1). However, at the same temperature, the amount of CO_2 adsorbed was approximately 10 times that of H_2 (e.g., 2.64 mol CO_2/kg coal at 3.302 MPa vs. 0.23709 mol H_2/kg coal at 3.382 MPa, both measured at 303 K). Iglauer et al. [7], also investigated the effects of pressure and temperature on H_2 and CO_2 adsorption rates through experiments on sub-bituminous coal. At moderate pressure and temperature (303 K, 3.3 MPa), 0.23709 mol H_2/kg coal could be adsorbed, whereas at higher pressures (14.3 MPa, 318 K), this value reached 0.60183 mol H_2/kg coal. Their study presented data supporting hydrogen storage in deep coal seams and the establishment of a large-scale hydrogen supply chain.

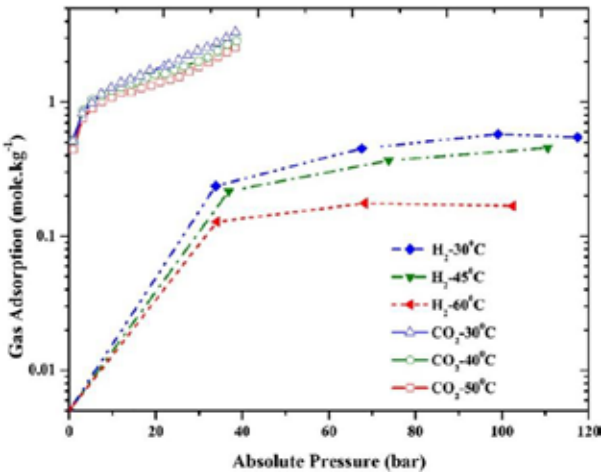

Fig. 1. Monte Hydrogen adsorption on sub-bituminous coal as a function of pressure and temperature. (CO_2 data included for comparison purposes.) [14]

Arif et al. [15] conducted hydrogen adsorption measurements on three coal samples of varying ranks at high pressures (0 to 102 bar) and high temperatures (303 K to 333 K) to evaluate their hydrogen storage potentials (Fig. 2). They observed that adsorption capacity increased with increasing pressure but decreased with rising temperature, regardless of coal rank. The highest recorded hydrogen adsorption was 0.721 mol/kg for anthracite coal at 303 K and 102 bar. Higher adsorption was observed in high-rank coal. All samples predominantly exhibited type I adsorption behavior across the entire pressure range. To investigate the microstructure and surface chemistry associated with these adsorption tendencies, micro-pore analysis, and Fourier transform infrared spectroscopy measurements were conducted. The micro-pore content of the three samples followed this order: anthracite > sub-bituminous > bituminous, while the H_2 adsorption tendency followed this order: anthracite > bituminous > sub-bituminous. In other words, they observed that there was no direct correlation between the micro-pore content of the coal and its H_2 adsorption capacity. This situation could potentially be attributed to the high clay content in bituminous coal, which reduces its micro-pore content. Furthermore, while bituminous and sub-bituminous samples exhibit a significant number of oxygen-containing functional groups, anthracite coal shows notable aromatic content; this reveals that the H_2 adsorption capacity is a complex function of both the coal's surface chemistry and micro-pore content [15]. Overall, high-rank coal seams at high pressure and temperature showed the highest hydrogen adsorption, similar to CO_2 adsorption potential, albeit at lower absolute values. Thus, these results provide preliminary data regarding the hydrogen storage potential of coal seams and the mechanisms behind hydrogen adsorption, contributing to the relevant scientific understanding.

The rankings of eight coals from significant coal fields in the United States, based on fixed carbon content, vitrinite reflectance, vitrinite content, O/C ratio, and H/C ratio, were measured and analyzed for their adsorption and diffusion

behaviors by Liu & Liu [4]. Adsorption data showed that all eight coals had considerable adsorption capacities. Among them, LvB coal has a maximum adsorption capacity of approximately 1.17 mol/kg, followed by coal with a maximum hydrogen adsorption capacity of ~0.95 mol/kg, and SemiAn coal with ~0.82 mol/kg [4]. The fixed carbon content and typically the O/C ratio are related to the maximum hydrogen adsorption capacity in coals, which can be attributed to oxygen-containing functional groups. Hydrogen has superior diffusivity and is characterized by its effective propagation.

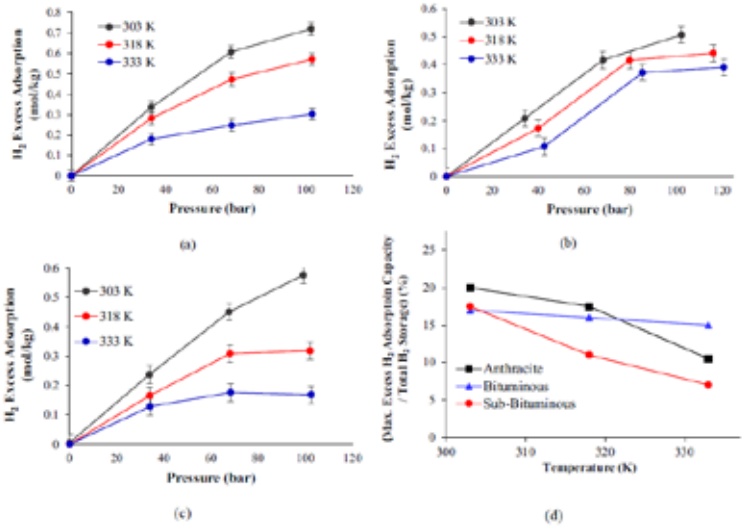

Fig. 2. Monte Hydrogen adsorption on coal samples as a function of pressure at different temperatures; a) anthracite, b) bituminous, c) sub-bituminous, d) Excess H_2 Adsorption/Total H_2 Storage (%) (at 102 bar) [15]

In the SemiAn coal, the effective diffusion of hydrogen decreases from ~0.00156 to ~9.26×10^{-4} 1/s with an increase in pressure from ~2.45 MPa to ~10.07 MPa; among these, the lowest diffusion at ~10.07 MPa is four times higher than that of CH_4 at the equivalent pressure [4]. This indicates that coal seams with maximum injectability are a promising area for hydrogen storage. The results suggest that the adsorption and diffusion behaviors of hydrogen in coals with different ranks, moving toward methane formation in depleted coal beds with injected hydrogen, could function as a geological "H_2-Battery."

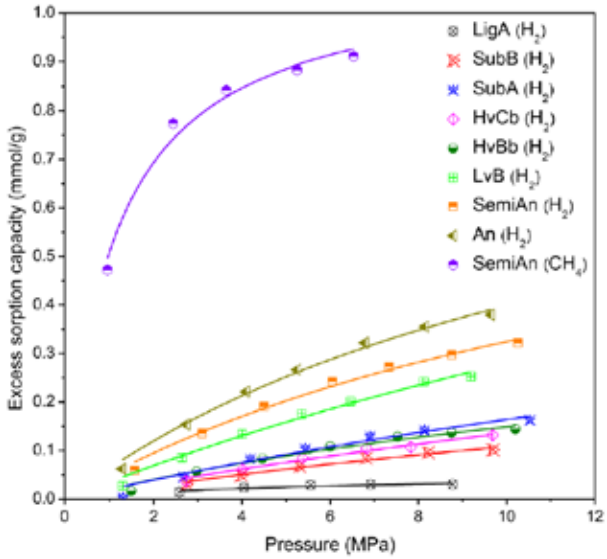

Fig. 3. Modeling of the hydrogen adsorption isotherm using the Langmuir adsorption model (Eq. 3) [4]

Wang and Chen [16] examined the hydrogen (H_2) adsorption behavior in dry and moist coals (moisture content 0-10% by weight) under different temperature (293.15 K - 333.15 K) and pressure (1.3 MPa - 15 MPa) conditions using large canonical molecular dynamics simulations. The effects of temperature, pressure, coal rank, and moisture on H_2 storage capacity were analyzed. The study showed that H_2 adsorption capacity is positively correlated with coal rank, linking it to the effects of surface chemical properties and pore structure. It was noted that as pore size decreases, the isosteric heat of adsorption increases, and in moist coal, the adsorption capacity of H_2 decreases due to the competitive adsorption

of water. It was concluded that anthracite coal seams, containing abundant micro-pores and few hydrophilic groups, have a high potential for H_2 storage. As pressure increased, the adsorption capacity also increased. Adsorption at 0.1 MPa was 0.005 mol/kg, while at 14.32 MPa, it reached 0.60183 mol/kg. An increase in temperature reduces the adsorption, which is attributed to the exothermic nature of adsorption. The adsorption capacity of CO_2 is approximately 10 times higher than that of H_2. This difference is due to CO_2's stronger interaction with the surface. Anthracite coal, with its high micro-pore content, has the highest adsorption capacity among the coal types [16].
Determining the H_2 adsorption capacity of the underground hydrogen storage (UHS) reservoir and its boundaries is crucial for assessing both storage capacity and well integrity [17]. The adsorption ranges of CO_2 and CH_4 in Turkish coals vary depending on coal type and regional conditions. However, they generally fall within the range of 1–10 m³/ton for CH_4 and 5–20 m³/ton for CO_2 [18]. These values are crucial for assessing the gas storage potential of coal seams. However, the H_2 adsorption capacity of Turkish coals remains unknown due to the lack of studies on this subject. In our future research, we plan to conduct these experiments by using the coal samples in Turkiye, as they are essential for evaluating their UHS potential..

4. CONCLUSIONS

This study has highlighted the hydrogen storage potential of coal seams. The hydrogen adsorption capacity can be optimized based on variations in pressure and temperature. High-rank coal types stand out with higher adsorption capacities. From a practical application perspective, the use of coal seams as geological hydrogen storage reservoirs offers a low-cost and sustainable energy storage solution. However, technical challenges such as improving competitive gas adsorption and desorption kinetics should be the focus of future research. The results are significant for energy security and sustainable energy management.

ABSTRACT
In this study, the electro-oxidation of 1-propanol and 2-propanol on Pt/PABA/GO and Pt/GO catalysts was investigated, highlighting the significant influence of alcohol molecular structure on electrochemical reactivity. The electrodeposition of Pt nanoparticles on PABA/GO resulted in smaller Pt particles compared to Pt on GO. 1-Propanol exhibited higher oxidation currents across a broader potential range than 2-propanol, indicating its more favorable electro-oxidation behavior. The Pt/PABA/GO composite demonstrated superior catalytic activity and a lower onset potential compared to Pt/GO, emphasizing the importance of structural conditions in optimizing propanol oxidation mechanisms. Furthermore, Pt/PABA/GO exhibited enhanced stability during oxidation, outperforming Pt/GO in terms of long-term catalytic activity. The improved performance of Pt/PABA/GO is attributed to the unique PABA-GO hybrid support, which prevents Pt nanoparticle agglomeration and promotes a uniform distribution. The interactions between PABA, carbon supports, and Pt nanoparticles not only reduce overpotentials but also significantly enhance catalytic efficiency, positioning the Pt/PABA/GO composite as a promising catalyst for alcohol oxidation reactions.

Keywords: Platinum, Conducting Polymer, Alkaline media, Propanol, Electrocatalyst

1. INTRODUCTION

In the expedition for sustainable and efficient energy sources, alcohols, particularly in direct alcohol fuel cells (DAFCs), have harvested significant attention due to their high energy density, ease of storage, and refueling capabilities compared to gaseous hydrogen [1, 2]. These attributes make alcohols ideal candidates for low-power demand applications, such as laptops and mobile phones. However, despite their potential, real commercial breakthroughs have been hindered by the high cost of fuel cell components, especially the use of noble metal catalysts [1, 3]. To lower the cost of these catalysts, it is essential to reduce the amount of noble metal required while maintaining high performance.

One promising approach to achieve this goal is the use of alkaline media, which enhances the reaction kinetics compared to acidic media. In alkaline solutions, the same current density can be achieved with lower catalyst loadings, offering a way to optimize the use of precious metals [1, 4]. The re-emergence of interest in alkaline media for DAFCs has been fueled by the development of new anion exchange membranes, which enable better performance in these environments. Among the various catalysts, platinum (Pt) is widely considered the most effective monometallic catalyst for the electro-oxidation of small organic molecules, such as alcohols, due to its ability to break carbon-hydrogen bonds and oxidize carbon monoxide at relatively low overpotentials [2 - 4].

Although much attention has been given to the electrochemical oxidation of shorter-chain alcohols, such as methanol and ethanol, the oxidation of C3 alcohols, like 1-propanol and 2-propanol, has been less explored [5, 6]. Electrochemical oxidation of C3 alcohols in DAFCs has the potential to generate significant electrical energy through dehydrogenation reactions and C–C bond cleavage [1, 5, 6]. However, the performance of C3 alcohols in DAFCs is generally inferior to that of methanol and ethanol, making it crucial to study the oxidation reactions of these alcohols to better understand the influence of their molecular structure on reaction behavior[2, 4 - 6]. 2-Propanol, in particular, stands out as an attractive fuel for DAFCs due to its relatively low toxicity, high boiling point, and low permeability through electrolyte membranes compared to methanol [1, 4 - 6]. Several studies have focused on the electrochemical oxidation of 2-propanol on platinum in acidic media, but further research in alkaline conditions is necessary to fully assess its potential for DAFC applications.

Graphene oxide (GO) and its reduced form (rGO) have gained significant attention as catalyst supports in electrochemical applications due to their high surface area, which provides abundant active sites for catalyst dispersion, thereby enhancing catalytic activity [1, 5, 6]. The oxygen-containing functional groups on GO facilitate metal nanoparticle anchoring, improving both stability and performance [7]. Moreover, rGO exhibits excellent electrical conductivity, which is essential for efficient electron transfer during electrochemical reactions. Graphene derivatives also offer strong mechanical properties, chemical stability, and durability, making them suitable for harsh electrochemical environments [7, 8]. Their cost-effectiveness and lightweight nature further enhance their attractiveness as catalyst supports in fuel cells and other electrochemical devices.

The modification of carbon materials with conducting polymers presents another promising approach to stabilize metal nanoparticles and enhance their performance. Conducting polymers, such as polypyrrole, polyaniline, and polythiophene, have been widely studied for their unique electronic properties, including electrical conductivity, low energy optical transitions, and high electron affinity [7, 8]. Among these conducting polymers, poly(aminobenzoic acid) (PABA), a derivative of polyaniline, is of particular interest. PABA's electron-rich nitrogen atom and high electron density of the

carbonyl group make it highly suitable for electropolymerization, providing a stable matrix for the deposition of metal catalysts and facilitating interactions with fuel molecules like propanol [9].
In this study, thin films of PABA/rGO composites were fabricated through electropolymerization of 3-aminobenzoic acid (ABA) onto electrodes. Pt was electrodeposited onto these composite films using cyclic voltammetry (CV). The electrochemical performance of the resulting Pt/PABA/GO catalysts was primary evaluated for propanol oxidation in alkaline solution, using both cyclic voltammetry (CV) and chronoamperometry (CA) to assess their activity and stability.

2. MATERIALS AND METHODS

Graphene oxide (GO) was made from graphite (powder < 20 um; Sigma-Aldrich) according to a previously published procedure [7, 8]. 2 mg GO was mixed in 1 mL of mixed solution (5 wt% Nafion/ethanol/DI water = 6.25:20:73.75) in an ultrasonic bath for 30 min. 5 μL of the suspension was drop-casted onto the GCE and dried under a lamp. 3-Aminobenzoic acid (ABA) was electropolymerized on the surface of the working electrode (GCE) by repetitive cyclic potential scan for 2 cycles between −0.2 and + 1.0 V at 50 mV s^{-1} in 14 mL of 0.5 M H_2SO_4 (Merck) containing ABA (1 mM). The electrode obtained was labeled as ABA-rGO. The monometallic catalysts were consequently electrodeposited in an electrolytic solution containing 1 mM $H_2PtCl_6 \cdot 6H_2O$ solution by two scanning cycles between −0.4 and 1.0 V. The metal loaded on the GO-modified GCE with and without ABA loading were denoted as M/ABA-rGO and M/GO (M = Pt), respectively. The electrochemical characterization of the catalyst electrodes was investigated in N_2-saturated 0.5 M KOH solution in the potential region from −0.85 to 0.2 V at a scan rate of 50 mV s^{-1}. In addition, the activities of the prepared catalyst electrodes for oxidation were measured in N_2-saturated 0.5 M 1-propanol and 0.5 M 2-propanol in 0.5 M KOH as a supporting electrolyte in the potential region from -0.85 to 0.2 V. The morphologies and chemical compositions of the prepared catalysts were determined by a JEOL transmission electron microscope connected to an energy dispersive X-ray spectroscope.

3. RESULTS AND DISCUSSION

After the electropolymerization of PABA on the GO surface, resulting in the PABA-GO support, Pt was electrodeposited onto the PABA-GO support to produce the Pt/PABA-GO catalyst. The surface morphology of the resulting Pt/PABA-GO and Pt/GO electrocatalysts was analyzed using TEM, with the images presented in Fig. 1 (a and b). The TEM images reveal that the surface structure of GO was notably influenced by the incorporation of Pt and PABA microparticles. Specifically, small Pt nanoparticles were observed to be deposited and agglomerated on the GO surface. In contrast, Pt nanoparticles on the PABA/GO support exhibited a more homogeneous distribution with fewer signs of agglomeration, and the particles appeared smaller.
The elemental compositions of the catalysts were further characterized using energy-dispersive X-ray (EDX) spectroscopy, as shown in Fig. 1(c and d). The EDX spectra revealed distinct peaks corresponding to platinum (Pt), nitrogen (N), oxygen (O), and carbon (C), which confirmed the presence of Pt nanoparticles. The high levels of carbon, nitrogen and oxygen observed in the spectra indicated the significant contribution of PABA and GO to the surface composition of the catalyst, highlighting the successful functionalization of GO with PABA and subsequent deposition of Pt nanoparticles.

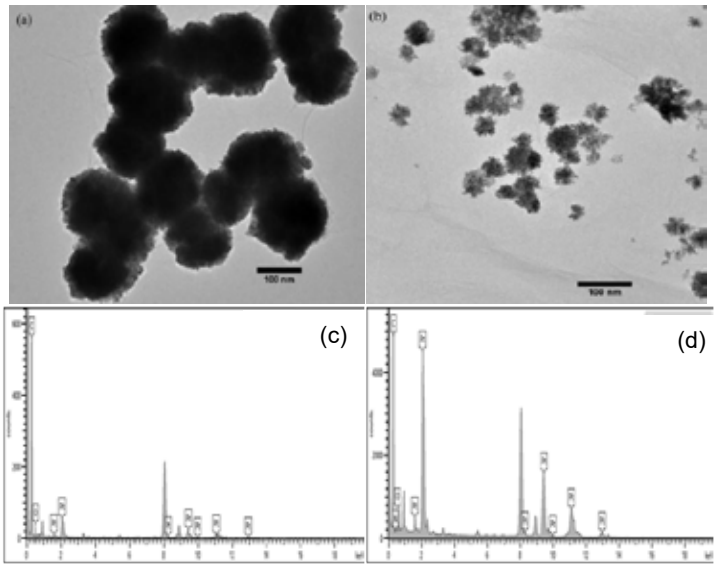

Fig. 1. TEM-EDX images of (a and c) Pt/GO and (b and d) Pt/PABA-rGO catalysts.

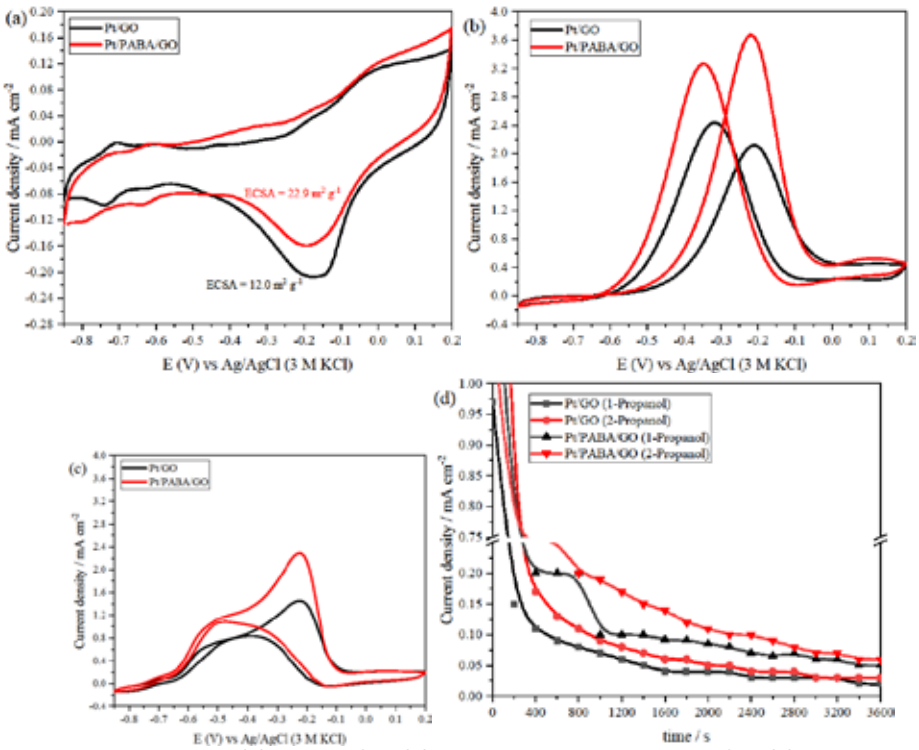

Fig. 2. CVs of the as-prepared catalysts in (a) 0.5 M KOH, (b) 0.5 M 1-propanol + 0.5 M KOH, (c) 0.5 M 2-propanol + 0.5 M KOH and (d) CA of Pt/GO (black line) and Pt/PABA-rGO (red line) in 1- and 2-propanol.

The electrochemical behavior of the obtained deposits was investigated in a 0.5 M KOH solution at a scan rate of 0.05 mV s^{-1}. As depicted in Fig. 2 (a), the voltammetric profiles of the Pt/PABA/GO and Pt/GO electrocatalysts exhibit similar features to those observed for electrodeposited Pt nanoparticles. Specifically, both catalysts show typical hydrogen and oxygen adsorption/desorption regions, along with the presence of a distinct double-layer region, which is characteristic of platinum-based electrocatalysts.

However, a notable difference is observed in the Pt/PABA/GO electrocatalyst, where the adsorption of oxygen species during the anodic scan (after -0.1 V) appears broader compared to the Pt/GO catalyst. This suggests an enhanced interaction between the oxygen species and the Pt/PABA/GO surface. Consequently, the peak current density associated with the reduction of Pt oxide is significantly enhanced on the Pt/PABA/GO catalyst. This improvement can be attributed to the unique structural and compositional properties of the Pt/PABA/GO catalyst, which facilitate more efficient oxygen adsorption and subsequent electrochemical processes.

Fig. 2 (b and c) presents the cyclic voltammograms for the oxidation of 1-propanol and 2-propanol in a 0.5 M KOH solution containing 0.5 M alcohol on a Pt electrode. The potential sweep was conducted at a rate of 0.05 V s^{-1} within the range of -0.85 V to 0.2 V. When compared to the cyclic voltammogram obtained in the absence of alcohol, a distinct alcohol oxidation peak is clearly visible. The oxidation of alcohol on the Pt electrode is characterized by two well-defined current peaks in both the forward and reverse scans.

In the forward scan, the oxidation peak, observed at E = -0.2 V, corresponds to the oxidation of freshly chemisorbed species resulting from alcohol adsorption. The reverse scan peak, observed at E = -0.4 V, is primarily associated with the removal of carbonaceous species that were not completely oxidized during the forward scan. The onset potentials for both 1-propanol and 2-propanol oxidation on the Pt/PABA/GO catalyst are lower than those observed on the Pt/GO catalyst, suggesting that the Pt/PABA/GO catalyst offers a lower energy barrier for oxidation, indicating it is more easily oxidized.

The magnitude of the peak current in the forward scan provides insight into the electrocatalytic activity of the electrocatalysts for alcohol oxidation in an alkaline medium. Notably, the current densities for the oxidation of 1-propanol at the corresponding potentials are higher than those for 2-propanol oxidation on both Pt/PABA/GO and Pt/GO electrodes. Furthermore, the Pt/PABA/GO catalyst demonstrates a higher current density compared to Pt/GO, signifying superior catalytic activity. This highlights that the activity order for alcohol oxidation on Pt electrodes is 1-propanol > 2-propanol, with the Pt/PABA/GO catalyst exhibiting enhanced electrocatalytic performance.

The stability of 1-propanol and 2-propanol oxidation on the Pt electrode in a 0.5 M KOH + 0.5 M alcohol solution was evaluated using chronoamperometry at a constant potential of -0.2 V. The results, shown in **Fig. 2(d)**, reveal a rapid decay in current, indicating the poisoning of the Pt electrode during the oxidation process. Despite this, it is noteworthy that at the conclusion of the test, the oxidation current for 2-propanol is higher than that for 1-propanol on the Pt electrode.

Furthermore, the current intensities measured after 3600 s for the Pt/PABA/GO catalyst are higher than those for the Pt/GO catalyst for both 1-propanol and 2-propanol. This indicates that the Pt/PABA/GO catalyst exhibits better stability, maintaining higher catalytic activity over time compared to Pt/GO, and is less prone to deactivation during the alcohol oxidation process.

Based on previous reports, the primary electrochemical reaction for 2-propanol oxidation is generally considered to be dehydrogenation, where 2-propanol is converted to acetone, accompanied by a charge-transfer reaction of hydrogen [1, 4, 10]. In addition to this main reaction, an alternative electrochemical pathway proceeds in parallel, involving an intermediate species, where 2-propanol is oxidized to an intermediate and then further oxidized to CO_2. While the exact molecular structure of this intermediate has not been definitively identified, it is likely to be an acetone species or acetone itself adsorbed on the Pt surface. Taking into account these possible reactions, a simple reaction model for 2-propanol electro-oxidation can be proposed. This model involves parallel reaction pathways, with the dehydrogenation of 2-propanol to acetone as the dominant process, while a secondary reaction pathway leads to the formation of CO_2 through the oxidation of an intermediate. The proposed pathway model highlights the complexity of the electrochemical oxidation of 2-propanol on the Pt electrode [10].

$$CH_3CHOHCH_3 + 2OH^- \rightarrow CH_3COCH_3 + 2H_2O + 2e^- \quad \text{Eq. (1.)}$$

$$CH_3COCH_3 + 16OH^- \rightarrow 3CO_2 + 11H^+ + 16e^- \quad \text{Eq. (2.)}$$

These two reactions highlight the distinct but interconnected pathways involved in the electro-oxidation of propanol on the electrode surface, with each contributing to the overall catalytic performance.

4. CONCLUSIONS

In conclusion, the Pt/PABA/GO composite catalyst demonstrates significantly improved electrochemical performance for the oxidation of 1-propanol and 2-propanol compared to the Pt/GO catalyst. The smaller Pt nanoparticles and their uniform distribution on the PABA/GO support contribute to enhanced catalytic activity and stability. The results show that 1-propanol exhibits more favorable oxidation behavior than 2-propanol, as evidenced by higher oxidation currents over a broader potential range. Additionally, the Pt/PABA/GO catalyst exhibits a lower onset potential and greater stability during oxidation reactions, indicating its superior performance in alcohol oxidation processes. The unique PABA-GO hybrid support plays a crucial role in preventing Pt nanoparticle agglomeration, reducing overpotentials, and improving the overall catalytic efficiency. This study highlights the potential of the Pt/PABA/GO composite as a promising catalyst for alcohol oxidation reactions, with implications for various electrochemical applications.

ABSTRACT
Pt catalysts supported on multi-walled carbon nanotubes (MWCNTs)-nickel (Ni)-carbon black (CB) composites were synthesized as anode catalysts for high-performance alcohol electrooxidation (methanol, ethanol, and propanol) in direct alcohol fuel cells (DAFCs). A simple method utilizing ethylene glycol as a reducing agent was employed to synthesize the metal electrocatalysts. The morphology and structure of the as-synthesized catalysts were characterized using Transmission Electron Microscopy (TEM), which revealed small Pt nanoparticles uniformly dispersed on the surfaces of xMWCNTs-Ni-yCB. The electrocatalytic performance of the catalysts was evaluated through various electrochemical techniques, including Cyclic Voltammetry (CV) and Chronoamperometry (CA). The Pt/xMWCNTs-Ni-yCB catalysts with different carbon ratios (x:y = 1:1, 1:2, and 2:1) exhibited significantly enhanced catalytic activity and stability compared to other catalysts and commercial PtRu/C towards alcohol oxidation. The design of the hybrid MWCNTs and CB carbon structure imparted remarkable structural and functional properties, contributing to improved electrochemical activation and catalytic performance of Pt nanoparticles. The synergistic effect between these components enhances the overall catalytic efficiency, demonstrating a promising strategy for advanced alcohol oxidation in fuel cell applications.

Keywords: Platinum, multiwalled carbon nanotubes, nickel, carbon black, alcohol oxidation

1. INTRODUCTION
Direct alcohol fuel cells (DAFCs) have gained significant attention as promising green energy generators, capable of converting renewable fuels directly into electrical energy with thermodynamic high efficiencies, as energy is converted without the limitations imposed by Carnot's theorem [1, 2]. These fuel cells are capable of selectively producing high-value products while generating electric power, which makes them attractive for both energy production and value-added byproducts [3, 4]. Among various alcohol fuels, methanol has long been the primary focus due to its high energy density, ease of decomposition, and ability to deliver high energy per unit volume of CO_2 produced during oxidation [2 - 4]. However, the primary challenge in using methanol in DAFCs lies in its toxicity to the catalyst caused by intermediate products formed during the oxidation process [3, 4]. This issue has prompted research into other alcohols, including C2-alcohols such as ethanol and isopropanol, which offer higher energy densities and can undergo complete oxidation, though they too introduce challenges related to catalyst stability due to the production of intermediates like CO or oxalic acid [3, 4].

Pt-based electrocatalysts are widely regarded as the most effective catalysts for alcohol oxidation reactions, particularly at low temperatures [5, 6]. However, due to the high cost and limited availability of platinum, there is a growing need to enhance its catalytic activity and utilization. Strategies to improve Pt-based catalysts include the dispersion of Pt nanoparticles onto carbon supports with high surface areas and good electrical conductivity, such as carbon black (CB) and carbon nanotubes (CNTs), as well as the development of Pt-alloy catalysts like Pt-Au [5, 6], Pt-Ni [7], and Pt-Pd [5, 6]. These materials are designed to improve catalytic performance while reducing the amount of Pt required.

Despite extensive research on the electrocatalytic oxidation of methanol and other alcohols in DAFCs, there remains a lack of comprehensive comparisons of the key factors that influence their performance, such as catalysts, fuels, and electrolytes, especially across different pH environments. This study aims to fill this gap by investigating the electro-oxidation behavior of methanol, ethanol, and isopropanol on various electrodes, including commercial Pt, Pd, and Au electrodes, as well as self-synthesized Pt/MWCNTs-Ni-CB electrodes. CV and CA are employed to evaluate the catalytic performance of these electrodes, offering new insights into the influence of different fuels, catalysts, and electrolytes on the electro-oxidation reactions, with the ultimate goal of optimizing DAFC performance.

2. MATERIALS AND METHODS

Catalyst synthesis were prepared as follows. The Pt/1MWCNTs-Ni-1CB catalyst was synthesized as follows: 50 mg Carbon Black - Vulcan XC 72 (Fuel cell Store) and 10 mL., nickel (II) chloride hexahydrate ($NiCl_2.6H_2O$ (1 mg/ mL; QReC) solution were dissolved in deionized water (30 mL) and sonicated for 20 min and 100 mL of ethylene glycol solution (70:30 (EG:DI-water), Ajax Finechem Pty Ltd) were mixed in the solutions with sonicated for 20 min. 50 mg of multiwalled carbon nanotubes (MWCNTs, Merck KGaA) was mixed in the solution and sonicated for 20 min. Then, 10 mL of hexachloroplatinic acid hexahydrate ($H_2PtCl_6.6H_2O.6H_2O$ (1 mg/mL); Sigma-Aldrich Merck) solution was added to the resulting mixture above in a flask under ultrasonication for 20 min. Then, the mixture was adjusted to pH ≈ 11.0 with 0.1 M NaOH (Merck KGaA), heated to 120 °C to perform a refluxed reaction for 2 h, centrifuged, washed with deionized water numerous times until neutral pH and dried at 60 °C overnight to obtain Pt/1MCNTs-Ni-1CB electrocatalysts. The Pt/1MWCNTs-Ni-2CB, Pt/2MWCNTs-Ni-1CB, Pt/1MWCNTs-1CB, Pt/MWCNTs and Pt/CB catalysts were synthesized with a similar process using different weight ratios of each carbons. For all catalysts synthesized, the Pt and Ni content in all the above electrocatalysts was controlled at 10.0 wt.%.

Electrochemical performance data were collected using the PalmSens4 electrochemical workstation in a standard three-electrode configuration. The working electrode was a glassy carbon electrode (GCE), while a Pt wire served as the counter electrode, and a silver/silver chloride electrode (Ag/AgCl) was used as the reference electrode. To prepare the GCE for testing, 5 µL of catalyst ink was drop-cast onto the electrode surface and allowed to dry naturally before electrochemical measurements. Cyclic voltammetry (CV) was performed to investigate the alcohol oxidation behaviors of methanol, ethanol, and iso-propanol in both acidic (0.5 M H_2SO_4) and alkaline (0.5 M KOH) solutions. Additionally, chronoamperometry (CA) was conducted at a constant potential of 0.1 V for 3600 seconds to assess the long-term stability and catalytic activity of the electrodes.

3. RESULTS AND DISCUSSION

TEM images of the catalyst regime and corresponding particle size distribution histograms are shown in Fig.1. As illustrated in Fig. 1(a)., spherical Pt nanoparticles are uniformly distributed on xMWCNTs-Ni-yCB. The average diameter of the prepared catalysts is approximately ca. 2.1-2.4 nm and selected Pt/1MWCNTs-Ni-1CB and Pt/1MWCNTs-1CB catalysts nanoparticles is shown. An EDX analysis of the prepared Pt/1MWCNTs-Ni-1CB revealed distinct peaks for Pt and Ni, indicating that Pt with Ni nanoparticles were successfully attached to the surface of MWCNTs-CB. Additionally, the atomic percentages of Pt and Ni were found to be 9.5 and 8.0, respectively, which closely align with the theoretical composition of 1:1.

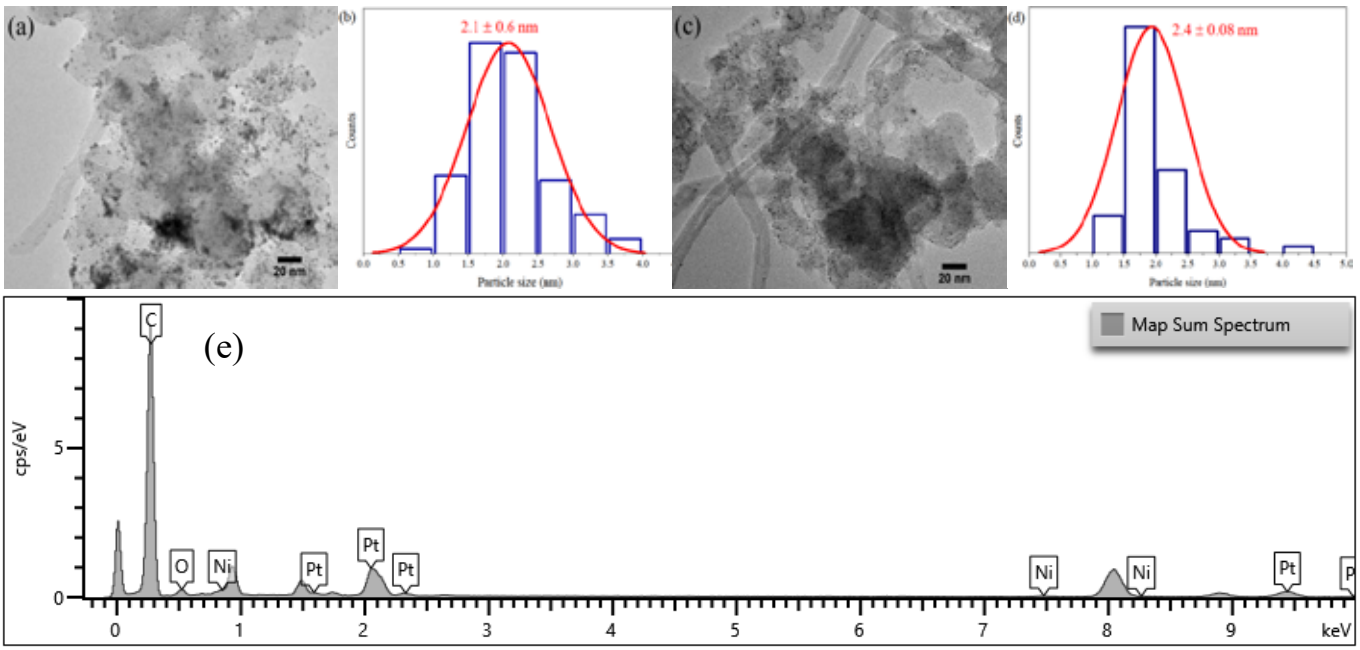

Fig. 1. TEM images and particle size distribution of Pt nanoparticles in (a, b) Pt/1MWCNTs-Ni-1CB, (c, d) Pt/1MWCNTs-1CB, and (e) EDX analysis of Pt/1MWCNTs-Ni-1CB catalysts.

The electro-oxidation behaviors of methanol, ethanol, and isopropanol were systematically investigated using cyclic voltammetry (CV) on Pt/xMWCNTs-Ni-yCB electrodes in both acidic and alkaline media. The results demonstrated that

the acid-base property of the electrolyte media plays a crucial role in influencing the catalytic activity of the electrodes. In alkaline media, oxidation peaks were observed in the expected potential range for all electrodes, indicating effective alcohol oxidation.

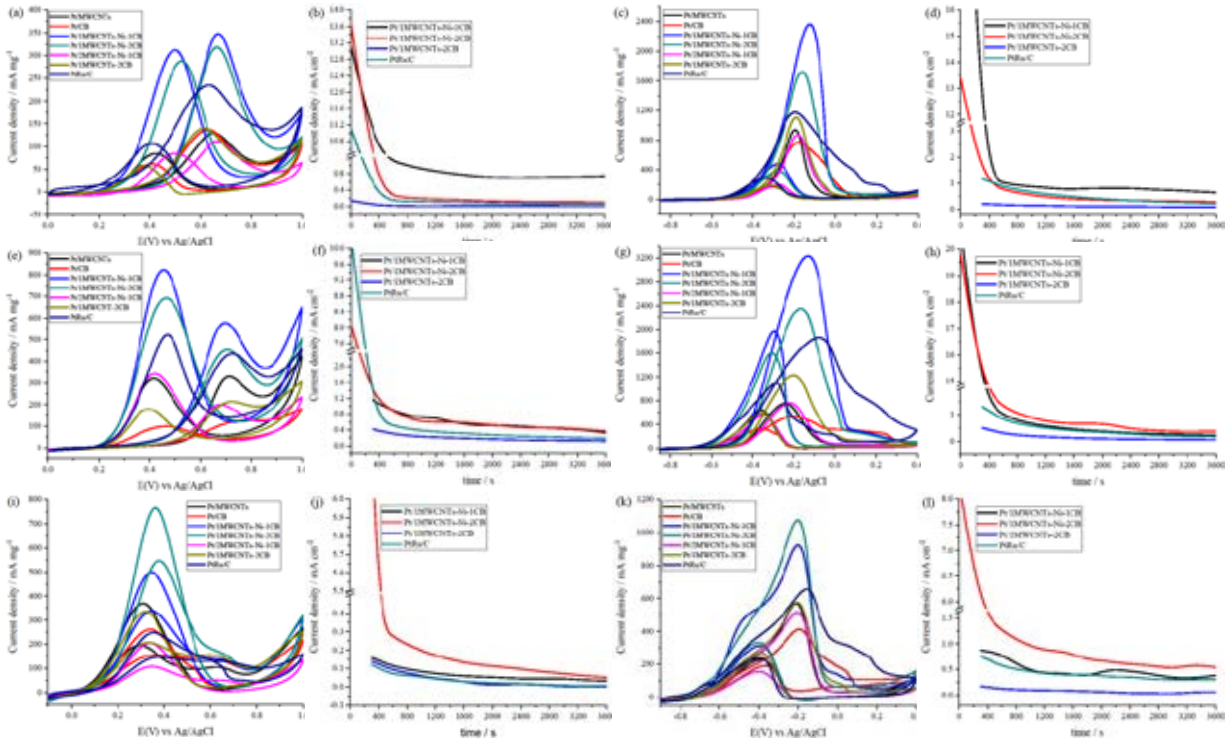

Fig. 2. CV and CA responses of the as-prepared catalysts for the electro-oxidation of methanol, ethanol, and isopropanol in (a, e, i and b, f, j) acidic and (c, g, k and d, h, l) alkaline solutions, respectively.

The comparison of the CV curves revealed that the lowest onset potential and the highest current density were generally observed in alkaline media, suggesting that alkaline media is optimal for the electro-oxidation of alcohols. This is consistent with the understanding that alkaline conditions facilitate easier dehydrogenation and oxidation reactions [5 - 7], which are essential for efficient alcohol oxidation. Additionally, the onset potential, which represents the energy barrier for the oxidation reaction, and the peak current density, which corresponds to the maximum reaction rate, were used to quantitatively assess the catalytic performance. The lowest onset potential and highest current density were mostly observed with the Pt/1MWCNTs-Ni-1CB electrodes, except in the oxidation of isopropanol. The comparison of the onset potentials for methanol (-0.51 V), ethanol (-0.73 V), and isopropanol (-0.80 V) revealed that alcohols with longer carbon chains required lower negative potentials for oxidation, indicating that the oxidation of larger alcohol molecules induces a lower energy barrier resulting from the increased complexity of the oxidation process as the chain length of the alcohol increases. The Pt/1MWCNTs-Ni-1CB electrodes exhibit the best catalytic activity while the Pt/1MWCNTs-Ni-2CB electrodes show highest stability for the oxidation of most alcohols, particularly in alkaline media. The findings emphasize the importance of optimizing both the catalyst composition and electrolyte medium to maximize the efficiency of alcohol oxidation in DAFCs. These results provide valuable understandings for the development of more effective catalysts for renewable energy applications.

4. CONCLUSIONS

This study investigated the electro-oxidation behavior of various alcohols over Pt/xMWCNTs-Ni-yCB electrodes in both acidic and alkaline media, revealing several key trends. The acid-base nature of the electrolyte significantly influences catalytic activity, with alkaline media demonstrating superior performance over acidic media. Specifically, the onset potentials for oxidation in alkaline media were approximately 0.6 V lower than in acidic media. This difference highlights the enhanced catalytic activity in alkaline conditions, which is likely attributed to the increased availability of hydroxide ions that aid in the oxidation process. Among the catalysts tested, Pt/1MWCNTs-Ni-1CB exhibited the best activity for methanol and ethanol oxidation in all media, while Pt/1MWCNTs-Ni-2CB showed exceptional activity for isopropanol oxidation in alkaline media. Both catalysts also demonstrated high stability in CA tests across media. Notably, Pt/1MWCNTs-Ni-2CB exhibited excellent stability for the oxidation of most alcohols. While the underlying reasons for these trends are still under investigation, the findings offer valuable insights for the development of DAFCs in the future.

ABSTRACT
Solid oxide fuel cells (SOFCs) are promising energy conversion devices due to their high efficiency and ability to operate at high temperatures. Among the various geometrical designs of SOFCs, flat-tubular cells combine the advantages of planar and tubular configurations, offering both enhanced thermal stability and improved performance. This study presents an innovative fabrication method for producing flat-tubular anode supports using a 3D-printed mold, which serves as a cost-effective alternative to traditional extrusion techniques. A detailed experimental procedure is outlined, including the design of the mold, fabrication of the anode support, and cell assembly. The electrochemical performance of the fabricated flat-tubular SOFC is evaluated, revealing a peak power density of 223 mW/cm^2 at 800°C. These results demonstrate the potential of the proposed approach for producing flat-tubular anode supports for SOFCs.

Keywords: Solid oxide fuel cell, Flat-tubular, Mold casting, Electrochemical performance

1. INTRODUCTION
SOFCs are high-temperature electrochemical devices that directly convert chemical energy into electrical energy with high efficiency. Therefore, SOFCs are regarded as a promising technology for sustainable energy production, driving ongoing research in materials science, manufacturing techniques, and system integration. Due to their ceramic-based solid-state structure, SOFCs can be fabricated in various geometries; however, planar and tubular configurations remain the most widely utilized designs. Planar SOFCs consist of flat, layered electrode-electrolyte structures that enable high power density and cost-effective manufacturing [1]. However, they are more vulnerable to thermal stress and necessitate effective sealing, making them more prone to gas leakage [2]. In contrast, tubular SOFCs, characterized by their cylindrical geometry, offer enhanced thermal stability while reducing gas leakage concerns [3]. Nevertheless, their design typically results in higher internal resistance due to longer current collection paths, leading to lower power density compared to the planar configuration [4]. Among other SOFC geometrical designs, which are primarily based on modifications of planar and/or tubular structures, the flat-tubular SOFC was developed as a hybrid structure that combines the thermal stability benefits of tubular geometry with the high-performance advantages of planar geometry [5]. Therefore, both numerical and experimental studies have been undertaken in the literature to investigate this design [6-9].

Similar to other SOFC geometries, flat-tubular cells are typically fabricated with an anode-supported structure to enhance cell performance by minimizing the thickness of the electrolyte layer. In this regard, the extrusion method is commonly employed to fabricate flat-tubular anode supports [10-13]. This established mass production method provides a cost-effective and versatile approach for fabricating both ductile and brittle materials with intricate cross-sectional shapes. However, besides high initial cost, maintaining the structural integrity, preventing warping or twisting, and avoiding defects in thin walls can be challenging during the fabrication process [14-16]. Therefore, this study seeks to investigate a more efficient and cost-effective approach for producing the anode support for flat-tubular SOFCs by utilizing a mold fabricated with a conventional 3D printer, as an alternative to the traditional extrusion method. Furthermore, a flat-tubular cell is fabricated, and its electrochemical performance is subsequently evaluated.

2. EXPERIMENTAL
2.1. Mold Design
The technical drawings of the mold designed for producing anode supports with flat-tube geometry are presented in Fig. 1. This mold is composed of six components: a bottom support, four sides, and a top cover. Following the design, the mold elements were produced using Creality Ender 3 S1 3D printer. Discharge channels were incorporated into the two side components to facilitate the easy removal of excess material, while holes were created in the other two side components to form the tube gaps in the flat-tube design. Additionally, holes were drilled into the components to allow for the placement of bolts, thereby enabling the assembly of the mold parts. Metal bars were then placed through these gaps during production of the anode support flat-tubes.

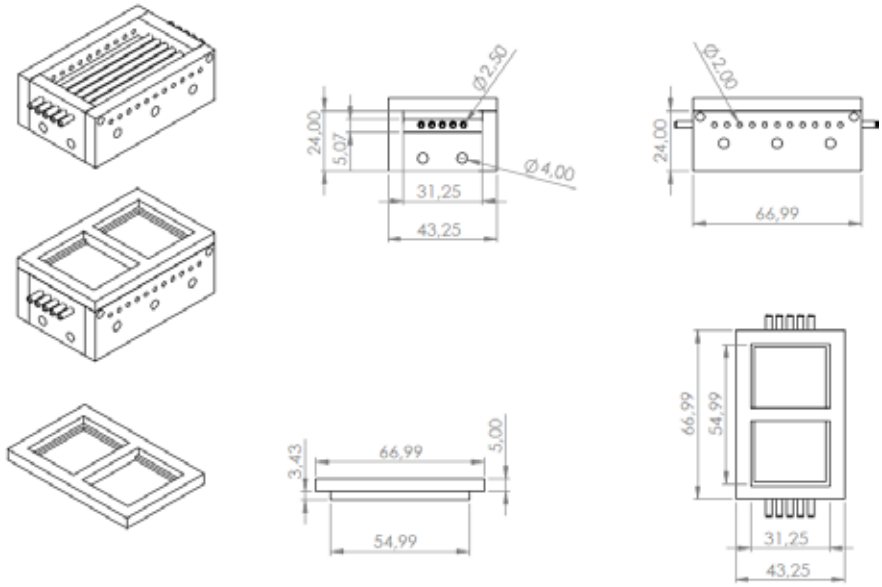

Fig. 1. Technical drawing of 3D printed mold

2.2. Flat-tubular Anode Support Fabrication

To prepare the paste for anode support fabrication, commercial NiO (NiO-A, Novamet, USA) and YSZ (yttria stabilized zirconia, YSZ8-TC, Nexceris, USA) powders were weighed in a ratio of 66% to 34% by weight. Appropriate proportions of dispersant (fish oil, Sigma-Aldrich, Germany) and solvent (a mixture of ethanol and methyl ethyl ketone, Sigma-Aldrich) were then added, and the mixture was subjected to 24 hours of ball milling. Subsequently, specific amounts of binder (Butvar, Sigma-Aldrich) and plasticizer (PEG, Sigma-Aldrich) were incorporated into the solution. The mixture was homogenized by mixing at 100°C with appropriate proportions of high-temperature paraffin and stearic acid using a mechanical mixer until the desired viscosity was achieved. The prepared paste was then placed into the mold fabricated by the 3D printer. After metal bars were positioned in the designated areas to create the tube spaces and the structure was pressed at 5 MPa using a uniaxial press. Next, it was transferred to an isostatic press for the final forming process, which was performed at 15 MPa for 1 min. The mold was dissembled after 24 h drying step and the flat-tubular anode support was obtained. The final shape was achieved using a laser cutter and the support was pre-sintered at 1150 ºC for 2 h. The support surface was dip-coated with YSZ electrolyte, leaving the areas at the edges reserved for current collection uncoated. The structure was then fired at 1400°C for 4 h. Similarly, LSM (LSM20-HP, Nexceris, USA)-YSZ (wt. %: 50-50) cathode functional and LSM (LSM20-P, Nexceris)-YSZ (wt. %: 90-10) cathode current collection layers were screen printed on the flat surfaces. The cathode layers were sintered at 1050 ºC for 2 h. The flat-tubular cell had a total cathode active area of ~10 cm^2.

2.3. Cell Fabrication and Testing

The components of the test setup are given in Fig. 2. After assembling cell, current collection meshes, sealants and endplates, the test apparatus was placed in an oven. Once the testing temperature of 800°C was reached, the anode side was reduced by applying a hydrogen flow of 1 NL/min for an hour. After 2 NL/min air was also supplied to the cathode and the cell performance was measured with a fuel cell test station (Arbin Instruments, FCTS, ABD).

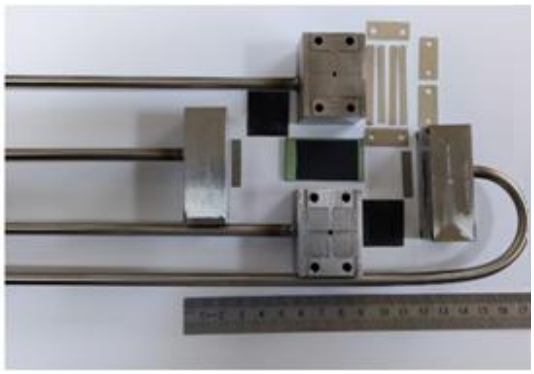

Fig. 2. Components of flat-tubular SOFC test setup

3. RESULTS AND DISCUSSION

The photo of the flat-tubular SOFC developed in this study is presented in Fig. 3, while the electrochemical performance of the cell is depicted in Fig. 4. No cracks or delamination are visible in the cell. Furthermore, the measured open circuit potential, which closely aligns with theoretical value, indicates that the electrolyte structure is free of cracks or pinholes. The cell exhibits a peak power density of 223 mW/cm^2 under 1NL/min hydrogen and 2 NL/min air flow at an operating temperature of 800 ºC. Although no optimization study was conducted, the obtained performances are found to be comparable to those reported in the literature [11, 12]. Therefore, the proposed method is regarded as a promising approach for the fabrication of anode support flat-tubes for SOFCs.

Fig. 3. Final flat-tubular cell

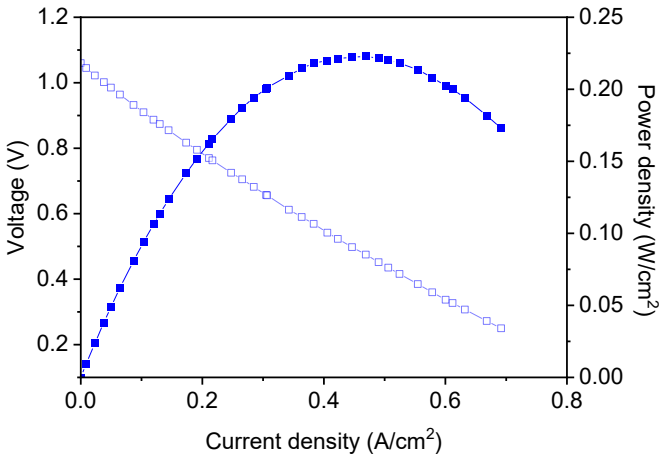

Fig. 4. Cell performance at 800 ºC

4. CONCLUSIONS

The results of this study indicate that using a 3D-printed mold for fabricating anode support flat-tubes is an efficient and promising alternative to the traditional extrusion method. The electrochemical performance of the flat-tubular SOFC fabricated in this study is comparable to those reported in the literature, with a peak power density of 223 mW/cm^2 at 800°C. The absence of cracks or delamination in the cell structure further supports the viability of this approach. This method offers significant advantages in terms of cost, production flexibility, and the potential for manufacturing of flat-tubular SOFC supports. Future work could focus on optimizing the fabrication process and further enhancing cell performance.

ABSTRACT

Electricity is expected to have a much larger share in future energy systems due to the electrification trends in buildings, industry, and transport sectors while most net-zero projections assume a very high penetration of variable renewables in their grid mix. These trends will be accompanied by further divestment from fossil fuels that normally balance the energy system variability. Therefore, there will be a need for long-duration energy storage in order to build resilience against the disruptive effects of intermittency and counter-correlation. The storage of gaseous hydrogen in salt caverns is proposed here as a viable energy storage option, based on wide geological availability. To that end, the existing plans for hydrogen blending are refuted and the synergies between hydrogen storage and enhanced geothermal systems are postulated.

Keywords: Variable Renewable Energy, Long-Duration Hydrogen Storage, Enhanced Geothermal Systems

1. INTRODUCTION

While national climate pledges proliferate, the global challenge for decarbonisation lies in the energy trilemma between sustainability, affordability, and security. Recently, there has been an exponential growth of wind and solar power plant installations as their costs continue to fall due to experience curve effects and the investments continue to flow into clean energy transition [1]. Nevertheless, electricity still accounts for just over 20% of the final energy consumption in most of the major economies. Going forward, the path towards decarbonisation is through the electrification of heat (buildings and low-temperature industrial processes) and mobility (road passenger and rail transport), both of which tend to have low load factors. Therefore, as illustrated in **Fig. 1** for the case of Türkiye, all of these tasks will require investment in grid infrastructure at unprecedented scales, prompting strategic decisions such as improving energy storage capacity [2].

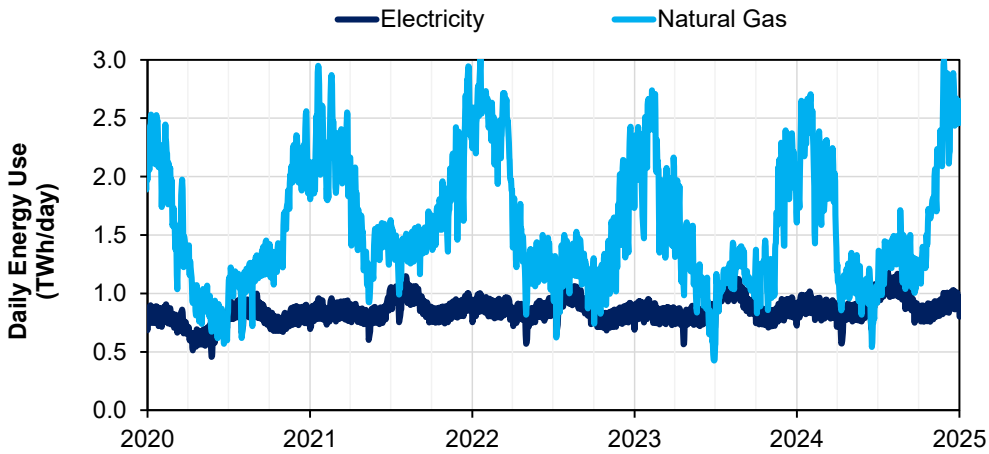

Fig. 1. Türkiye's daily energy use in the forms of electricity and natural gas, based on data from EXIST [3]

On the other hand, as the future energy systems become more electrified, they will also be inherently more efficient, owing to the fact that typically two-thirds of the primary energy supply is currently being lost as waste heat. This fact counteracts the fallacy that electricity from renewables must replace an equivalent amount of primary energy from fossil fuels (coal, oil, and gas) when it will actually reduce the total demand for primary energy. Yet the selective imposition of externalities upon the prices of electricity and fossil fuels remains as the main barrier against this drive towards efficiency. If these are all priced in, then fossil fuels can gradually be phased out. However, this will also imply the loss of fossil fuel buffers that normally balance the variability in energy systems. For resilience concerns, energy stocks are just as important as energy flows; and how to replicate their storage functions in a net-zero world is still an unresolved issue.

2. ANALYSIS AND MODELLING

There has been an emerging quest to mitigate the disruptive effects of intermittency and counter-correlation. Different combinations of demand side response, interconnections, and overcapacity have been proposed as potential solutions

[4]. Yet there is still a need to bridge the extended periods of dark lulls. While well suited for this type of operation, nuclear power plants and pumped hydro projects are often over budget and over schedule. Hydrogen storage can be a viable option but most of the industrial strategies were influenced by post-pandemic hype cycles and hydrogen, despite its low heat value, was misallocated into blending with natural gas [5]. As illustrated in **Fig. 2**, this brings minimal reduction to the carbon intensity of natural gas while causing its energy cost to rise significantly. Besides, no practical benefit is being offered to avoid the curtailment of wind and solar output. As the large funding gap for the required interventions becomes evident, there will be calls for a hydrogen reset, this time with a clear focus on the merit order of hydrogen use cases [6].

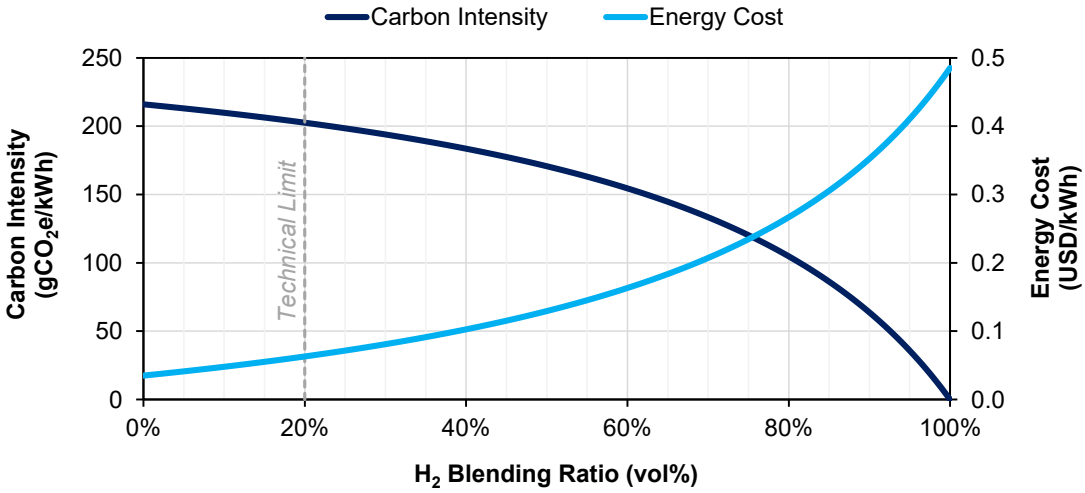

Fig. 2. The impact of hydrogen blending on the carbon intensity and energy cost of natural gas

Gaseous hydrogen stored in salt caverns or depleted reservoirs can deliver the capacity needed for long-duration energy storage [7]. Hydrogen is a suitable energy storage medium because it has a very high energy density by mass and salt caverns are widely available geological formations that can store large volumes with relatively low maintenance [8]. These storage facilities can be operated centrally and infrequently as an expensive but strategic reserve which can be procured through a resilience levy. As illustrated in **Fig. 3**, resilience of the variable renewable energy (VRE) resources, such as wind and solar, can be quantified as the share of their capacity that is being firmed by hydrogen storage over periods of dark lulls which can last for multiple days. There is a trade-off between the duration and proportion of firming which can be partly offset by requiring larger volumes of hydrogen storage per unit capacity of VRE. The breakeven conditions for arbitrage in the power markets will depend on the roundtrip efficiency and leakage losses of storage.

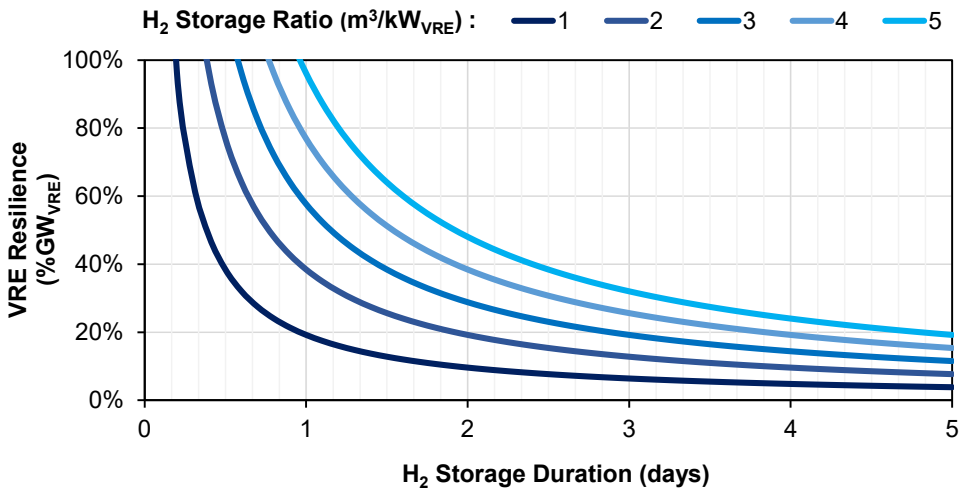

Fig. 3. Resilience of the variable renewable energy resources, firmed by long-duration hydrogen storage

3. RESULTS AND DISCUSSION

Storing hydrogen in salt caverns can prove to be a cost-effective resilience strategy for countries like Türkiye with abundant renewable energy resources and favourable geological formations. Türkiye targets to reach 120 GW of wind

and solar capacity by 2035 [9]. In that case, more than half of the country's installed capacity will be in the form of VRE, posing a resilience risk to the power system. According to Fig. 3, firming 20% of this VRE capacity for 5 days would require a hydrogen storage volume of 0.6 bcm. This would fill half of the capacity currently available at the underground natural gas storage facilities near Lake Tuz, located in Central Anatolia Region. These salt caverns, which are engineered by solution mining, will quadruple in storage capacity once the construction is complete. As the country's natural gas consumption is expected to peak and decline, instead of stranding these assets, vast quantities of gaseous hydrogen can be injected into them. The roundtrip efficiency and leakage losses of storage can be verified in advance through pilot projects and model simulations that will be able to characterise the geological conditions with some degree of uncertainty.

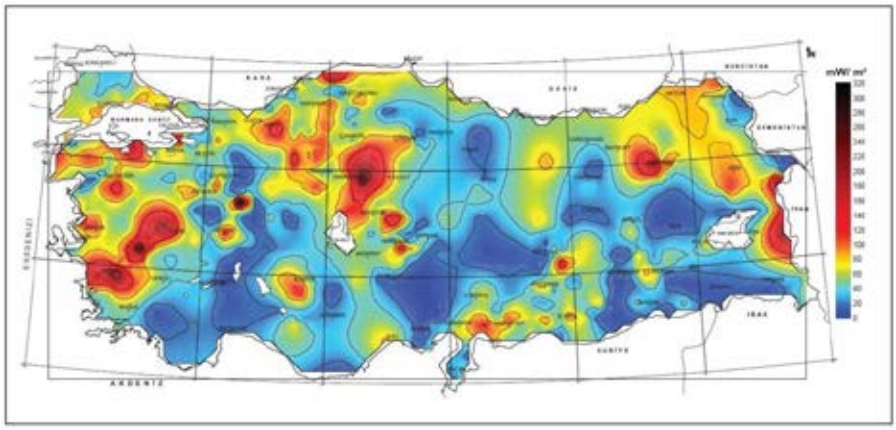

Fig. 4. Geothermal heat flow map of Türkiye [10]

Geothermal energy is particularly well suited to be coupled with long-duration hydrogen storage as it can reduce the levelised cost of storage due to its low marginal cost and high capacity factor [11]. Türkiye has a high geothermal potential because of its tectonic and volcanic features, and utilises this resource both directly and indirectly in many areas [12]. As illustrated in the geothermal heat flow map of Türkiye (**Fig. 4**), Central Anatolia Region is home to the country's largest untapped geothermal fields. Reaching temperatures well above 300°C [13], these fields may be suitable for deploying enhanced geothermal systems (EGS) which can power the electrolysers and compressors for the production and storage of hydrogen at the nearby Lake Tuz facilities. As the technology readiness levels improve with recent breakthroughs, EGS can expand the technical potential of geothermal energy in such fields that have high temperatures but low fluid volumes and low reservoir permeability. Furthermore, the techniques of horizontal drilling and hydraulic fracturing apply similarly to the development of EGS and salt caverns; thus synergies can be explored through regional planning.

4. CONCLUSIONS

Achieving decarbonisation through clean energy transition is a complex task in growth economies like Türkiye. Therefore, maximising efficiency in terms of both energy and exergy needs to be the main objective of all conversions between heat, electricity, and fuels. In buildings, industry, and transport sectors, the process of electrification will follow as the corollary of this objective. It also follows that, if not hindered by incumbents such as the proponents of hydrogen blending, the process of degasification will lead to the decommissioning and repurposing of many stranded assets. Most net-zero projections assume a very high penetration of variable renewables in their grid mix. At that point, the concept of "reserve margin" will replace the current practice of "baseload" as the underlying mechanism of resilience in the power system architecture. Under these new circumstances, long-duration hydrogen storage is proposed here as a critical component of that reserve margin. As a next step, the techno-economic prospects for developing geological hydrogen storage in Türkiye can be further investigated through detailed feasibility studies.

ABSTRACT
Ammonia is considered as the future alternative fuel to overcome emissions from low-quality fuel. Despite ammonia being a promising alternative fuel, its toxic and corrosive properties are the main drawbacks and increase risks on a ship. This study aims to determine the events and failures that lead to ammonia leakage from the high-pressure ammonia fuel system of a ship. Five experts from the maritime industry and academy prepared the basics of the study by doing HAZOP. After this step, an FTA diagram was formed to show which basic and intermediate events result in ammonia leakage.

Keywords: Ammonia, Fault tree analysis, Fuel system, HAZOP, Maritime transport

1. INTRODUCTION

Maritime transportation is the most important transportation mode worldwide. There were 108,789 merchant ships of 100 gross tons and above in January 2024, and the ship number increased by 3.4% from 2023 to 2024 [1]. Since 98% of these ships use low-quality fossil fuels [2], maritime transportation accounts for 9.84% of global sulfur oxide (SO_X) emissions, 14.74% of nitrogen oxides (NO_X) emissions, 6.75% of particulate matter 2.5 (PM2.5) emissions, 3.56% of particulate matter 10 (PM10) emissions, 0.61% of carbon monoxide (CO) emissions [3], and 2.89% of global carbon dioxide (CO_2) emissions [4]. To overcome these emissions, using alternative fuels on ships is the most promising and attractive solution due to a higher emission reduction potential [5]. There are various alternative fuels, such as liquefied natural gas (LNG), methanol, ammonia, and hydrogen. But ammonia is considered as the future alternative fuel for maritime transportation. Despite ammonia being a promising alternative fuel, its toxic and corrosive properties are the main drawbacks and increase risks on a ship.
In this study, an ammonia leakage event at a high-pressure ammonia fuel system is investigated. Possible events and failures that lead to ammonia leakage are determined by hazard and operability analysis and a fault tree diagram of the events and failures is formed.

2. PROPERTIES OF AMMONIA

Ammonia consists of one nitrogen atom and three hydrogen atoms, and it does not contain carbon or sulfur atoms. Therefore, its combustion is free of carbon dioxide, carbonaceous emissions, sulfur oxides, and particulate matter. On the other hand, ammonia combustion results in water, nitrogen, NO_X, nitrous oxide (N_2O), and a small amount of ammonia slip [6]. Ammonia is a low-reactivity fuel with a low heating value (LHV) of 18.5 MJ/kg. The auto-ignition temperature of ammonia is 651 ˚C and the flammability limits in the air are between 16 -25% by volume. The low burning velocity of ammonia at 14 cm/s affects the combustion reactivity of this fuel [7]. Although it has low reactivity, ammonia is suitable for large marine diesel engines thanks to their large cylinder displacement volume, low engine speeds, and constant high engine loads [8]. The storage options for ammonia as a fuel are either at -33 ˚C at 1 bar or at room temperature at 10 bars [9]. Thus, ammonia-fueled ships require 2.4 times larger tank volume than the conventional-fueled ships [10]. Using ammonia as a fuel brings some risks that are associated with its properties. Ammonia is a toxic chemical that has a toxicity level of more than three times higher than other marine fuels, marine diesel oil, and methanol [11], [12]. The toxicity of ammonia causes dehydration, caustic burning, and freezing when human contact [9]. The toxicity of ammonia to aquatic life is an issue. Ammonia spilling into the sea can cause extreme risk to aquatic life. Corrosiveness is another risk of ammonia. Ammonia is incompatible with aluminum, brass, copper, magnesium, and zinc alloys [8]. Moreover, ammonia can cause stress corrosion in tanks and fuel supply lines. The last risk of ammonia is fire and explosion risk. Due to its low combustion reactivity, the risk of fire and explosion is lower than the other alternative fuels, such as LNG, LPG, methanol, etc. But ammonia has a high reaction speed with halogens and oxidizers that may lead to explosions [6].

3. METHODOLOGY

This study uses a combination of hazard and operability analysis (HAZOP) and fault tree analysis (FTA). The opinions of the specified experts in Table 1 are taken at a brainstorming session to apply the methodology.

2.1. Hazard and Operability Analysis (HAZOP)

HAZOP is an analysis that is developed to identify the operational problems and potential hazards of a system [13]. The

analysis was formed to find the possible defects and deviations that result in explosions, fires, and toxic releases [14]. HAZOP analysis is done according to the opinions of the experts related to the specific field of the study.

2.2. Fault Tree Analysis (FTA)

The FTA is a top-down approach that starts by identifying the top event. The next steps are the formation of a fault tree diagram, qualitative evaluation, and quantitative evaluation [15]. The fault tree is drawn by using symbols in Table 2. This study focuses on only one top event, and the fault tree diagram of this top event with its intermediate events, basic events, and their logic gates is formed.

Table 1. The specifications of the experts

Expert	Position / Experience / Education	Information
1	Oceangoing Chief Engineer / 11 years / BSc.	The expert has a good knowledge on fuel systems and their risks.
2	Oceangoing Chief Engineer / 2 years / MSc.	The expert has worked on chemical tankers and has a good knowledge on ammonia.
3	Oceangoing Chief Engineer – Academician / 10 years – 19 years / PhD.	The expert had worked on chemical tankers and has academic studies on alternative fuels.
4	Academician / 10 years / PhD.	The expert has academic studies on alternative fuels and their risks.
5	Academician / 4 years / PhD.	The expert has academic studies on alternative fuels and their risks.

Table 2. Fault tree analysis symbols and descriptions [16]

Symbol	Meaning	Description
	AND gate	The output event commences if all input events arise
	OR gate	The output event commences if any of the input events arise
	Basic event	The basic cause of a failure or intermediate event
	Undeveloped event	Undeveloped primary cause due to lack of knowledge
	Intermediate event	An event that commences due to one or more sub-events

4. RESULTS AND DISCUSSION

4.1. Ammonia-fueled Ship Fuel System Components

In this study, it is assumed that the ammonia fuel system is a high-pressure fuel system. Thus, the components of the system are a bunkering station, fuel storage area, fuel preparation, supply and recirculation unit (FPSR), fuel valve train (FVT), double-walled piping, the main engine components, ammonia catch system, and vent mast [17]. The FTA diagram is formed by considering these components.

4.2. FTA Diagram

The FTA diagram of ammonia leakage (TE) from the ammonia-fueled ship fuel system is constituted by brainstorming with the experts. Fig. 1, the FTA diagram, contains 23 intermediate events (IE) and 39 basic events (BE). All events are shown in Table 3. The TE mainly depends on the IEs from 1 to 6. IE-1 is associated with IE-7 to IE-10; IE-2 is associated with IE-11 and IE-12; IE-3 depends on IE-13 to IE-16; IE-4 depends on IE-17 and IE18; IE-5 is associated with IE-19 and IE-20; and IE-6 is associated with IE-21 to IE-23. All IEs are connected to OR gates which means any of the input events arise for the output event to commence. The IEs depend on 39 BEs as the basic events that have to happen to constitute intermediate events. The IEs result in TE, ammonia leakage from the fuel system.

Table 3. Definition of the events in FTA diagram

Event	Description	Event	Description
TE	Ammonia fuel leakage	BE-9	Ammonia-induced stress corrosion cracking
IE-1	Storage tank leakage	BE-10	External environmental exposure
IE-2	Piping and valve leakage	BE-11	Leaking flanges or couplings
IE-3	Transfer system leakage	BE-12	Improper assembly
IE-4	Control system failure	BE-13	Faulty valve seals or internal wear
IE-5	External factors	BE-14	Material fatigue from repeated temperature fluctuations
IE-6	Human factor	BE-15	Wear and tear over time
IE-7	Corrosion	BE-16	Poor material compatibility
IE-8	Structural failure	BE-17	Pressure build-up causing weak points to fail
IE-9	Seal failure	BE-18	Frozen ammonia leading to rupture
IE-10	Overpressure	BE-19	Improper closing or wear
IE-11	Corrosion of piping	BE-20	Actuator failure
IE-12	Joint failures	BE-21	Cracks or wear in flexible parts
IE-13	Pump seal failure	BE-22	Misalignment or improper installation
IE-14	Pipeline blockage	BE-23	Failure to detect pressure or temperature abnormalities
IE-15	Valve malfunction	BE-24	Late detection of leaks
IE-16	Hose or flexible connection failure	BE-25	Incorrect valve actuation
IE-17	Sensor failure	BE-26	Inability to trigger safety shutoff systems
IE-18	Control unit malfunction	BE-27	Alarm system failure
IE-19	Operational errors	BE-28	Faulty software leading to incorrect actions
IE-20	Third-party damage	BE-29	Extreme weather conditions causing material degradation
IE-21	Improper operation	BE-30	Mishandling of equipment
IE-22	Maintenance errors	BE-31	Inadequate maintenance or inspections
IE-23	Insufficient training	BE-32	Accidental impact during loading/unloading
BE-1	Material degradation due to exposure to ammonia	BE-33	Fire or explosion near storage or piping
BE-2	Poor maintenance or protective coatings	BE-34	Incorrect valve or pump operation
BE-3	Cracks caused by pressure fluctuations	BE-35	Lack of adherence to procedures
BE-4	Physical damage during operations	BE-36	Failure to detect wear or damage
BE-5	Degraded gaskets or seals	BE-37	Use of incompatible materials during repair
BE-6	Improper assembly	BE-38	Lack of knowledge about system operation
BE-7	Faulty pressure relief valves	BE-39	Failure to recognize early signs of leakage
BE-8	Temperature variations causing pressure build-up		

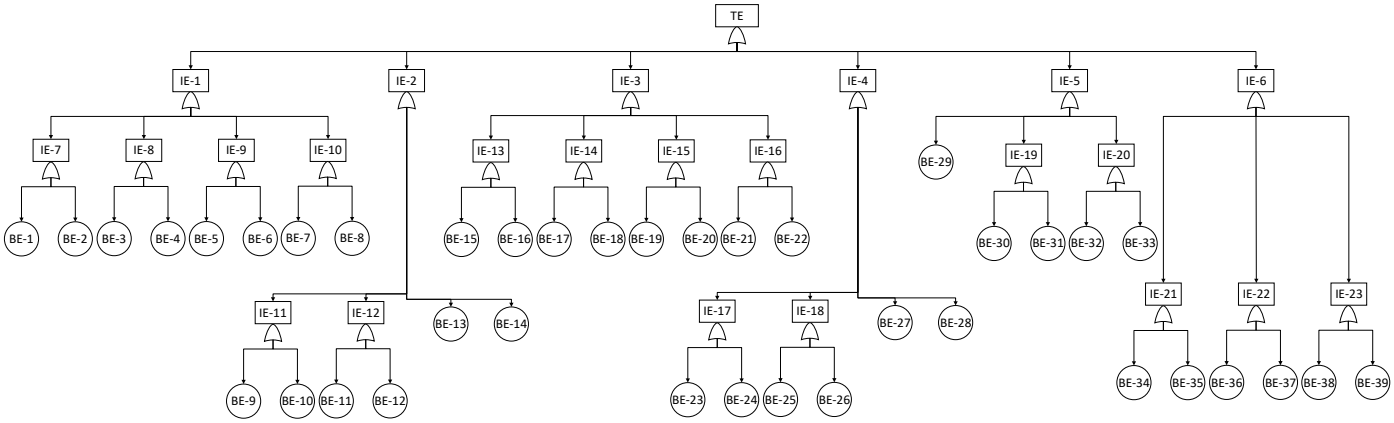

Fig. 1. Ammonia leakage FTA diagram

5. CONCLUSION

This study aims to determine the events and failures that lead to ammonia leakage from the high-pressure ammonia fuel system of a ship. Five experts from the maritime industry and academy prepared the basics of the study by doing HAZOP. After this step, an FTA diagram was formed to show which BEs and IEs result in ammonia leakage (TE). IE-1 Storage tank leakage, IE-2 Piping and valve leakage, IE-3 Transfer system leakage, IE-4 Control system failure, IE-5 External factors, and IE-6 Human factor are the related IEs to TE. The next study will be an extended version that contains quantitative analysis of the ammonia leakage FTA diagram. Furthermore, other TEs will be analyzed by the same expert team to further enlarge the safety analysis of the ammonia fuel system of a ship.

ABSTRACT

This study investigates the performance of Hydrogen Single Cell (HSC) for production of HHO gases using two methods. First, Solar Cell and DC-DC controller. Second, Institiute's AC and AC-DC converter. The study focuses on the fluid flow of electrolyte and stagnant electrolyte at specific concentration 30 w.t % which is using the latter method.Then, the evolution process of hydrogen,specially,is photographed at different current and specific inlet velocity of 0.03 m/s.The results show that the maximum Gain Output Ratio (GR) in stagnant fluid around 2.6 Volt is 75% better than all inlet velocities of 0.03,0.06 and 0.09 m/s.The findings of photographing indicate that there is a positive relationship between the hydrogen evolution rate and input current.As a result of these investigations, suggestions are identified for future research that will be an extension for different concentrations besides photographing of each case to more explanation of fluid flow behaviour
Keywords: Hydrogen Production; Fluid Flow; Hydrogen Cell Design

1. INTRODUCTION

The global reliance on fossil fuels leads to pressing challenges such as pollution, climate change, and resource depletion. Consequently, a shift toward renewable energy sources like solar and wind is underway, although their intermittent nature heightens the need for efficient energy storage. Hydrogen fulfills this requirement, with global demand expected to rise from 87 million tons in 2020 to as high as 680 million tons by 2050 [1]. Hydrogen's combustion produces only water, making it a crucial clean energy vector [2]. Water electrolysis, especially alkaline water electrolysis (AWE), is widely recognized for its simple operation and lack of harmful emissions [3]. Despite these advantages, AWE's relatively low efficiency and current density necessitate further research [4]. Numerous studies have addressed bubble behavior, including bubble-induced and forced convection within electrolyzers [5-6]. Cao et al. [7] highlighted that the hydrogen bubble curtain width scales with electrolyte inlet velocity, significantly affecting overpotential. Meanwhile, Sakr et al. [8] reported higher hydrogen production rates using polymeric membranes and narrower electrode gaps.
The present study experimentally assesses a Hydrogen Single Cell (HSC) powered by a solar panel under varying electrolyte velocities, documenting gas evolution at different currents to better understand and optimize performance. It aims to provide insights into critical operational parameters that influence hydrogen generation efficiency.

2. MATERIALS AND METHODS

The Hydrogen Single Cell (HSC) was designed to accommodate both flowing and stagnant electrolytes. As shown schematically in Figure [1], it comprises two outer Teflon covers chosen for their nonconductive, anticorrosive properties and ability to withstand mechanical stress. Each cover houses a square stainless steel (SS316L) electrode (10 cm × 10 cm), separated by a transparent acrylic spacer (1.5 cm gap) that facilitates direct observation of gas evolution within the cell. Although literature suggests that nickel electrodes can offer superior performance, SS316L was selected as a cost-effective alternative. Rubber gaskets are placed between the Teflon covers and the acrylic spacer to prevent electrolyte or gas leakage, and the assembly is secured using bolts, washers, and nuts.
To ensure adequate electrical conductivity, potassium hydroxide (KOH) is dissolved in water instead of relying on pure water. The specific KOH concentration strongly influences both current conduction and hydrogen evolution rate, as described by Equation (1):

$$v_{H_2} = \frac{i}{FZ} \tag{1}$$

Here, v_{H_2} is the volumetric flow rate of hydrogen, i is the current, F is Faraday's constant, and Z is the number of electrons transferred per molecule. KOH was selected over sodium hydroxide (NaOH) based on evidence indicating superior conductivity at equivalent concentrations and temperatures [9].

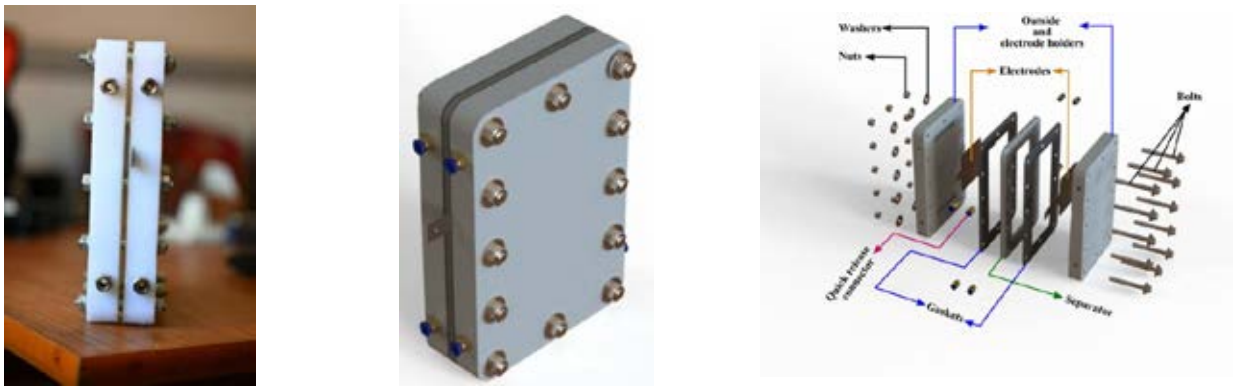

Fig. 1. Real photo and CAD model of Hydrogen Cell

When fluid flow is needed, a centrifugal pump and ball valves control the electrolyte's inlet flow rate. The Hydrogen Single Cell (HSC) has four quick-release fittings, two inlets and two outlets, so it can switch easily between flowing and stagnant modes. Valves and a bubbler help separate gases from the circulating electrolyte.Two main power sources are used to cover a wide range of currents. First, a solar panel (see Table [1]) supplies direct current (DC) for electrolysis, managed by a DC–DC controller (see Table [2]). This setup allows for multiple measurements and fine-tuning of power input, enabling high-quality photographs to be taken under carefully controlled conditions.

Table 1. Characteristics of the PV module

Parameter	Specs.	Parameter	Specs.
Model	JAM72S30 -550/MR/1500V.	I_{mp}	13.11 A
Dimension	2279 x 1134 mm	V_{Oc}	49.9 V
P_m	550 W	I_{SC}	14 A
V_{mp}	41.96 V	STC	1000 W/m^2 at 25 C and 1.5 Am

Table 2. Charachteristics of Riden DC-DC converter

Parameter	Specs	Parameter	Specs
Output voltage	0-60.00V	**Output voltage accuracy**	±0.3%
Output current	0-18.000A	**Output current accuracy**	±0.5%
Output power	0-1080W		

For currents higher than 18 A (the limit of the DC–DC controller), an AC–DC converter (see Table [3]) is used. This setup allows the higher current levels needed to study greater hydrogen production rates under more demanding conditions.A Nikon Z8 camera with an AF 85 mm f/1.8 Z lens (see Table [4]) captures the gas evolution between the electrodes. Photos are captured at different current settings, showing how hydrogen and oxygen bubbles form and spread in the 1.5 cm gap, offering clear insights into electrochemical reactions.

Table 3. Charachteristics of BK-Precision 1900B AC-DC converter

Parameter	Variable Output Voltage	Variable Output Current	Maximum Output Power
Specs	1-16 V	0-60A	0-960W

Table 4. Technical specifications of Nikon Z8

Parameter	Specs	Parameter	Specs
Max resolution	8256 x 5504	**Boosted ISO (maximum)**	102400
Sensor size	Full frame (35.9 x 23.9 mm)	**Minimum shutter speed**	900 sec
Boosted ISO (minimum)	32	**Maximum shutter speed**	1/32000 sec

The Hydrogen Single Cell (HSC) is built with Teflon covers, SS316L electrodes, and a clear acrylic spacer, sealed by rubber gaskets. It can run with either flowing or stagnant electrolyte made by dissolving KOH in deionized water. A solar panel and DC–DC controller handle low-to-medium currents, while an AC–DC converter handles higher currents beyond 18 A. During testing, electrolyte flow rate, KOH concentration, and current are systematically changed, and measurements of current, voltage, and hydrogen output are registered. A Nikon Z8 camera captures images of bubble formation to show how different conditions affect hydrogen production and overall cell performance.

3. RESULTS AND DISCUSSION

The system performance is evaluated by analyzing the variation of current, hydrogen production rate, and gain output ratio with voltage under natural conditions and at flow velocities of 0.03 m/s, 0.06 m/s, and 0.09 m/s.
Figure [2] illustrates the relationship between current and voltage for natural generation and different velocities. Generally, the current increases proportionally with voltage in all cases. Notably, the current variation under natural conditions

closely aligns with that at a velocity of 0.09 m/s, albeit with slightly lower values. for instance, in natural case a current lower value could be observed at voltage lower than 2.55 volt. This is because in the natural case, where there is no forced flow, ion transport relies primarily on diffusion. This results in slower reaction rates and a lower current compared to cases with forced flow. Conversely, for a given voltage, the current decreases at 0.06 m/s but increases again at 0.09 m/s, exceeding the values observed at 0.03 m/s. The current values for 0.03, 0.06 and 0.09 m/s at 3.25 volt are equal 35, 24 and 45 amperes, respectively.

Figure [3]. illustrates the variation of the gain output ratio with voltage under natural generation and different velocities. A consistent trend is observed, where the gain output ratio initially increases slightly with voltage before decreasing. The highest gain output ratio is achieved in the natural generation case. For forced flow, at constant voltage, the gain output ratio rises from velocity 0.03 to 0.06 m/s and then declines at velocity 0.09 m/s. The recorded values of grain output ratio at 3.5 volt are 48%, 50%, and 43% for velocities of 0.03, 0.06, and 0.09 m/s, respectively.

Figure [4]. illustrates the variation of the gain output ratio with voltage under natural generation and different velocities. A consistent trend is observed, where the gain output ratio initially increases slightly with voltage before decreasing. The highest gain output ratio is achieved in the natural generation case. For forced flow, at constant voltage, the gain output ratio rises from velocity 0.03 to 0.06 m/s and then declines at velocity 0.09 m/s. The recorded values of gain output ratio at 3.5 volt are 48%, 50%, and 43% for velocities of 0.03, 0.06, and 0.09 m/s, respectively.

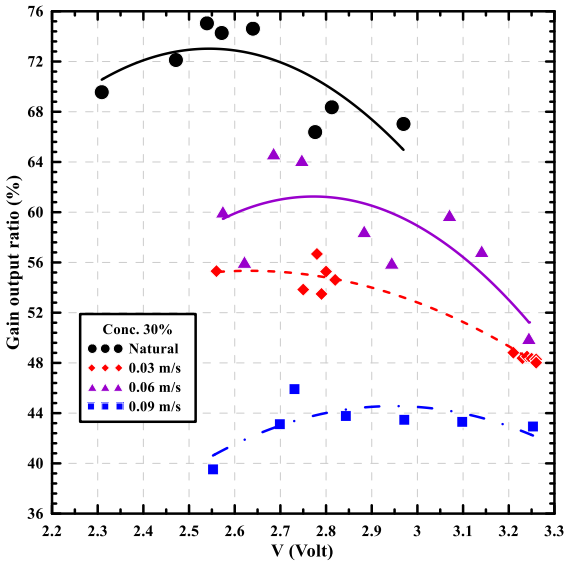

Fig. 4. The variation of the gain output ratio with the voltage at natural generation and different velocities

Figure [5] shows the developing hydrogen layer over the electrode. The images are presented with different applied

currents between the electrodes. The gap distance between the two electrodes is 16 mm. The area of the electrodes is 10cm x 10 cm. The concentration of the electrolyte is 10%. The flow rate of the electrolyte is 3.5 L/m (velocity equals 0.03 m/s). Regarding the presented images, it is clearly observed that hydrogen production increases with the increase in the applied current.

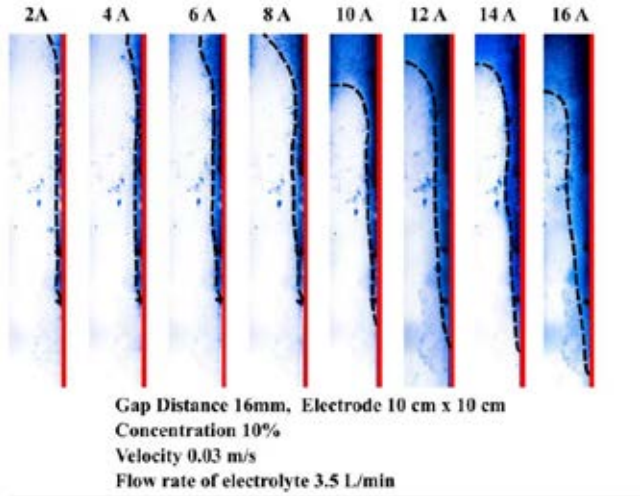

Fig. 5. Photograph of hydrogen gas layer at different currents

4. CONCLUSIONS

This study investigated the fluid flow and stagnant fluid at 30 w.t% concentration influencing hydrogen production in AWEs with a square electrode 10 cm x 10 cm. Our findings revealed that stagnant fluid and 0.09 m/s inlet velocity consumes much current at the same voltage and the consumption decreases from 0.03 m/s to 0.06 m/s then increases at 0.09 m/s. where stagnant fluid gains maximum flow rate larger than 0.09m/s at the same power consumed. This makes GR is maximum trend for AWEs for stagnant fluid which is 75% at around 2.6 Volt. In addition to photographing, we deduced the current is vital in hydrogen production rate wich increases by increasing the current. The aim is to enhance the GR of the hydrogen production process in AWE by testing different operational mehods.

ABSTRACT
$(Yb_2O_3)_x(ZrO_2)_{1-x}$ powders are synthesized by a modified sol-gel method for $0.08 \leq x \leq 0.12$ and tested as an electrolyte material for microtubular solid oxide fuel cells (SOFCs). XRD measurements reveal that stabilization of face-centered cubic (fcc) zirconia (ZrO_2) is observed at all doping ratios studied, resulting in ytterbium(III)-stabilized zirconia (YbSZ). Electrochemical performance tests show that the Yb content of 10 mol% gives the best results. This is attributed to the ionic conductivity and grain size of the corresponding YbSZ powders. Therefore, zirconia stabilized with 10 mol% Yb_2O_3 (10YbSZ) is considered as a promising alternative to conventional yttria-stabilized zirconia (YSZ) electrolytes in SOFCs and a peak power density of 0.357 W/cm^2 is obtained at 800 ^oC.

Keywords: Ytterbium stabilized zirconia; Synthesis; Solid oxide fuel cells; Microtubular; Electrolyte.

1. INTRODUCTION
SOFCs consist of three basic components: anode, electrolyte and cathode. The electrolyte component is the heart of the SOFC systems. Although proton conducting electrolytes have recently been investigated for future low temperature applications, oxygen ion conducting electrolytes are more common in SOFCs. In addition to conducting oxygen ions, electrolyte materials also act as a barrier to prevent direct contact between hydrogen and oxygen. The most common electrolyte material is zirconium oxide stabilized with yttrium oxide (YSZ). However, YSZ exhibits the desired ionic conductivity values at very high temperatures. In this context, some electrolyte materials such as doped cerium oxides or zirconium oxide stabilized with scandium oxide have been developed (Fergus, 2006). However, they exhibit structural problems and performance degradation due to short circuiting (Zheng et al., 2009). Therefore, new research has focused on ZrO_2 systems with different dopants. It has been shown in the literature that doping ZrO_2 with Sc, Yb, Y, Sm can increase ionic conductivity in the order Sc > Yb > Y > Sm (Feng, Ren, Wang, Zhou, & Pan, 2012). Due to the high price of Sc_2O_3, Yb_2O_3 (YbSZ) doped ZrO_2 material is an excellent candidate material for SOFCs as an electrolyte. The ionic radius of $Yb3^+$ is also closer to Zr^{4+}. Therefore, Yb_2O_3 co-doping can be adopted as an approach to enhance the stability of the cubic phase and improve the conductivity of scandia-stabilized zirconia electrolytes. The nanocrystalline structure of the powders has also been shown to improve the electrical properties of solid oxide electrolytes (Vijaya Lakshmi & Bauri, 2011). In a planar electrolyte-supported SOFC cell, a maximum power density of 0.56 W/cm^2 at 830 ^oC was achieved using 5YbSZ electrolyte material (Xue et al., 2015). Yamaji et al. (Yamaji, Koshikawa, Araki, & Adachi, 2008) successfully stabilized the cubic phase and obtained a maximum conductivity of 0.30 S/cm and a maximum power density of 210 mW/cm^2 at 1000 °C from 1Yb8ScSZ by co-doping Sc_2O_3 and Yb_2O_3 into ZrO_2. However, their research was limited to a specific range of Yb_2O_3 doping from %1 mol to %2 mol.

The literature on Yb_2O_3-doped zirconia materials mainly focuses on synthesis characterization and planar SOFCs. There is less emphasis on practical SOFC applications with regular electrode materials, especially for microtubular SOFCs, which have attracted great interest due to their high tolerance to thermal cycling, fast start-up capabilities, high power density per unit volume, and robust portability (Sahu, Panthi, Soliman, Feng, & Du, 2022). Therefore, in this study, $(Yb_2O_3)_x(ZrO_2)_{1-x}$ (x= 0.08, 0.09, 0.10, 0.11 and 0.12) is tested as an electrolyte material for microtubular SOFCs with conventional anode (NiO-YSZ) and cathode (LSM (lanthanum strontium manganite)-YSZ) materials. For this purpose, NiO-YSZ anode support microtubes are fabricated by conventional extrusion method. The NiO-YSZ anode functional layer was then coated by dip coating technique. Ytterbium-doped zirconia materials are synthesized using the sol-gel method, which is a very common method (Wang, Dommati, & Hsieh, 2019). After characterization of the obtained powders, a corresponding dip coating slurry is prepared and applied onto the anode functional layer acting as electrolyte. The cathode layers are similarly coated, and electrochemical measurements are performed on the resulting microtubular cells.

2. EXPERIMENTAL

2.1. Materials synthesis

$(Yb_2O_3)_x(ZrO_2)_{1-x}$ (x= 0.08, 0.09, 0.10, 0.11 and 0.12) binary systems were synthesized using a modified sol-gel technique. First, commercially available pure $ZrCl_4$ (99.9% purity) and $Yb(NO_3)_3.5H_2O$ (99.99% purity) were dissolved in stoichiometric amounts in pure water at room temperature. Citric acid ($C_6H_8O_7$) was then slowly added while stirring on a magnetic stirrer. Ethylene glycol ($C_2H_6O_2$) was added to the solution and completely dissolved (citric acid and ethylene glycol in a molar ratio of 1:4). The colorless solution was stirred and then heated on a hot plate at 80 ºC until it formed a viscous gel. Afterwards, the gel was transferred to alumina crucibles of appropriate size and dried in an oven at 120 ºC for 18 hours. Next, the gel was subjected to pre-heat treatment at 900 ºC for 12 hours to decompose the organic components. The final heat treatment was carried out at three different temperatures (1000 ºC, 1100 ºC and 1200 ºC) to decide the calcination temperature for the desired crystal structure. The obtained powders were milled in ethanol for 10 hours at 400 rpm with a planetary ball milling machine (PM100, Retsch, Germany).

2.2. Microtubular anode support fabrication

Commercial NiO (NiO-A, Novamet, USA) and YSZ (YSZ8-TC, Nexceris, USA) powders were mixed in a 1:1 mass ratio to formulate an extrusion slurry for the fabrication of anode support microtubes. Appropriate amounts of dispersant (fish oil, Sigma-Aldrich, Germany) and solvent (mixture of ethanol and methyl ethyl ketone, Sigma-Aldrich) were added to the mixture and then subjected to a 24-hour mixing process using a ball mill. The binder (Butvar, Sigma-Aldrich) and plasticizer (PEG, Sigma-Aldrich) were then added to the solution in the specified proportions. After a second 24-hour ball milling, the mixture was transferred to a magnetic stirrer and stirred for another 2 hours. The solution was then combined with paraffin and stearic acid in appropriate proportions and homogenized using a mechanical mixer until the desired viscosity was reached. The prepared extrusion slurry was extruded through a die with an inner diameter of 4 mm and an outer diameter of 5 mm using a laboratory-scale vertical extruder. After drying at room conditions for 24 hours, the microtubular anode supports were cut into 80 mm lengths and then pre-sintered at 1100 °C for 2 hours. After the micro-tube fabrication process, a solution was prepared by mixing the anode functional layer (50:50 wt%) NiO/YSZ powders and HVS 085 resin (Heraeus, Germany), thinner and alcohol in certain proportions. The mixture was then mixed in a ball mill with zirconium balls for 24 hours. The bilayer structure coated with AFL using the dip coating method on micro-tubes was co-sintered at 1150 °C. Different YbSZ powders (8-12YbSZ) and standard YSZ electrolyte solution were prepared similarly to the AFL solution. Then, AFL-coated anodes were coated with various electrolytes by dip coating method. The prepared ternary structures were then subjected to sintering at 1450 ºC. Similar to electrolyte coating, LSM-YSZ (40:60 wt%) cathode functional layer (CFL) and LSM-YSZ (90:10 wt%) cathode current collector layer (CCL) were coated on the electrolytes by dip coating technique, respectively. After both cathode layers were sintered together at 1050 °C, the anode supported microtubular cells were ready for testing and characterizations (Table 1). The outer diameter, length and cathode length of the final microtubular SOFCs were measured as ~4.5 mm, ~6.5 mm and ~3 mm, respectively. The cells are named according to the electrolyte materials as YbSZ 8-12 and RC (reference cell with a YSZ electrolyte).

Table 1. Details of the cell layers

Cell layer	Material(s)	Composition (wt. %)	Sintering conditions
AFL	NiO (NiO-F, Novamet)-YSZ	50:50	1150 ºC for 2 h
Electrolyte	8-12 mol % Yb-doped zirconia /YSZ	-	1450 ºC for 5 h
CFL	LSM (LSM20-HP, Nexceris)-YSZ	40:60	1050 ºC for 2 h
CCL	LSM (LSM20-P, Nexceris)-YSZ	90:10	1050 ºC for 2 h

2.3. Cell Fabrication and Testing

The electrochemical performance of the cells at 800 ºC was measured via a fuel cell test station (Arbin Instruments, FCTS, USA). The anode side was fed by 0.3 NL/min hydrogen for an hour through a pipe welded to the corresponding manifold. Performance tests were performed without additional air supply (i.e., stagnant air inside the test furnace as oxidant), maintaining hydrogen flow at 0.3 NL/min. Cell resistances under open circuit potential were determined immediately after the performance measurements by an impedance analyzer (Parstat 2273, Princeton Applied Research, USA) for the frequency range 0.1 Hz-250 kHz. Three cells were fabricated for each case and the highest electrochemical performances are reported in this study.

3. RESULTS AND DISCUSSION

Images of microtubular SOFCs prepared with different YbSZ electrolyte materials are given in Fig. 1, while electrochemical performance comparison is depicted in Fig. 2. The cells with YbSZ electrolytes exhibit performances compared to that with a YSZ electrolyte. In this context, the best peak performance is obtained with 10YbSZ electrolyte, although ionic conductivity is found to decrease with Yb_2O_3 content. Moreover, open circuit potentials also vary depending on the electrolyte material and some of them are found to be lower than the theoretical one, indicating incomplete electrolyte sintering as shown in Fig. 3. These findings reveal that sinterability and resultant grain size are also significant

for the performance of YbSZ electrolytes.

Fig. 1. Microtubular cells with %12-8 YbSZ and YSZ electrolyte (from top to bottom)

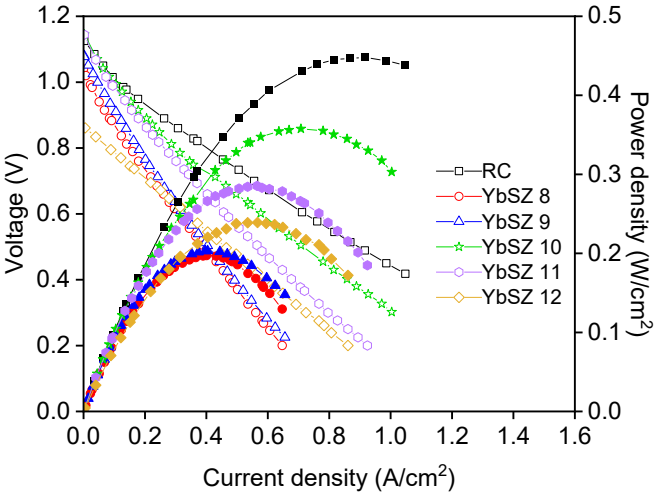

Fig. 2. Cell performances at 800 ºC

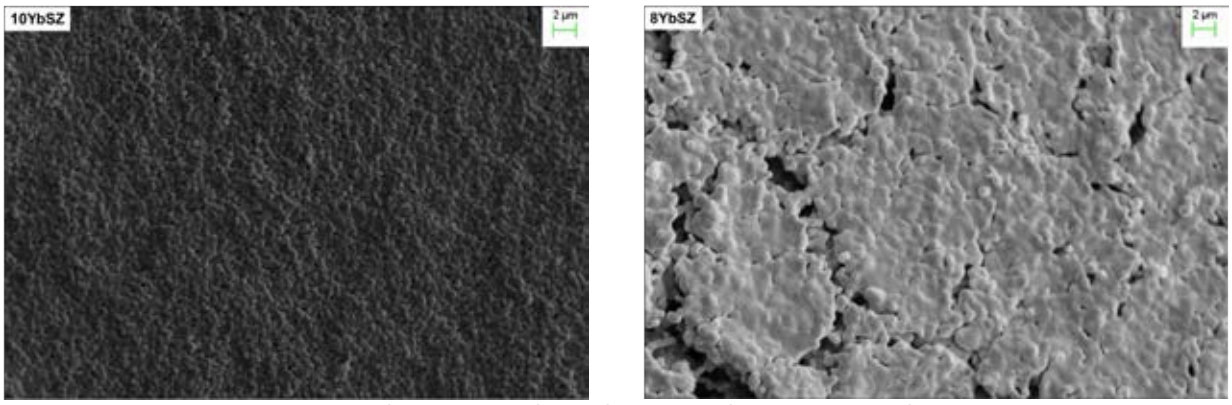

Fig. 3. SEM images of 10YbSZ and 8YbSZ electrolyte surface

4. CONCLUSIONS

The results of this study show that YbSZ can be an alternative to YSZ in microtubular SOFCs as an electrolyte material. In this context, a peak power density of 0.357 W/cm² is achieved with 10YbSZ, while the reference cell with a YSZ electrolyte shows 0.448 W/cm² maximum power density under the same conditions. However, electrochemical performance tests and microstructural analyses indicate incomplete sintering of YbSZ electrolytes. Therefore, sintering

conditions and/or coating solution formulation need to be studied and optimized for high performance. Moreover, long-term performance and phase stability of the YbSZ electrolyte should be investigated in detail.

ABSTRACT

In this study, the high thermal and chemical stability PMMA-b-PS anion exchange membrane was obtained by blending poly(methyl methacrylate) (PMMA) and polystyrene (PS) through the film casting method.PS was synthesized via the radical polymerization method and subsequently chloromethylated. Chloromethylated polystyrene was quaternized by adding trimethylamine (TMA) to the PS ring. Characterization and electrochemical tests (Electrochemical Impedance Spectroscopy (EIS)) were carried out from 10^{-1} Hz to 10^{5} Hz. The synthesis, chloromethylation, and quaternization of polystyrene were characterized by FTIR analysis. According to the TGA results, the first thermal degradation began at approximately 200°C, which indicates that the membranes maintained their thermal stability at high temperatures. Thermal measurements determined that the membranes exhibited backbone degradation at 450°C. The solution resistance was measured in 1 M KOH using EIS measurements. The PMMA-b-PS membrane exhibited a resistance of 75 Ω at room temperature. At 80°C, its resistance decreased to 66 Ω.

Keywords: Anion Exchange Membrane, Green Hydrogen, Polymer

1. INTRODUCTION

Nowadays, AEMs have become a highly active research area in electrochemical systems, including electrolyzers, fuel cells, and membranes. All electrochemical devices for energy storage and conversion (such as redox flow batteries, fuel cells, and electrolyzers) require selective ion transport under various conditions, including temperature, pH, and electrochemical voltage [1]. Anion exchange membranes are used in applications requiring hydroxide transport because they contain cationic groups in their polymer chains. AEMs should have high ionic conductivity, dimensional stability, film-forming ability, and long-term alkali resistance stability [2].

One of the biggest challenges in the application of AEMs is their stability. Stability tests are conducted. Most of the research focuses on developing high OH^- conductivity. Zhang et al. synthesized a poly(ether ether ketone) (PEEK) membrane and achieved an extremely high OH^- conductivity of 155 mS/cm at 60°C [3]. Shang et al. obtained conductivities of 49.6 and 30.9 mS/cm at 80 °C with the PEEK membrane they synthesized [4]. Tuli et al. developed a polystyrene-based cross-linked AEM and achieved a high conductivity of 156 mS/cm in their tests [5]. Yang et al. synthesized a polystyrene-co-4-vinyl pyridine copolymer, and its conductivity reached 74.29 mS/cm [6].In previous studies, Zhang et al. synthesized a PEEK membrane and determined a 56% water uptake and a 15% low swelling ratio at 60°C [3]. Xu et al. synthesized imidazolium- and zinc/graphene oxide-doped PEEK in their study and obtained 35.45% water uptake and an 18.87% swelling ratio [7]. Ren et al. (2022) obtained an 8.3% swelling ratio and 24.3% water uptake at 80°C in their study [2]. It has been determined in several studies that alkyl chain length increases water uptake and swelling ratio [8]. An increase in the swelling ratio may extend the life cycle of the membrane, but excessive swelling negatively affects the mechanical properties [9].

In this study aims to synthesize and make commercially available original, high-performance and durable membranes that exhibit high conductivity and strength. Methyl groups attached to the polymer chain structure of AEMs play a crucial role in stability and ionic conductivity. It has been determined that the methyl groups in the PS chain provide an advantage in terms of increasing the ionic conductivity of the membrane. Additionally, the phenyl rings in the PS chain restrict the rotation of the chains around the carbon-carbon bonds and contribute to the polymer's significant hardness. PMMA, which contains methyl groups, was selected as polymer.

2. MATERIALS AND METHODS

2.1. Synthesis of PMMA-b-PS Membrane

The required styrene, trimethylamine, benzoyl peroxide, and methanol were all obtained from Sigma Aldrich. Toluene (99.5%) and ethanol (99.9%) were acquired from ACS. Methyl methacrylate polymer (PMMA) was purchased from TCI and chloroform was purchased from Merck.

In the first stage of membrane production; after preparing the styrene/toluene solution, the benzoyl peroxide initiator is added, and the polymerization reaction is started at 70 °C. It is precipitated in methanol, which becomes viscous. The

polymer solution was filtered, and poured into a glass petri dish and dried at room temperature for 24 h. The filtered polymer is dried in a vacuum oven at 40 °C for 12 hours.The chloromethylation reaction was carried out in a three-necked flask of 100 mL equipped with a mechanical stirrer and a thermometer. Polystyrene was dissolved in toluene and added to the flask. $AlCl_3$ was slowly added to the flask at 60 °C and stirred for 6 h. After 6 h polymer solution precipitated in methanol and was filtered and poured into a glass petri dish and drying at room temperature for 24 h.The membrane was peeled from the petri dish and immersed in deionized water to wash away residual solvent. The membranes were then soaked in a TMA solution at 60 °C for 48 h. The membranes were soaked in a 1 M NaOH (aq) solution. The membrane was then washed with distilled water.In the second stage of membrane preparation, PMMA-b-PS polymeric blend with different compositions were prepared by the solution casting method. Membranes were dried in a vacuum at 60 °C, for 24 h in order to ensure the removal of the solvent.

2.2. Characterization Tests

FT-IR measurements of the membranes were performed using a Thermo Infrared Spectrometer. The measurements were conducted within a wavenumber range of 4000–500 cm^{-1}. The thermal stability of the membranes was evaluated using a Perkin Elmer thermogravimetric analyzer. The samples were heated from 15°C to 700°C at a heating rate of 20°C/min.The Tg values of the polymers were obtained by analyzing of their DSC curves in the temperature range of 100°C to 300°C, with a heating and cooling rate of 10°C/min.

Water uptake (WU) and swelling ratio (SR)

WU and SR were defined as the percentage change in mass and size of the membranes after water absorption, respectively. The membrane was dried in an oven at 60°C for 1 day, and its weight and average thickness were measured and recorded. The dried membrane was then soaked in deionized water at fixed temperatures for 24 hours. Afterward, the hydrated membrane was removed, surface water was wiped off, and its weight and thickness were measured and recorded. The WU and SR values of the AEMs were calculated using the following equations.

$$\%\mathrm{WU} = \frac{\mathrm{Wwet-Wdry}}{\mathrm{Wdry}}\ \mathrm{x}100 \quad (1)$$

$$\%SR = \frac{\mathrm{Lwet-Ldry}}{\mathrm{Ldry}}x100 \quad (2)$$

2.3. Electrochemical Measurements

The solution resistance of the membranes was measured using Electrochemical Impedance Spectroscopy (EIS) with a three-electrode method. The EIS measurement was performed in a 1M KOH solution using Pt electrodes over a frequency range of 10^{-1} to 10^{-5} Hz. The membrane and non-membrane solution resistances were measured using the glass cell shown in Figure 1.

Fig. 1. The glass cell used in the EIS measurement

3. RESULTS AND DISCUSSION

FT-IR spectra were used to confirm the chemical structure of anion exchange membranes. As shown in Fig. 2.a., 1216 cm^{-1} chloromethyl rocking vibration and 695 cm^{-1} C-Cl stretching vibration emerged, this results demonstrated the success of PS chloromethylation (KPS) [10]. The absorption band at 1600 cm^{-1} and 1422 cm^{-1} correspond to the stretching vibrations to the ammonium group [11]. The appearance of new characteristic peaks at 1651 and 3377 cm^{-1} assignable to the C-N and O-H stretching vibration indicates the successful quaternization reaction (QPS) [12].

The thermal stability of AEMs was measured using a TGA and DSC. As shown in Fig. 2.b., the membranes exhibited similar curves for weight loss. The first weight loss in PMMA-b-PS was observed at around 200, which corresponded to

the degradation of the ammonium group as a conducting head group. Secondly, in all two polymer membranes, backbone degradation was observed at a similar temperature of around 450 °C. In Fig 2.c. the DSC curve shows that Tg of the PS membrane is observed at 105 °C. while in Fig 2.d., Tg of the PMMA-b-PS membrane is 129 °C. PMMA-b-PS membrane exhibits the thermal properties of PMMA and PS.

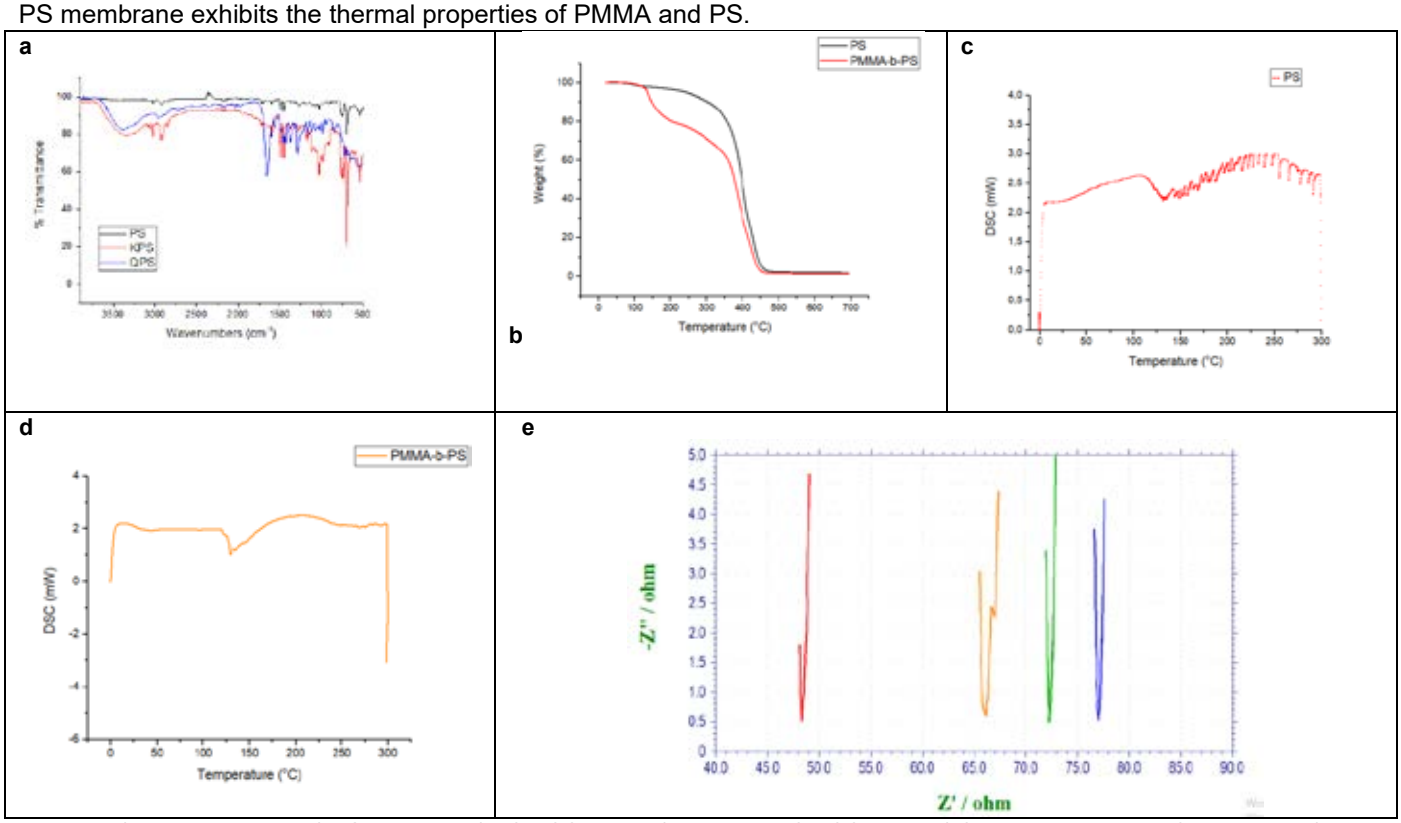

Fig. 2. a) FTIR spectrum b) TGA curves c) PS DSC curve d) PMMA-b-PS DSC curve e) Solution resistance of membranes(non-membrane-red, PMMA-b-PS in 80°C-orange, PMMA-b-PS in 30°C-green, PMMA-b-PS in 20°C-blue)

The resistance of membranes was measured in 1 M KOH. According to the obtained results, the resistance decreases with rising temperature (Table 1). According to Fig. 2.e., the solution resistances of the membranes are higher than the non-membrane solution resistance. The difference between the measurements shows the transfer of hydroxide ions in the solution.

Table 1. The resistance of membranes

Membrane	Temperature (°C)	Resistance (Ω)
Non-membrane	20	**48**
Fumasep-FAAM-20	20	**360**
Fumasep-FAAM-20	30	**270**
Fumasep-FAAM-20	80	**90**
PMMA-b-PS	20	**75**
PMMA-b-PS	30	**71**
PMMA-b-PS	80	**66**

4. CONCLUSIONS

In this study, quaternary ammonium polymer blends based on polystyrene were synthesized. FTIR results demonstrated the successful quaternization of PS. When compared to the commercial Fumasep-FAAM-20 membrane, the obtained membranes exhibited low resistance. Upon examining the %WU and %SR ratios of the membranes, the PMMA-b-PS membrane exhibited %18 WU and %11 SR. The swelling and water uptake ratios indicate that the membranes maintain their stability. Considering the TGA results, no significant thermal degradation is observed in either membrane up to approximately 200°C. The membranes exhibit thermal stability at high temperatures.

ABSTRACT
This study investigates the structural optimization of end plates in proton exchange membrane fuel cells (PEMFCs) to enhance mechanical integrity while reducing weight. End plates are critical for maintaining uniform pressure distribution, minimizing contact resistance, and preventing fuel leakage. Various configurations, including bolted and steel belt connections, were analyzed using finite element analysis (FEA) and validated through experimental pressure distribution tests with Fujifilm Prescale films. The bolted end plate model exhibited the best pressure distribution, with a uniformity improvement of approximately 30% compared to steel belt configurations. However, it also resulted in a 66% increase in weight. A manually optimized bolted design reduced mass by up to 50%, while maintaining a von Mises stress profile close to the bulk model. Topology optimization further contributed to a 39% reduction in material usage without compromising structural integrity. Although steel belt connections provided improved pressure homogeneity, localized pressure concentration led to efficiency limitations. These findings emphasize the need for optimized end plate designs to enhance PEMFC performance, especially in weight-sensitive applications like aerospace and portable energy systems.
Keywords: PEM fuel cells, end plates, pressure distribution, structural optimization, finite element analysis, topology optimization, lightweight design, metal additive manufacturing

1. INTRODUCTION

Proton Exchange Membrane Fuel Cells (PEMFC) stand out as an important innovative technology due to their potential to provide environmentally friendly energy production. PEM fuel cells offer a zero-emission power source by directly converting chemical energy into electrical energy. Thanks to their advantages such as low operating temperature, high power density, and fast start-up, they are attracting attention in many areas such as automotive, portable energy, and stationary power generation systems. PEMFCs, which use hydrogen as a feedstock and produce only water as a by-product, play a critical role in the transition to sustainable energy technologies. However, the efficient operation of these systems depends on the mechanical, electrical, and chemical compatibility of their components, especially the membrane-electrode assembly (MEA), gas diffusion layer (GDL), and bipolar plates [1,2,3]. In PEM fuel cells, end plates have critical functions such as ensuring the assembly of cell stacks as well as maintaining the mechanical integrity and appropriate contact pressure distribution of the system. These plates hold the cell components together, prevent fuel leakage, and minimize electrical contact resistance by optimizing the contact pressure on the membrane electrode assembly (MEA). Inappropriate contact pressure can negatively affect cell performance and lead to excessive hot spots and component damage. The design of the end plates has a direct impact on performance, depending on the connection method used (bolt, steel belt, reinforcement plate, etc.), material properties (low density, high mechanical strength, corrosion resistance), and geometric structure. Several innovative connection methods and designs are being investigated to increase fuel cell efficiency and optimize the mass-to-power ratio [4,5,6].

In this study, the connection methods used in the end plates of PEM fuel cells were discussed and a comparative analysis of different designs was performed. In addition to the bolt-nut connection, a novel connection method compressed with steel tapes was examined in detail within the scope of the study. Stack models were created and optimized for both connection methods using computer-aided design (CAD) software. These models were designed to analyze the effects of different connection methods on mechanical and electrical performance by keeping the dimensions constant (rectangular end plates with dimensions of 58.9 x 175 mm). As a result of parametric analyses, the effects of the connection methods on performance criteria such as contact pressure distribution, sealing, corrosion resistance, and mechanical strength were evaluated. In addition, the weight optimization of the end plates was also performed; this offers a significant advantage, especially in applications where weight is critical such as unmanned aerial vehicles and in cost optimization. The study revealed that the steel tape connection method provides a more homogeneous pressure distribution compared to the bolt-nut connection in some cases, but requires careful optimization in terms of design and assembly.

2. MATERIALS AND METHODS

This study focuses on the design and optimization of the end plates of PEM fuel cell stacks, and the performances of

these structures are analyzed by comparing bolt and steel belt connection methods. In the stack designs, critical features of the end plates such as mechanical strength, low weight, and corrosion resistance are provided for the efficient operation of the PEM fuel cell. First, in the bolted end plate design, a rectangular model with dimensions of 58.9 x 175 mm and a thickness of 8 mm is created, and a total of 10 bolt holes are placed, five on each long edge. Hydrogen and air inlets and outlets are placed on the short edges of the plates. In the steel belt connection design, 3 curved surfaces are added and the steel belts are passed through these surfaces and tightened with worm screws.

In the design and analysis stages, the geometric structures of the end plates are optimized by applying topology optimization for both models. In this process, material usage is reduced and mechanical strength is preserved. Topology optimization is performed using the FEA (Finite Element Analysis) program which is ANSYS; Aluminum 7075 T6 was preferred due to its high strength, low density, and suitable elastic modulus. The Young modulus of this material was determined as 71.7 GPa, density as 2.88 g/cm³, and Poison ratio as 0.33. In the topology optimization, the mass reduction in the bolted model was performed manually for different parameters, and then verifications were made with FEA. In the steel belt model, the optimization for mass reduction was applied in a similar way, but the compressive pressure was increased by removing the inclined surfaces. As a result, structural analyses for both models were performed with the structural analysis module of the FEA program. In the bolted model, 2.5 MPa pressure was applied to the bolt areas, while 13,500 N force was applied to the belt section in the steel belt model.

3. RESULTS AND DISCUSSION

The obtained results include the comparison of the mechanical performance and pressure distribution of bolted and steel belt-connected end plate designs. In the bolted design, 2.5 MPa pressure resistance and a homogeneous pressure distribution were achieved, but it was observed that irregularities that may occur during the placement of the bolts may affect the pressure homogeneity. In contrast, in the steel belt-connected design, the pressure was distributed more evenly between the plates thanks to the compression with three curved surfaces and worm screws. However, it was also determined that this method may cause deformation in applications requiring high compression pressure. The topology optimization results provided significant improvements in terms of mass reduction and mechanical strength in both models. In the bolted model, the risks of strength loss were determined in the manual optimizations, whereas the compression pressure was increased by removing the curved surfaces in the steel belt model. In the fifth model, a mass reduction of up to 50% was achieved in line with the optimization results obtained with the FEA program, which offered advantages in terms of both cost and efficiency. Table 1 shows the comparison of different end plates (rod and belt types) and Table 2 shows the ANSYS structural analysis results of them.

Table 1. Comparison of end plate models with different parameters as; bolt bulk (a), belt bulk (b), bolt manual optimized (c), belt manual optimized (d), and belt topology optimized (e)

#	Model	Mass (g)	Maximum Total Deformation (mm)	Maximum Directional Deformation (mm)	Equivalent Stress (MPa)
a		332.8	0.000209	0.000115	3.60
b		366.5	0.000114	0.000124	1.32
c		113.2	0.000328	0.000246	2.92
d		137.9	0.000445	0.000445	3.48
e		201.1	0.000290	N/A	2.79

Table 1. ANSYS structural analysis results for bolt bulk (a), belt bulk (b), bolt manual optimized (c), belt manual optimized (d), and belt topology optimized (e)

#	Model	ANSYS Structural Analysis
a		b		c		
d		
e		
The experimental results were verified with Fujifilm Prescale films used to observe the pressure distribution, and it was determined that a homogeneous pressure distribution has a critical effect, especially on fuel cell performance. While the pressure distribution was controlled by the cross-tightening technique in the bolted model, homogeneity was achieved by precisely adjusting the torque value of the worm screws in the steel belt model. The use of AISI 430 quality steel as the steel belt material contributed to the durability of the design, but this connection method required additional cost and labor during the production and assembly process. As a result, the advantages and disadvantages of both connection methods were determined, and it was seen that the steel belt-connected design was superior in terms of homogeneous pressure distribution, but it needed improvement in factors such as manufacturing complexity and cost. Figure 1 shows the comparison of pressure distribution for all end plate designs.

Fig. 1. Comparison of pressure distribution of bolt bulk (a), belt bulk (b), bolt manual optimized (c), belt manual optimized (d), and belt topology optimized (e), respectively from left to right

4. CONCLUSIONS

The results of this study demonstrate that structural optimization of PEMFC end plates significantly impacts both weight and mechanical performance. The bolted end plate model achieved the best pressure distribution, with a 30% improvement compared to steel belt designs, but was found to be 66% heavier. The manually optimized bolted model emerged as the most effective alternative, reducing mass by 50% while maintaining an equivalent von Mises stress level. Topology optimization further decreased material usage by 39%, enhancing efficiency without compromising strength. While the steel belt connection improved pressure uniformity, it led to localized pressure concentrations that reduced efficiency. Future studies should explore advanced materials and hybrid connection techniques to optimize both weight and structural stability for PEMFC applications.

ABSTRACT
Meeting Turkey's growing electricity demand requires a balanced approach to ensure reliable generation and consumption at all times. The study focuses on addressing the variability introduced by renewable energy sources, such as solar and wind, through the integration of energy storage systems. An optimization model is developed to determine the optimal storage locations, types, and capacities, with a particular emphasis on hydrogen-based batteries. The approach aims to minimize total costs while enhancing grid stability and supporting renewable energy integration. By using Turkey as a case study, the findings provide valuable insights for sustainable energy planning and storage technology deployment.
Keywords: Energy system optimization, Renewable energy integration, Hydrogen-based energy storage, Cost minimization, Turkey energy planning

1. INTRODUCTION
Global energy systems are undergoing a profound transformation as nations strive to meet growing electricity demand while transitioning to sustainable energy sources. Turkey, as one of the fastest-growing economies, faces significant challenges in balancing demand and supply. Between 2000 and 2019, Turkey's electricity demand increased from 128 TWh to 303.3 TWh, driven by industrial expansion, urbanization, and population growth. Meeting this increasing demand necessitates expanding generation capacity and addressing critical issues such as supply reliability, grid stability, and cost efficiency. The integration of renewable energy sources like solar and wind, which have become a significant part of Turkey's energy system, has increased the challenges of balancing electricity supply. These sources produce energy intermittently, depending on weather conditions and time of day, leading to daily and seasonal fluctuations in generation that can threaten the stability of the grid [1].

Unlike lithium-ion or flow batteries, hydrogen batteries can store energy for extended periods, aligning with global decarbonization goals by utilizing surplus renewable energy for hydrogen production through electrolysis. This capability positions hydrogen-based systems as a crucial component in modernizing energy infrastructures and achieving sustainability targets [3]. This study develops an optimization model tailored to Turkey's energy landscape to identify optimal locations, types, and capacities for storage facilities, particularly focusing on hydrogen-based solutions, to minimize system costs while enhancing grid reliability and supporting the clean energy transition [2].

2. MATERIALS AND METHODS
This study develops an optimization model to address the challenges of balancing Türkiye's growing electricity demand and integrating renewable energy sources. The model focuses on determining the optimal locations and sizes of battery storage systems, including hydrogen-based, lithium-ion, and flow batteries. It aims to minimize total system costs while ensuring grid reliability and accommodating the variability in both electricity demand and renewable generation. By considering factors such as system stability, economic feasibility, and Türkiye's energy transition goals, the model provides a comprehensive framework for strategic investment in energy storage technologies. To model the problem effectively, a representative day was selected from a 365-day dataset obtained from EPİAŞ to capture the load profile of Türkiye, considering daily variations in electricity demand across the country.

2.1. Problem Definition
The optimization model addresses the critical challenge of designing a cost-effective and reliable energy system for Turkey, capable of balancing the increasing electricity demand and integrating renewable energy sources while adhering to carbon emission reduction targets. This problem arises from the intricate dynamics of energy systems, where electricity supply and demand fluctuate across different times of the day and regions. These fluctuations are influenced by factors such as industrial activity, residential energy use, and seasonal variations in consumption patterns. Additionally, the integration of renewable energy sources like solar and wind further complicates the system due to their inherent intermittency, as their generation is highly dependent on weather conditions and time of day, leading to unpredictable and variable energy outputs.

The model seeks to determine the optimal investment strategies in ESS, particularly hydrogen-based batteries, alongside the optimal expansion of power generation capacities. It considers multiple objectives, including minimizing total system

costs, maintaining grid stability, and meeting strict emission targets. To achieve these goals, the model incorporates detailed constraints such as hourly demand satisfaction, production capacities, energy storage dynamics, and emission limits. By evaluating trade-offs between economic and operational factors, the model provides actionable insights for decision-makers to ensure a resilient and sustainable energy future for Turkey.

2.2. Model Formulation

The optimization problem is structured to minimize the total cost of meeting energy demand while considering investments, operational costs, and carbon emission constraints. The objective function is defined as follows:

$$\min Z = \sum_{t=0}^{T}\Big(\sum_{e\in E} c_e \cdot I_{e,t} + \sum_{e\in E}\frac{o_e}{100}\cdot c_e \cdot \big(C_e + \sum_{\tau=0}^{t} I_{e,\tau}\big) + \sum_{e\in E}\sum_{g\in G}\sum_{h\in H} w_g \cdot 365 \cdot p_e \cdot P_{e,t,g,h} + \sum_{g\in G}\sum_{h\in H} u \cdot U_{t,g,h} + \sum_{b\in B}\Big(c_b \cdot B_{b,t} + \frac{o_b}{100}\cdot B_{b,t}\Big)\Big) \quad (1)$$

$$\sum_{e\in E} P_{e,t,g,h} + \sum_{b\in B} BD_{b,t,g,h} + U_{t,g,h} = d_{g,h}\cdot(1 + r\cdot t) + \sum_{b\in B} BC_{b,t,g,h}, \quad \forall t \in \{0,1,\dots,T\}, \forall g \in G, \forall h \in H \quad (2)$$

$$P_{e,t,g,h} \le \big(C_e + \sum_{\tau=0}^{t} I_{e,\tau}\big)\cdot CF_{e,h}, \quad \forall t \in \{0,1,\dots,T\}, \forall g \in G, \forall h \in H, \forall e \in E \quad (3)$$

$$S_{b,t,g,h} = S_{b,t,g,h-1}\cdot(1 - SDR_b) + BC_{b,t,g,h-1}\cdot \eta_b - BD_{b,t,g,h-1}\cdot \eta_b, \quad \forall t \in \{0,1,\dots,T\}, \forall g \in G, \forall b \in B, \forall h \in \{1,2,\dots,H\} \quad (4)$$

$$S_{b,t,g,0} = 0, \quad \forall t \in \{0,1,\dots,T\}, \forall g \in G, \forall b \in B \quad (5)$$

$$BC_{b,t,g,h} \le MCR_b \cdot \big(\sum_{t'=0}^{t} B_{b,t}\big), \quad \forall t \in \{0,1,\dots,T\}, \forall g \in G, \forall h \in H, \forall b \in B \quad (6)$$

$$BD_{b,t,g,h} \le S_{b,t,g,h}, \quad \forall t \in \{0,1,\dots,T\}, \forall g \in G, \forall h \in H, \forall b \in B \quad (7)$$

$$S_{b,t,g,h} \le \big(\sum_{t'=0}^{t} B_{b,t}\big), \quad \forall t \in \{0,1,\dots,T\}, \forall g \in G, \forall h \in H, \forall b \in B \quad (8)$$

$$\sum_{e\in E}\sum_{g\in G}\sum_{h\in H} P_{e,t,g,h}\cdot EF_e \cdot 365 \cdot w_g \le ET_t \quad (9)$$

$$I_{e,t}, P_{e,t,g,h}, U_{t,g,h}, S_{b,t,g,h}, BC_{b,t,g,h}, BD_{b,t,g,h}, B_{b,t} \ge 0 \quad (10)$$

$$\sum_{b\in B} BC_{b,t,g,h} \le IsC_{t,g,h}\cdot M, \quad \forall t \in \{0,1,\dots,T\}, \forall g \in G, \forall h \in H \quad (11)$$

$$\sum_{b\in B} BD_{b,t,g,h} \le \big(1 - IsC_{t,g,h}\big)\cdot M, \quad \forall t \in \{0,1,\dots,T\}, \forall g \in G, \forall h \in H \quad (12)$$

where;

- c_e : Investment cost for energy type e ($/MW)
- $I_{e,t}$: Investment amount for energy type e in year t (MW)
- o_e: Operation and maintenance cost percentage for energy type e (% of CAPEX per year)
- C_e: Initial installed capacity for energy type e (MW)
- w_g: Weight of representative day g
- p_e: Production cost for energy type e ($/MWh)
- $P_{e,t,g,h}$: Production amount for energy type e in year t, day g and hour h (MWh)
- u: Cost of unmet demand ($/MWh)
- $U_{t,g,h}$: Unmet demand in year t, day g and hour h (MWh)
- c_b: Investment cost for battery type b ($/MW)
- $B_{b,t}$: Investment amount for battery type b in year t
- o_b: Operation and maintenance cost percentage for battery type b (% of CAPEX per year)
- $BD_{b,t,g,h}$: Discharging amount for battery type b in year t, day g and hour h (MWh)
- $d_{g,h}$: Hourly demand at day g and hour h (MWh)
- r: Annual demand growth rate
- $BC_{b,t,g,h}$: Charging amount for battery type b in year t, day g and hour h (MWh)
- $CF_{e,h}$: Capacity factor for energy type e at hour h (reflects seasonal and hourly variations)
- $S_{b,t,g,h}$: State of charge for battery type b in year t, day g and hour h (MWh)
- SDR_b : Self-discharge rate for battery type b
- η_b : Charge/discharge efficiency for battery type b
- MCR_b: Maximum charging rate for battery type b (MW)
- $IsC_{t,g,h}$: Binary variable indicating charging 1 or discharging 0
- M : Large positive constant (Big-M)

The objective function, as presented in Eq. (1), minimizes the total cost, encompassing investment costs for energy and battery systems, operation and maintenance expenses, production costs, unmet demand penalties, and battery-related costs. Eq. (2) ensures that the total energy supply, including production, battery discharge, and unmet demand, meets or exceeds the growing hourly energy demand while considering battery charging requirements. Eq. (3) limits energy production to the available capacity, factoring in capacity expansion investments and capacity factors specific to each energy type and hour. Eq. (4) tracks battery state dynamics, balancing self-discharge, charging, and discharging activities

across hours, starting from $h = 1$. Eq. (5) resets the battery state to zero at the beginning of each day. Eq. (6) enforces limits on battery charging rates relative to their installed capacities. Eq. (7) ensures that battery discharging does not exceed the stored energy in the battery, while Eq. (8) ensures that the battery state does not exceed the total installed capacity of the battery system. Eq. (9) imposes annual carbon emission limits, aligning with predefined reduction targets. Eq. (10) mandates non-negativity for all decision variables, ensuring practical feasibility. Finally, Eqs. (11) and (12) enforce logical constraints to prevent simultaneous charging and discharging of batteries by using a binary variable $IsC_{t,g,h}$ and a large constant M.

3. RESULTS AND DISCUSSION

To evaluate the economic impact of integrating battery storage into Türkiye's energy system, the optimization model was executed under six different scenarios. BatteryLevel0 represents a case with no additional battery capacity, while BatteryLevel1 to BatteryLevel5 correspond to increasing storage capacities of 1, 2, 4, 8, and 10 GWh for each battery type, respectively. These battery technologies were chosen for their complementary characteristics, with hydrogen-based batteries offering long-term storage, lithium-ion batteries providing high energy density and rapid response, and flow batteries delivering scalability and durability for large-scale applications. The aim was to determine how the presence of battery systems could influence total production costs compared to a scenario without battery storage. Fig. 1 shows that increasing battery capacities leads to a reduction in production costs. In the BatteryLevel0 scenario, where no batteries are installed, the total production cost was approximately 27.85 billion USD, reflecting a high reliance on conventional energy sources and higher operational expenses. As battery capacities increased, production costs steadily declined. For instance, in the BatteryLevel1 scenario, where 1 GWh of each battery type was added, the cost decreased to 27.79 billion USD. By the BatteryLevel5 scenario, with 10 GWh of capacity for each battery type, the cost further dropped to 27.72 billion USD. This highlights the role of batteries in optimizing energy production by enhancing supply flexibility and reducing reliance on expensive conventional generation.

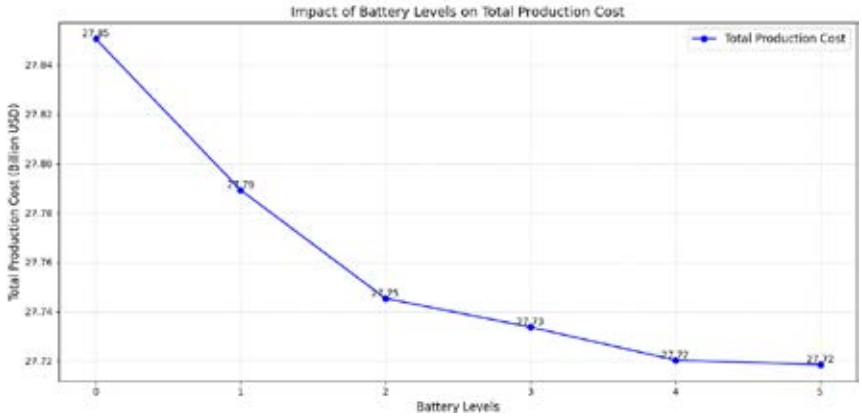

Fig. 1. Impact of battery capacities on total system cost

The impact of battery storage on total carbon emissions was also analyzed. As seen in Fig. 2, increasing battery capacities leads to a steady decline in total emissions. In the BatteryLevel0 scenario, where no batteries were installed, total carbon emissions reached approximately 141.91 million tons. However, as battery capacities increased, emissions gradually decreased. By the BatteryLevel5 scenario, where each battery type had a capacity of 10 GWh, total emissions dropped to 140.80 million tons. This trend highlights the role of battery storage in reducing reliance on fossil fuel-based generation, thereby lowering carbon emissions and supporting a more sustainable energy system.

Fig.3 illustrates the hourly usage of battery storage across different capacity levels on a representative day. As the battery capacity increases, its utilization becomes more prominent, particularly during periods of high demand. For example, scenarios with higher battery levels (BatteryLevel4 and BatteryLevel5) exhibit greater flexibility in storing and discharging energy throughout the day, especially during peak hours. This demonstrates how increased battery capacity provides the system with enhanced flexibility to optimize energy production and consumption patterns.

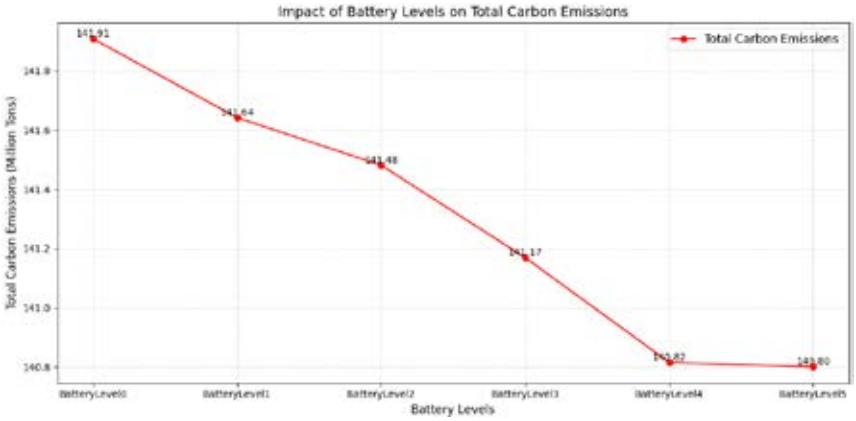

Fig. 2. Impact of battery capacities on total carbon emissions

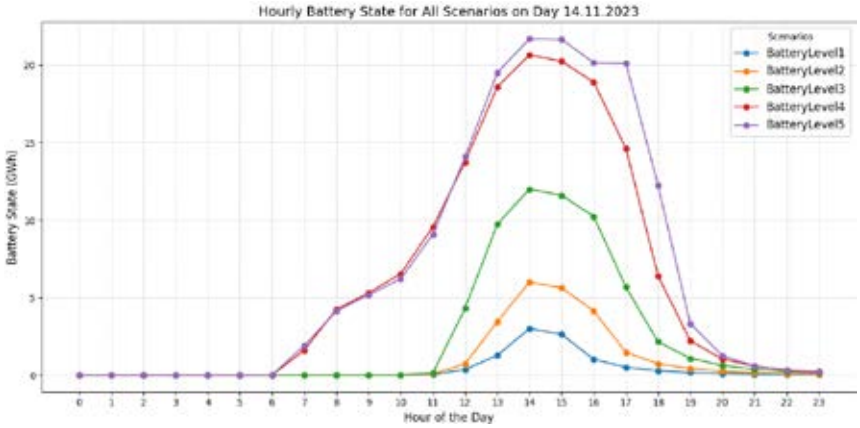

Fig. 3. Hourly battery state for different capacity scenarios on two representative days

4. CONCLUSIONS

Integrating battery storage into the energy system enhances flexibility, reduces production costs, and minimizes unmet demand penalties by storing surplus energy during low-demand periods and discharging it during peak hours. This improves the integration of renewables like wind and solar, stabilizing the grid and reducing reliance on conventional generation. Higher battery capacities help balance supply and demand, cutting the need for costly on-demand generation and minimizing energy wastage. Additionally, increased battery storage lowers total carbon emissions by reducing fossil fuel dependency, supporting both economic efficiency and environmental sustainability.

ABSTRACT
Recently, there has been an intense focus on the development of mild condition ammonia synthesis (MCAS) to overcome the scalability issues associated with the Haber Bosch process. In this study, the main interest was to clarify the impact of the precursors for Ca_2NH synthesis on Ru-Ca_2NH catalyst activity for ammonia synthesis. For this reason, β-Ca_2NH was synthesized using CaH_2 and N_2, which is different from reported in the literature. The structure of the synthesized material was thoroughly analyzed and confirmed via X-ray diffraction (XRD). Subsequently, Ru-Ca_2NH catalysts were prepared at varying percentages, ranging from 1% to 18%, to determine the optimum amount of Ru. After that, these samples underwent XRD and scanning electron microscopy (SEM) analysis. Finally, the performance of these catalysts was investigated in ammonia synthesis reaction conducted under continuous gas flow (80 ml/min, H_2: N_2=3: 1) in a quartz-tube reactor at 340°C and 0.1MPa. The outlet gas was monitored via mass spectrometer, and showed 5% Ru-Ca_2NH had the best activity. Additionally, UV-Vis spectrometry was carried out to determine total ammonia production rate, and was calculated as 1.6 mmol/g cat. h. This production rate was higher than the performance of most of the reported Ru-based catalysts.

Keywords: Ammonia, heterogeneous catalyst, energy, hydrogen storage.

1. INTRODUCTION

The global impact of the COVID-19 pandemic and Russia's war on Ukraine on the energy sector highlighted the significant importance of the need for greater energy diversification and reliance on local, renewable energy sources. Additionally, how vital of the energy storage and its use when needed has been revealed explicitly. NH_3 is seen as one potential energy storage medium due to having several advantageous properties listed below. Also, the well-developed procedures make ammonia such an attractive hydrogen carrier material and an environmentally friendly fuel [1, 2]. The expectation is to boost hydrogen powered system via essential chemical buy 2050 [3].

- ✓ It has a significant weight fraction of hydrogen, 17.65%.
- ✓ It can be liquefied under mild conditions (25°C and 0.99MPa).
- ✓ Its volumetric hydrogen density is higher than that of liquid hydrogen.
- ✓ It can be stored in a pressure vessel having a reasonable cost, like propane.
- ✓ It can be burned directly in an internal combustion engine (ICE) with no carbon emission.
- ✓ Globally well-established infrastructures for its production, storage, transport and utilization.

The current and major production method of NH_3 depends on steam reforming of methane via the Haber-Bosch process which requires high pressure (150-300 bar) and temperature (350-500°C) in the presence of Fe-based catalyst. Steam reforming of methane results in 500 million tonnes of CO_2 release into the atmosphere each year [4]. The industrialization of NH_3 synthesis dates back a hundred years. However, an ideal catalyst preparation has always been non-stop work to set up mild synthesis conditions [5].

$$N_2(g) + 3H_2(g) \xrightarrow{\text{Catalyst}} 2NH_3(g) \quad (1)$$

NH_3 is utilised in industrial, agricultural and domestic products and processes, but its main use is as fertilizer (70%) with a stabile production of about 150 million metric tonnes each year [6,7]. It is predicted novel applications of the chemical such as energy storage and power generation will result in a three fold rise in production by 2050 [8]. As a result of climate change policy, the production of NH_3 will have to shift away from carbon intensive methods. However, cost will still play an important role in the production method of ammonia. To achieve these goals, replacement of conventional iron (Fe) catalyst that show better activity at lower temperatures (around 300°C) are required. Second generation heterogeneous ruthenium (Ru) catalysts have shown promise for MCAS [9].
As for catalyst development, heterogeneous, homogeneous, and natural types of catalysts have been studied to activate N_2 molecules for NH_3 formation [10].Beyond this, research has focused on developing electronically and ionically active support materials. Previously research has shown the undeniable influence these catalyst/support materials have on the catalytic performance of the system. So far, carbon materials, nitrides, zeolites, oxides, and ceria nanocrystals have been well-developed and achieved competitive ammonia synthesis [11]. Especially, using Ru-based heterogeneous catalysts

were accepted as promising solution to reach desired production rates. The complex compounds such as $Ru_3(CO)_{12}$ and Ru $(NO)(NO_3)_3$ have been prevalently reported as Ru source for more than two decades [12-14].
The more detailed search pointed out that when nitrogen-hydrogen based alkali and alkaline earth metal compounds such as Li-N-H, CaNH, Ca_2NH, Ba-$Ca(NH_2)_2$, Sr_2NH etc. supported the catalyst, a satisfactory NH_3 production rate was achieved under mild conditions. Specifically, Ca_2NH-supported Ru catalyst showed superior performance in MCAS even in long-term tests [14-16]. The outstanding performance of the Ca_2NH was attributed to its better ionic conductivity than that of CaNH [17]. In particular, the crucial role of β-Ca_2NH, a fast H- ionic conductor, for promoting ammonia synthesis in Ru-based catalyst was emphasized in the literature [18]. Different Ca_2NH synthesis routes resulted in different ionic conductivities [14-18]. However, how the selection of starting materials for the synthesis of Ca_2NH affects the performance of Ru-Ca_2NH catalyst in the ammonia synthesis has not been clarified so far.
In this study, our motivation is to solve this puzzle and enlighten the relation between catalyst (Ru-Ca_2NH) activity and support material (Ca_2NH) synthesis route. With this aim, first, Ca_2NH was synthesized using CaH_2 and N_2. Next, catalysts involving Ru in different ratios were prepared to compare their performance for making a decision about optimum amount of Ru. After determination of the ideal catalyst composition, its long-term activity was investigated for NH_3 production. Finally, the performance of the catalyst was evaluated by making comparison with some other Ru-based catalysts.

2. EXPERIMENTAL.

2.1. Ca_2NH synthesis

Ca_2NH was synthesized via CaH_2 (Merck, Cas number: 7789-78-8) and N_2 using dosing and continuous flow reactions in a sealed reactor. Basically, CaH_2 reacted with N_2 in the sealed reactor to synthesize β-Ca_2NH. The reactor temperature was ramped up 5 °C/min to 600 °C inside a furnace (EUROTERM) and dwelled for 6 hours under N_2 flow. It was then cooled to room temperature and purged with argon [19].

2.2. Ru-Ca_2NH catalyst preparation

Ru-loading was carried out by heating a mixture of Ca_2NH powder and $Ru_3(CO)_{12}$ (Sigma Aldrich, Cas number: 15243-33-1) in the sealed reactor under continuous argon gas flow. The temperature program had five steps: 2 C/min up to 40 C, held for 1 h; 0.5 °C/ min up to 70°C, held for 1 hour; 0.9 °C/min up to 120°C, held for 1 hour; 0.9 °C/min up to 230-250 °C, held for 2 hours by using a furnace (EUROTERM) and then cooled to ambient temperature. Five different percentages (w/w) of Ru from 1% to 18% were selected to load the Ca_2NH samples in accordance with previous studies [14,20]. For comparison, 5%Ru-Ca_2NH* (Ca(m) + N_2+ H_2 → Ca_2NH*), 5%Ru-Ca_2NH +BaH_2 and 5%Ru-Al_2O_3 catalysts prepared with the same heat treatment.

2.3. Catalytic reaction for ammonia synthesis

The performance of the prepared catalysts were investigated in a NH_3 synthesis reaction. A quartz-tube reactor involving the prepared Ru-Ca_2NH catalyst powder (0.1g) was used for ammonia synthesis by applying 80 ml flow of the inlet stream with the ratio, H_2:N_2=3:1 at 340°C and 0.1MPa. The composition of the outlet stream was analysed instantaneously via the mass spectrometer (CIRRUS – MKS Spectra Products).

2.4 UV spectroscopy analysis to measure ammonium (NH_4^+)

The total amounts of synthesized ammonium were determined via a UV-Vis spectrophotometer (Thermo-Scientific, Evolution 220). All analyses were carried out by using a 640 nm wavelength.1 ml standard/sample-filled UV cuvettes were prepared for detection by following the procedures given in the literature [21,22]. Principally, 10 µl of the sample was diluted to 1 ml by adding 0.99 ml of water. 0.5 ml of alcoholic phenol, 0.5 ml of sodium nitroprusside, and 1 ml of oxidizing solution were added to all samples. The final reaction mixture was incubated at room temperature for 1 h, and the resulting coloured-sample was measured at 640 nm.

2.5 X-Ray Diffraction (XRD) Characterization Analysis

XRD patterns of the samples were collected to clarify their structure via STOE STADI P diffractometer using Mo radiation (λ Mo Kα1 = 0.70932 Å) and MYTHEN position-sensitive detector (DECTRIS) at the room temperature in reflection mode. All samples were prepared inside the glovebox and transferred within a sealed capillary (0.7mm) tube. Data were collected between 30 and 45 min per scan with two-theta range of 2° to 50°. The XRD patterns of Ca_2NH samples (before and after the reaction) were evaluated to identify their purity. First, the material identification database search program, File-4(PDF-4), helped to clarify the sample structure by taking data from the International Centre for Diffraction Data (ICDD). After all the peaks in the sample matched were matched with ICDD data, the amounts of the different phases were quantified via refinement using JANA2006.

2.5 Scanning Electron Microscope (SEM) Analysis

SEM analysis was conducted to investigate the microstructure of Ru nanoparticles on the catalysts' surface using JSM-IT800 scanning electron microscope with a JEOL energy dispersive X-ray spectrometer (EDS). Air-sensitive samples were prepared inside the glovebox and transferred in a closed transfer vessel to JSM-IT800.

3. RESULTS AND DISCUSSION

Calcium nitride-hydride (β-Ca_2NH) was successfully synthesized from CaH_2 and N_2 precursors and proved via XRD analysis sketched using OriginPro9 software, as seen in Figure-1. Here, the sample pattern was compared with the Inorganic Crystal Structure Database (ICSD) data [23].

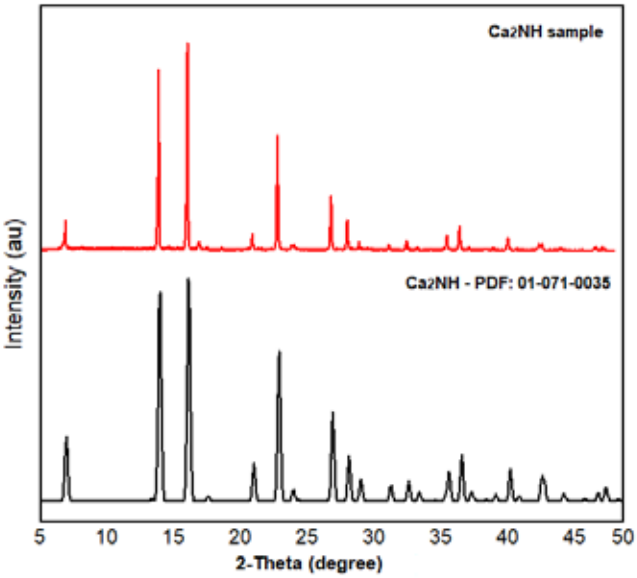

Fig. 1. XRD pattern of Ca_2NH sample and literature data [23]

The XRD pattern of the main component belonged to Ca_2NH. However, the sample also contained CaO as an impurity resulting from oxygen or air exposure in the synthesis procedure (3 %). The prepared of β-Ca_2NH was then used as a support material for adding the metal source to prepare a final form of catalyst involving 1, 2, 5, 10, and 18 % Ru. The heat treatment was applied, 1-10% and 18% Ru-loaded samples up to 240°C and 250 °C, respectively. Briefly, the samples' crystal structures were mainly in conformity with the Ca_2NH structure. When its Ru content exceeded 2%, it could be detectable via XRD. In addition to structure characterization of these catalyst, their surfaces were analysed to clarify distribution of Ru particles on Ca_2NH support materials. Ru particle distribution on the surface was more homogeneous and smaller at the 5°C/min heating rate as seen in Figure-2 (3kV, WD:3.9-4.00mm, 130k).

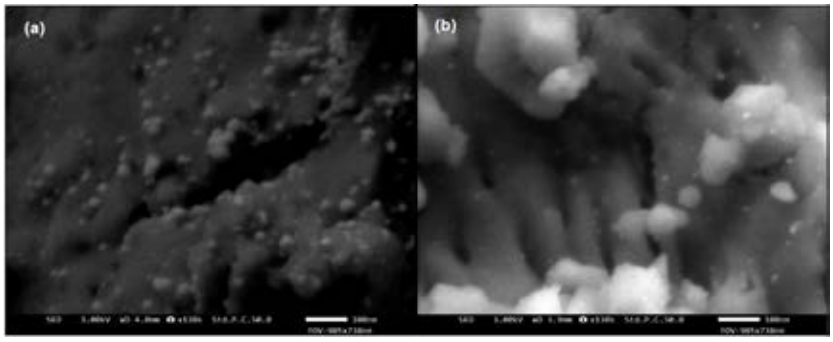

Fig. 2. SEM images of 5%Ru-Ca_2NH (a) 5°C/min (b) 10°C/min

The samples were tested for ammonia synthesis at the mentioned conditions in the experimental part. The synthesized ammonia was captured in a distilled water trap during the reactions, and then the phenol-hypochlorite method was applied to quantify the amount of ammonia present [21,22]. UV results indicated that 2 % and 5 % Ru-load Ca_2NH samples had similar performance. NH_3 production rate for 5% Ru-loaded Ca_2NH catalyst was calculated as 1.6 mmol/ g cat. h. This amount was smaller compared to the given amount in the literature (~3.5 mmol/g cat. h) for 2% Ru-loaded Ca_2NH [14]. This difference could be caused by using different types of reactors and applying higher flow rates. Despite this difference, there was no doubt that its performance was much better than that of other Ru-based catalysts producing up to 1 mmol/g cat. h reported in the literature [14]. Also, the long-term activity of 5%Ru-Ca_2NH was examined to illuminate its stability characteristics. The result of this test demonstrated that its performance decreased sharply at the 20th hours of the reaction. Consequently, its ammonia production rate was compared with Al_2O_3, Ca_2NH* and Ca_2NH +BaH_2 supported Ru catalysts.

4. CONCLUSIONS

In this study, Ca_2NH was synthesized successfully starting from CaH_2 and N_2 as following procedure given in the literature [19]. This recently promising support material was utilized to prepare Ru-based catalyst for mild condition NH_3 synthesis. The results indicated that ammonia synthesis rate, 1.6 mmol/ g cat. h., was pretty satisfactory at the beginning of the reaction when compared to literature [14]. According to UV results, ammonium synthesis rate row for these support materials was Ca_2NH > Al_2O_3 > Ca_2NH^* > Ca_2NH +BaH_2, but changed to Ca_2NH +BaH_2 > Ca_2NH^* > Ca_2NH > Al_2O_3 at the end of the monitored period. All these catalysts were deactivated in the long-term. However, the cumulative ammonium amount rose significantly when %5Ru-Ca_2NH +BaH_2 was used for the reaction. Hence, BaH_2 could be a solution to reach higher and more stable NH_3 production.

ABSTRACT
The rapid increase in global demand for clean energy has highlighted green hydrogen production as a sustainable solution. This study examines the role of energy islands (EAs) in hydrogen production based on renewable energy sources through Power-to-X (P2X) systems. Energy islands, which integrate distributed energy resources (DER) such as photovoltaic (PV) panels and wind turbines (WT), enable local and independent energy production, allowing for the efficient and stable production of green hydrogen. To enhance the effectiveness of these systems, the performance of power electronic converters (PEC) has been optimized using machine learning (ML)-based control techniques. Machine learning is utilized to ensure system stability and improve production efficiency. Furthermore, this study emphasizes that energy islands can play a significant role in the transition to sustainable energy. The paper comprehensively discusses the components of energy islands, the technical and economic challenges faced, strategies that could contribute to the energy transition, and perspectives for future development.

Keywords: Energy islands, Green hydrogen production, Power electronic converters, Machine learning, Power-to-X

1. INTRODUCTION

Traditional fossil fuels continue to dominate global energy consumption. The decreasing lifespan of currently used fossil fuels, along with their negative impacts on the environment and human health, is leading countries to turn towards renewable energy sources. Renewable energy sources such as solar, geothermal, wind, biomass, and wave energy have become preferred alternative energy sources in recent times [1]. However, the production levels of renewable sources like wind and solar fluctuate instantaneously depending on meteorological and environmental conditions [2]. This situation increases the need for innovative solutions and technologies that support the integration of renewable energy sources, enabling energy systems to operate more efficiently and continuously. Turkey is rapidly increasing its dependence on solar and wind energy in line with ambitious renewable energy targets. The global energy transition from fossil fuels to zero-carbon emission clean technologies is progressing rapidly with a sense of urgency [3]. Green hydrogen production (GHP) from renewable sources is emerging as a viable solution for energy storage and carbon reduction, particularly in energy islands (EAs). However, ensuring the stability and reliability of hydrogen production in these systems requires advanced control methodologies such as ML-based optimization. Machine learning is highly capable in tasks such as data classification, regression, and other related tasks. Artificial intelligence and machine learning can efficiently manage energy storage in the energy grid by shaving peak points or using stored energy when these resources are unavailable [4].

2. RENEWABLE ENERGY SOURCES FOR GREEN HYDROGEN PRODUCTION

Green hydrogen production emerges as an important option in the search for solutions to the global clean energy demand. Green hydrogen is produced through electrolysis using renewable energy sources such as solar and wind energy.

In this study, the role of energy islands (EAs) in hydrogen production from renewable energy sources (RES) using Power-to-X (P2X) systems is discussed. As seen in Figure 1, energy islands equipped with distributed energy sources such as photovoltaic (PV) panels and wind turbines (WT) ensure a stable and efficient production process, improving the system's efficiency and reliability. The proper management of power electronic converters (PEC) is crucial for efficiently distributing renewable energy to the load side. In this process, artificial intelligence (AI) and machine learning (ML)-based control techniques offer solutions that improve system performance and predict failures in advance. ML algorithms are increasingly preferred for solving control problems in distributed generation systems. Additionally, the management of PECs in energy islands has been optimized with ML-based methodologies. The study discusses strategies that could contribute to Turkey's renewable energy goals and presents solutions that enable high penetration of solar and wind energy. The aim of the study is to demonstrate how ML-based methods contribute to the creation of reliable and efficient energy islands.

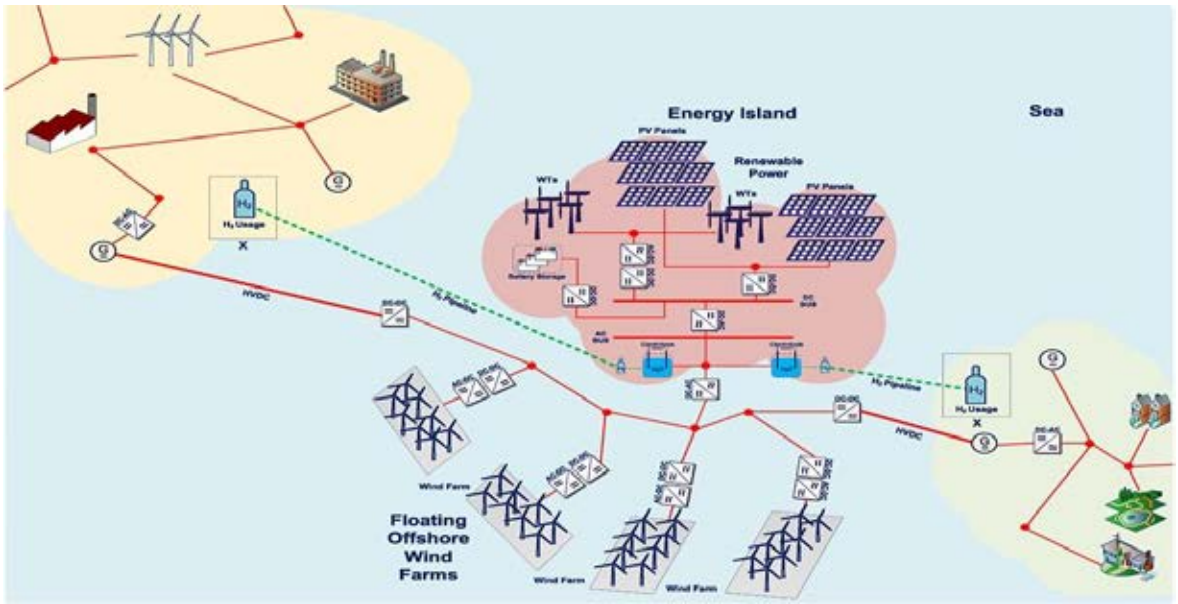

Fig. 1. The P2X systems can also be located onshore or offshore. For an EI with large-scale offshore WTs and PVs, a P2X station on the island, and a power connection to the shore, this connection can be made both electrically with high voltage DC (HVDC) and with a gas (hydrogen-H2) pipeline. [5].

3. CASE STUDY

Green hydrogen production is a process that involves renewable energy sources and is free from carbon emissions. In this process, hydrogen is produced using electrolysers powered by electricity obtained from sources such as solar, wind, biomass, and hydroelectric energy. Electrolysers work by splitting water into hydrogen and oxygen gases using electricity. The efficiency of solar energy varies depending on environmental factors, so it is optimized using energy storage and Maximum Power Point Tracking (MPPT) techniques. PEM electrolyzers play a significant role in hydrogen production and provide advantages in terms of efficiency. The potential for hydrogen production from solar energy can be examined according to local irradiation and temperature conditions. Offshore wind energy holds great potential among renewable energy sources, but technical analyses are required for successful projects. Small-scale wind turbines can operate efficiently even at low wind speeds. Microgrids and Distributed Energy Resources (DERs) play an important role in energy transmission. In these systems, Power Electronic Converters (PECs) are critical for ensuring energy transfer and efficiency. Additionally, the integration of energy storage systems enables the efficient operation of energy systems. Energy Island (EI) structures aim to reduce fossil fuel dependency and decrease carbon dioxide emissions by establishing local energy production and sustainable energy systems. Artificial intelligence and deep learning techniques can be applied in areas such as energy management and load forecasting, ensuring the efficient operation of systems. The integration of these technologies can make energy transitions more efficient.

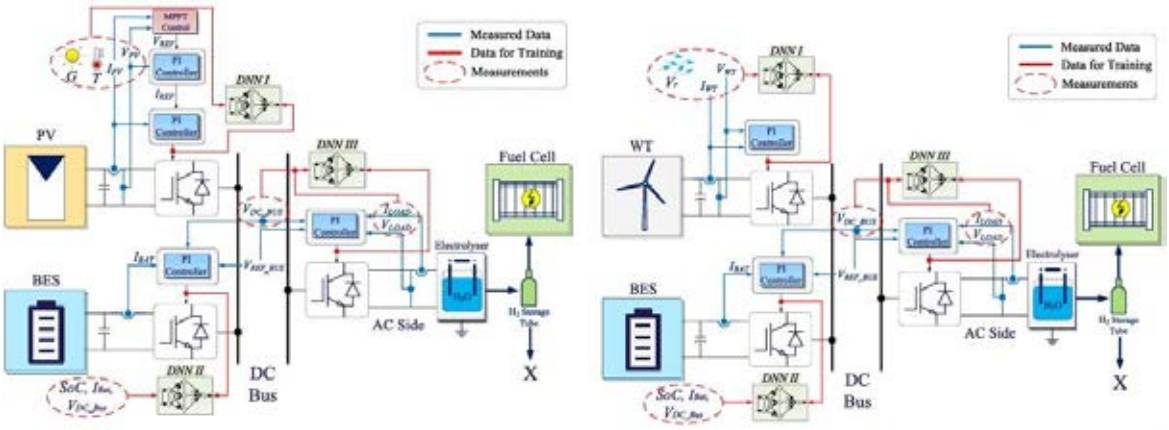

Fig. 2. Operational overview of the structure and control scheme of a photovoltaic (PV) and wind turbine (WT)-based green hydrogen production (GHP) system [6].

This study was simulated in the MATLAB/Simulink environment. The general system model is shown in Figure 2. The DC bus voltage was maintained at 48V and remained stable between 50-55V despite variable input-output conditions. Voltage fluctuations in the DC bus were reduced by 3.47%. The system exhibited a response time that was 6.6 ms faster compared to traditional methods. Hydrogen production efficiency, determined by Faraday efficiency (ηF), ranged from 67% to 82%. The operating temperature for the PEM electrolyzer was set between 50 - 80°C, the pressure was kept below 50 bar, and the lifetime was determined to be between 60,000 and 90,000 hours. High-accuracy predictions with a 39.6% error (MSE = 0.0396) were made in the system using deep learning (DNN)-based control strategies. The training time was 89.69 seconds, and the model was optimized with the best parameters. The proposed design demonstrated satisfactory results by reducing voltage oscillation, providing a faster rise rate, and delivering an early response.

4. CONCLUSIONS

Green hydrogen production in energy islands represents a transformative step towards achieving global renewable energy targets. This study proposes the use of machine learning (ML)-based techniques to enhance the continuity, stability, and reliability of energy islands (EAs). Power electronic converters (PECs) play a critical role as the backbone of renewable energy transfer. In this context, it is crucial to maintain the inputs and outputs of the converters as stable as possible. This study presents modern engineering solutions for the integration and optimization of renewable energy systems, addressing sustainable energy production, storage, and utilization.

ABSTRACT
This study investigates the effects of H_2 enrichment and gravitional forces on soot formation in laminar n-dodecane ($C_{12}H_{26}$) diffusion flames using Computational Fluid Dynamics (CFD) simulations in ANSYS Fluent 24 R1. A stretched quadrilateral mesh with 10,500 elements and for an axisymmetric domain is employed to reduce computational cost. The SIMPLEC solver is implemented with a pseudo-time Courant number of 0.001 for transient solution stability, and radiative heat transfer is modeled using the P1 radiation model. Combustion is simulated with a skeletal $C_{12}H_{26}$ mechanism (54 species, 269 reactions) validated against multiple combustion configurations. Soot formation is predicted using the Method of Moments soot model, with acetylene (C_2H_2) as the primary precursor. Four cases were analyzed, varying H_2concentrations (0%, 10%, and 50%) and gravity conditions. The results show that H_2 enrichment significantly reduces the soot volume fraction (fvmax) by approximately 50%. For instance, the 10% H_2case exhibits a soot volume fraction of about 80 ppm, compared to the 169 ppm in the pure $C_{12}H_{26}$ case. Gravity's effect on soot formation is minimal, as the soot volume fraction for the 10% H_2 cases (both gravity off and on) remains nearly identical. These findings suggest that while H_2 enrichment is effective in reducing soot formation, gravity has a minor role in altering soot levels in the tested cases. The results provide valuable insights for optimizing combustion strategies to reduce soot emissions in energy and aerospace applications.
Keywords: N-dodecane, H_2, Soot, Laminar Diffusion Flames

1. INTRODUCTION
Hydrocarbon combustion in engines and gas turbines is a major energy source but contributes significantly to environmental pollution, particularly through soot and polycyclic aromatic hydrocarbons (PAHs). Soot formation occurs via the nucleation and growth of PAHs, leading to particulate emissions that pose environmental and health concerns. Weakening soot emissions is essential as global energy demand increases. One approach is H_2 enrichment, which, as a zero-carbon fuel, modifies the chemical pathways leading to PAH and soot formation [1].
Recent studies have demonstrated that H_2enrichment reduces soot precursor formation. Akram et al. [2] found that H_2 addition suppresses key soot precursors such as acetylene (C_2H_2) and benzene, leading to a lower soot volume fraction. Wang et al. [3] highlighted how fuel composition affects soot and aromatic species distributions, emphasizing the role of non-premixed diffusion flames in soot formation. Additionally, Das et al. [4] showed that fuel molecular structure, particularly aromatic content, influences soot production, reinforcing H_2's role in reducing soot. Beyond its effect on soot precursors, $C_{12}H_{26}$ decomposition plays a crucial role in flame behavior. Smolke et al. [5] found that $C_{12}H_{26}$ decomposes into smaller hydrocarbons such as ethylene (C_2H_4) and H_2, which affect flame propagation and extinction. Furthermore, Qiu et al. [6] reported that H_2 blending reduces soot formation by modifying reaction pathways, increasing OH radical concentrations, and enhancing oxidation mechanisms.
Building on these findings, this study investigates the impact of H_2 enrichment and gravity on soot formation in $C_{12}H_{26}$ laminar diffusion flames using CFD simulations in ANSYS Fluent. The results provide insights into how H_2 enrichment and gravity influence soot dynamics, advancing the development of cleaner combustion technologies.

2. MATERIALS AND METHODS
The data presented in Table 1 summarizes four cases with varying compositions of H_2 and $C_{12}H_{26}$, gravity conditions, temperature (T), inner radius (r_i), outer radius (r_o), and flow velocity (v_f). Cases 1 and 2 both have 10% H_2 and 90% $C_{12}H_{26}$, but Case 1 has gravity turned OFF, while Case 2 has gravity ON. Cases 3 and 4 explore different fuel volumetric compositions, with Case 3 volumetricly having a 50% H_2 and 50% $C_{12}H_{26}$ mixture, and Case 4 using 100% $C_{12}H_{26}$. All cases are conducted at 700 K, with identical inner and outer radii (5 mm and 80 mm, respectively) and a flow velocity of 0.1 m/s. This study employs CFD simulations in ANSYS Fluent 24 R1 [7] to examine the effects of H_2 enrichment and gravity on soot formation in $C_{12}H_{26}$ laminar diffusion flames.
Fig. 1 (a) illustrates a stretched quadrilateral mesh with 10,500 elements ensures the computational efficiency in the simulations. The computational domain used for the axisymmetric simulations, representing half of the full geometry. The fuel jet (i.e. fuel inlet) has a radius of 5 mm, the air flows (i.e. air inlet) in a coflow arrangement through an annulus with a radius of 80 mm, with the velocity set to 0.1 m/s (Fig. 1(b)) while height of the domain is 150 mm. The SIMPLEC solver is used for numerical stability, with a pseudo-time Courant number of 0.001 for proper transient solution control. Additionally, the P1 radiation model is implemented to account for radiative heat transfer effects, ensuring a comprehensive analysis of the combustion dynamics under varying conditions.
Combustion is modeled using a skeletal chemical mechanism with 54 species and 269 reactions, developed to predict

$C_{12}H_{26}$ pyrolysis and oxidation under both high-temperature (high-T) and low-temperature (low-T) conditions [8].

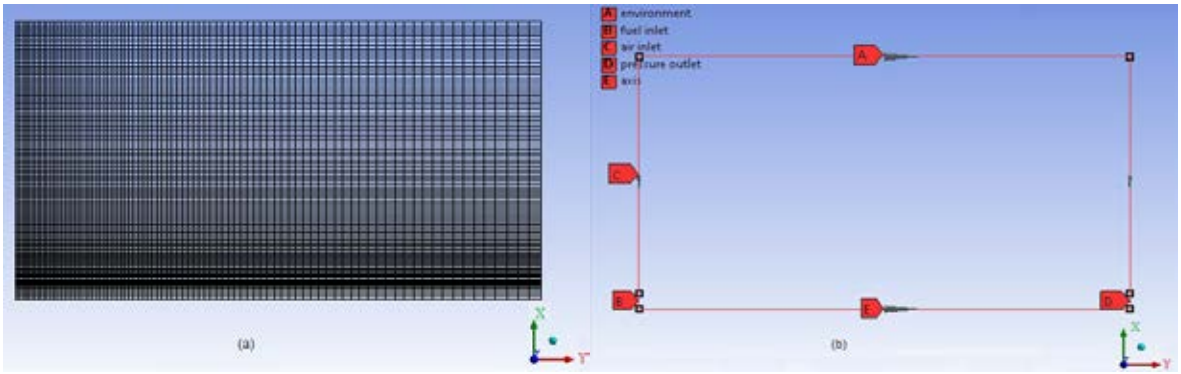

Fig. 1. Computational Domain (a) Stretched Quadrilateral Mesh, (b) Boundary Types Set

This mechanism was derived from a semi-detailed mechanism developed at the University of Southern California (USC) and reduced using reaction flow analysis (RFA) and isomer lumping [8]. The mechanism was validated across auto-ignition, perfectly stirred reactors (PSR), flow reactors, and laminar premixed flames and was previously used to model turbulent spray flames under compression ignition engine conditions [8]. Soot formation is modeled using the method of moments soot model, with acetylene (C_2H_2) as the primary soot precursor, considering soot agglomeration and soot-radiation interactions.

Table 1. Summary of the cases

Case	H_2	$C_{12}H_{26}$	Gravity	T (K)	r_i (mm)	r_o (mm)	v_f (m/s)
1	10	90%	OFF	700	5	80	0.1
2	10%	90%	ON	700	5	80	0.1
3	50%	50%	ON	700	5	80	0.1
4	0%	100%	ON	700	5	80	0.1

3. RESULTS AND DISCUSSION

Table 2 summarizes the peak values of key combustion parameters for four cases with different H_2 contents and gravity conditions. A nuanced analysis reveals several trends and interactions between H_2 enrichment, gravity, and soot formation.

Table 2. Peak values for the considered cases

	Case 1	Case 2	Case 3	Case 4
T_{max} (K)	1941.5	1941.3	1949.8	1947.4
f_{vmax} (ppm)	80.1	80.0	81.7	169.0
x_{C2H2}	0.0092	0.0092	0.0092	0.0103
x_{CO}	0.0466	0.0464	0.0438	0.0483
x_{CO2}	0.1339	0.1362	0.1316	0.1352
x_{OH}	0.0031	0.0031	0.0032	0.0030

3.1 Soot Formation Trends with Hydrogen Addition

The simulations show a significant reduction in soot volume fraction (fv) when hydrogen is added to n-dodecane, particularly between the pure hydrocarbon case (Case 4) and the hydrogen-enriched cases (Cases 1–3). The maximum soot volume fraction decreases from 169 ppm in Case 4 (0% H_2) to approximately 80 ppm in the 10% H_2 cases (Cases 1 and 2), corresponding to a reduction of over 50%. This sharp decrease suggests that even low levels of hydrogen significantly alter the flame structure and suppress soot formation. However, increasing hydrogen to 50% (Case 3) does not lead to further soot reduction. Instead, fvmax slightly increases to 81.7 ppm.

3.2 Temperature and Transport Effects

Interestingly, the peak flame temperatures remain relatively constant across all cases, ranging narrowly from 1941 K to

1950 K. This suggests that hydrogen enrichment, despite increasing reactivity and reducing soot formation, does not significantly raise flame temperature. A key reason is the low mass fraction of hydrogen, which corresponds to only about 1.16% by mass at 50% hydrogen volume (approximately 0.13% by mass for 10% hydrogen). Hydrogen's high diffusivity and low molecular weight allow it to rapidly move toward hot regions via thermal diffusion, altering flame shape and combustion intensity. This results in a more spatially distributed heat release, rather than an overall temperature increase. Additionally, since hydrogen-rich flames tend to produce less soot, radiative heat losses are reduced, contributing to the stabilization of the temperature across all cases.

3.3 Gravity's Limited Influence

When comparing Case 1 (gravity off) and Case 2 (gravity on), both with 10% H_2, the fvmax values are nearly identical (80.1 vs. 80.0 ppm), and Tmax is unchanged. This suggests that, under these laminar and symmetric conditions, gravity has a minimal effect on soot suppression. The weak buoyancy-driven flows in these small, low-speed diffusion flames do not significantly alter the mixing or oxidation processes of soot. In Case 3 (50% H_2 with gravity), a slight increase in soot is observed compared to the 10% H_2 cases, indicating that while gravity enhances upward convection of heat and reactive species, it is not enough to counteract the broader flame structure and intensified burning induced by the high hydrogen content.

3.4 Speculations on Species Stability and Soot Reduction

Despite significant changes in soot volume fraction (f_v), the volume fractions of key species such as C_2H_2, OH, CO, and CO_2 remain relatively stable across all cases, including the 10% H_2 and 50% H_2 cases. C_2H_2, a known soot precursor, and OH, a primary oxidizer, exhibit minimal fluctuations even with hydrogen addition. This stability suggests that hydrogen enrichment does not drastically alter the reaction pathways for soot formation and oxidation. The rate constants for key reactions, such as $C_2H_2 + O \rightleftharpoons CH_2 + CO$ and $CO + OH \rightleftharpoons CO_2 + H$, are temperature-dependent, and with the peak flame temperature remaining stable across cases, these reactions do not experience significant shifts in equilibrium. As a result, the concentrations of C_2H_2, OH, CO, and CO_2 remain relatively constant despite the changes in soot formation.

The slight reduction in soot volume fraction with hydrogen addition is largely attributed to enhanced oxidation due to the presence of hydrogen, which improves oxygen availability. However, hydrogen's primary role seems to be in modifying the flame's diffusivity and structure rather than directly affecting the fundamental fuel chemistry or precursor species. As hydrogen is introduced into the flame, it shifts the flame geometry, potentially allowing soot particles to persist longer in hotter regions, which might explain the minimal change in the intermediate species levels. At higher hydrogen concentrations, the dilution effect on the carbon content suppresses soot formation, but the stability of C_2H_2 and OH levels suggests that hydrogen's effect is more on soot oxidation efficiency rather than altering the core reaction dynamics of soot precursors.

4. CONCLUSIONS

The addition of H_2 to $C_{12}H_{26}$ flames results in a significant reduction in soot volume fraction, particularly at low to moderate hydrogen concentrations (10% H_2), where a sharp decrease from 169 ppm to around 80 ppm is observed. However, when hydrogen is increased to 50%, the soot volume fraction stabilizes at approximately 81.7 ppm. This non-linear trend can be attributed to changes in flame structure, where the enhanced thermal diffusivity of hydrogen shifts the combustion zone, increasing the residence time of soot particles in hotter regions, partially counteracting the soot reduction benefits.

Despite the reduction in soot volume fraction, the volume fractions of key species such as C_2H_2, OH, CO, and CO_2 remain largely unchanged across all cases, even with varying hydrogen concentrations. This suggests that hydrogen's role is more focused on altering the flame's diffusivity rather than directly influencing the chemical pathways for soot formation and oxidation. The stable temperature profile across all cases (ranging from 1941 K to 1950 K) further supports this, as temperature-dependent reaction dynamics for species like C_2H_2 and OH are not significantly altered. Overall, H_2 enrichment effectively suppresses soot at moderate concentrations, with higher hydrogen levels introducing competing effects that may offset the benefits of soot reduction, primarily due to changes in flame morphology and soot residence time in hot regions.

Future studies could explore the effects of varying flame velocities on soot formation and species concentration in H_2-enriched $C_{12}H_{26}$ flames. Flame velocity significantly influences flame structure, mixing, and the residence time of soot particles, which could provide insights into the interplay between velocity, thermal diffusion, and soot suppression at different hydrogen concentrations. Additionally, examining a broader range of volumetric hydrogen enrichment (beyond 50%) would help to further understand the non-linear behavior observed at higher hydrogen concentrations, potentially revealing new dynamics related to soot formation, flame shape, and thermal transport.

Investigating the combined effects of different velocities and hydrogen enrichment levels could also enhance the understanding of H_2's role in modifying flame characteristics under realistic combustion conditions. This would contribute to more robust models for soot formation in practical applications such as combstion engines or industrial burners, where variable operational conditions are common.

ABSTRACT
This study aim at preparing a highly efficient binary hydroxide electrocatalyst ($NiCo(OH)_2$) with Nickel Carbonyl on stainless steel (304) as an anode for alkaline water electrolysers. In order to increase the efficiency, Iridium (Ir) and Rutheniun (Ru) were doped as well as Silver (Ag) precipitation. Electrochemical techniques, such as Electrochemical Impedance Spectroscopy (EIS) and Linear Sweep Voltammetry (LSV) were applied in 1 M KOH while Scanning Electron Microscopy (SEM) and Energy Dispersive X-ray spectroscopy (EDX) analysis were used for characterisation and surface morphology. Considering the charge transfer resistances of the electrodes determined from the EIS results obtained at 0.8 V, the OER efficiency of ruthenium doping was over 90%. Considering the increase in current density, it was determined that silver precipitation upon ruthenium and iridium doping increased the OER efficiency.

Keywords: Electrocatalysts, OER, water splitting, binary hydroxide

1. INTRODUCTION
Highly effeicient, environmentally friednly and sustainable energy sources have been the current interest in research in order to counter fort he increased in demand of energy alternatively. Hydrogen energy received great attention in this perspective. From research water electrolysis tend to be the best form for hydrogen production. In the process of producing hydrogen on one side (cathode) tends to come with oxygen on the other side (anode) and thats fort he importance of water electrolysers. Water electrolysis consists of two half-cell reactions, the formation of H_2 (HER) at the cathode and O_2 (OER) at the anode. While the rapid production of the purest hydrogen is achieved through the electrolysis of water, the release of oxygen also causes the reaction, which is theoretically expected at 1.23V, to appear at overpotentials and not occur at this voltage [1,2]. Electrocatalysis for the oxygen evolution reaction (OER) plays an important role in this sense. It is known that metal oxide materials form the basis of the OER mechanism, and non-oxide materials exhibit very promising performance for general water splitting. Synthesizing electrocatalysis for OER is at least as important as the electrocatalysis synthesized for the cathode in obtaining hydrogen by electrolysis of water [3]. Research has attempted to design low-cost and effective catalysts. Nitride, sulfur, carbide and phosphide compounds of transition metals are widely used in the preparation of catalysts for HER in acid or alkaline solution [4-8].
The OER performance of the catalyst produced by ruthenium and iridium doping then silver precipitation of a binary hydroxide produced by hydroxidation and direct immersion was assessed in this work. Energy dispersive X-ray spectroscopy (EDX) analysis and scanning electron microscopy (SEM) were used to accomplish the characterisation. In a 1 M KOH solution, electrochemical behavior was investigated using linear sweep voltammetry (LSV) and electrochemical impedance spectroscopy (EIS).

2. EXPERIMENTAL
Synthesis of Catalysts; $NiCo(OH)_2$ coated on nickel plated steel by direct dipping method. Coating was carried out by dipping and hydroxidation. For this, 1.0 M $NiNO_3$ solution, 30% KOH solution and 1.0 M $CoNO_3$ solutions were used. The electrode was immersed first in $NiNO_3$ solution, then in KOH solution, then in $CoNO_3$ solution and again in KOH solution. In order to obtain oxyhydroxide forms, a potential of 0.8 V was applied to the electrode in 1.0 M KOH solution for 60 minutes using the three-electrode technique. In this process, 2 cm^2 Pt mesh was used as the counter electrode and Ag/AgCl (3 M KCl) was used as the reference electrode. Then, a solution was prepared with 0.005 M $IrCl_3.H_2O$ boric acid to pH 3.5, and iridium was doped on the $NiCo(OH)_2$ structure by applying a -1.5 V potential for 30 seconds using the chronoamperometry technique [9]. Silver precipitation was performed on the iridium-doped electrode surface by dissolving 1.0 M $AgNO_3$ solution in 0.1 M HNO_3 acid and applying it for 30 s at a current density of 1 mA cm^{-2}. Additionally, 0.1 M $RuCl_3.H_2O$ solution was prepared to dope ruthenium onto the $NiCo(OH)_2$ double hydroxide structure. For chemical doping in the prepared ruthenium solution, the $NiCo(OH)_2$ double hydroxide electrode was kept in the ruthenium solution for 30 minutes, then ruthenium doping was done in 10 cycles using the cyclic voltammetry technique in the range of -0.2 - 1 V [10]. Silver precipitation on ruthenium was carried out using the same method as on iridium.
All electrochemical experiments were performed using a Gamry Interface 1000 potentiostat/galvanostat. The Ag/AgCl (3M KCl) electrode was utilized as the reference electrode, and a 2 cm^2 Pt sheet was employed as the counter electrode. Using a Gamry Interface 1000 electrochemical workstation at room temperature in an open atmosphere, the electrochemical experiments were performed in a 1 M KOH solution. Electrochemical Impedance Spectroscopy (EIS)

measurements were taken with an amplitude of 5 mV and a frequency range of 10^5 -0.01 Hz at 0.8 V. To determine the OER efficiency of the electrodes, current potential curves in the anodic direction were obtained in 1.0 M KOH solution at a scan rate of 1 mV s^{-1} in the range of 1.0 V with the open circuit potential.

3. RESULTS AND DISCUSSION

In Fig. 1, the SEM images of $NiCo(OH)_2Ir$ doped (a), $NiCo(OH)_2IrAg$ precipitation (b), $NiCo(OH)_2Ru$ doped (c) and $NiCo(OH)_2RuAg$ precipitation (d) electrodes are presented to demonstrate their surface characteristics. These SEM images provide valuable insights into the surface characteristics of these electrodes.

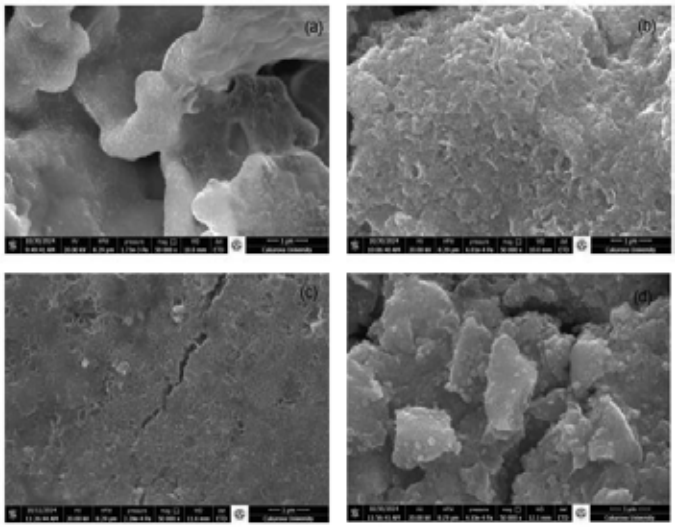

Fig. 1. SEM images (X50000) of $NiCo(OH)_2Ir$ doped (a), $NiCo(OH)_2IrAg$ precipitation (b), $NiCo(OH)_2Ru$ doped (c) and $NiCo(OH)_2RuAg$ precipitation (d) electrodes

$NiCo(OH)_2Ir$ doped electrode (Fig.1.a), seems to have a uniform distribution of nanoscale structures and the presences of well-defined agglomerates could mean favourable sites for OER, possibility of enhanced conductivity and catalytic activity could also be due to dense coating. In Fig.1.b, $NiCo(OH)_2IrAg$ precipitation electrode, addition of Ag may influence the surface roughness and particle distribution. A more heterogeneous morphology compared to the Ir doped electrode, which could enhance catalytic efficiency by providing additional active sites. Incorporation of Ru resulted in a relatively smoother morphology with densely packed features and better electrocatalytic performance facilitated by electron transfer could have been improved by the uniform dispersion of Ru in Fig.1.c. Ru and Ag combinations introduced complex surface structure with fine and coarse agglomerates which might have lead to enhanced surface area and catalytic efficiency through synergistic effect as seen in Fig.1.d, $NiCo(OH)_2RuAg$ coated electrode. Overall, the SEM analysis provides insights into the surface texture, particle distribution and potential active site density, all of which are crucial for optimizing OER performance.

Table 1. EDX analysis of the $NiCo(OH)_2Ir$, $NiCo(OH)_2IrAg$, $NiCo(OH)_2Ru$ and $NiCo(OH)_2RuAg$ electrodes

Elements	$NiCo(OH)_2Ir$ electrode (%wt)	$NiCo(OH)_2IrAg$ electrode (%wt)	$NiCo(OH)_2Ru$ electrode (%wt)	$NiCo(OH)_2RuAg$ electrode (%wt)
C	2.68	1.62	1.91	2.26
O	9.54	21	25.86	17.44
Ag	-	12.07	-	11.64
K	1.17	2.60	3.60	1.72
Co	1.02	24.49	45.16	0.5
Ni	83.78	37.51	20.33	59.05
Ir	0.58	0.71	-	-
Ru	-	-	0.45	0.13
Fe	1.23	-	2.66	7.37

EDX analysis results show the presence of iridium, ruthenium doped and silver precipitation on the nickel cobalt hydroxide surface (Table 1).

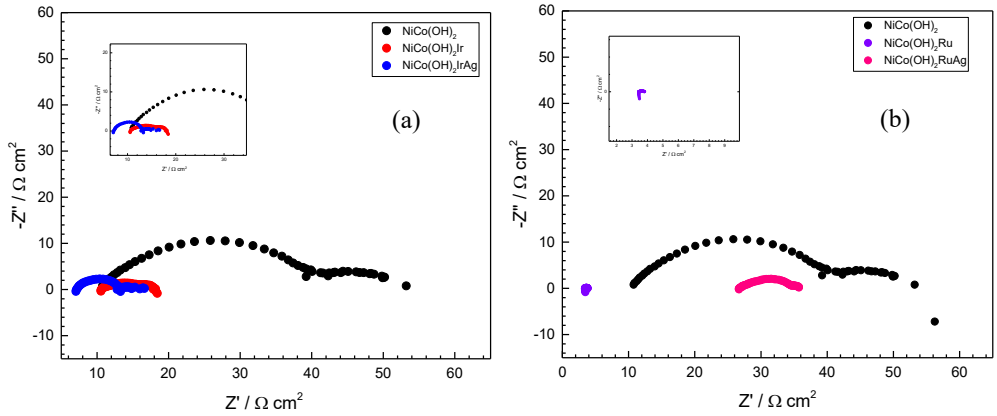

Fig. 2. Nyquist diagrams of $NiCo(OH)_2$, $NiCo(OH)_2Ir$ and $NiCo(OH)_2IrAg$ (a), $NiCo(OH)_2$, $NiCo(OH)_2Ru$ and $NiCo(OH)_2RuAg$ (b)

Nyquist curves of $NiCo(OH)_2$, $NiCo(OH)_2Ir$ and $NiCo(OH)_2IrAg$ electrodes obtained at 0.8 V are given in Fig.2(a). It is seen from the Nyquist curves that the charge transfer resistances (Rct) decreased significantly as a result of iridium doping and silver precipitation. The charge transfer resistance of the electrode was determined as ~43.48 Ω cm^2, ~10.32 Ω cm^2, ~9.06 Ω cm^2 for $NiCo(OH)_2$, $NiCo(OH)_2Ir$ and $NiCo(OH)_2IrAg$ electrodes respectively. A lower charge transfer resistance, which is a good factor for OER efficiency study was observed for $NiCo(OH)_2IrAg$ electrode compared to the others. This may be attributed to the presence of the Iridium and Silver. Nyquist curves of $NiCo(OH)_2$, $NiCo(OH)_2Ru$ and $NiCo(OH)_2RuAg$ electrodes obtained at 0.8V are given in Fig.2(b). It can be interpretated from Figure 2.b. that doping ruthenium significantly reduces the charge transfer resistance. The charge transfer resistance of the $NiCo(OH)_2$ electrode was determined as ~43.48 Ω cm^2, ~0.69 Ω cm^2 for $NiCo(OH)_2Ru$ and that of $NiCo(OH)_2RuAg$ as ~10.09 Ω cm^2. The charge transfer resistance of $NiCo(OH)_2Ru$ electrode was lower compared to the other electrodes. Therefore, it was determined that the electrode formed as a result of ruthenium doping on the binary hydroxide structure significantly increased the OER efficiency.
The charge transfer resistances of the prepared electrodes determined from the Nyquist curves obtained at 0.8 V potential are given in Table 2. Percentage efficiencies from load transfer resistors were calculated according to Eq. (1).

$$\%\eta = \frac{R_{ct,double\ hydroxide} - R_{ct,metal\ coated}}{R_{ct,double\ hydroxide}} x100 \quad (1)$$

Table 2. Charge transfer resistances (Rct) of the electrodes determined from the EIS results obtained at 0.8 V.

Electrode	Rct	Efficiency (η%)
$NiCo(OH)_2$	43.48	-
$NiCo(OH)_2Ir$	10.32	76.26
$NiCo(OH)_2Ru$	0.69	98.41
$NiCo(OH)_2IrAg$	9.06	79.16
$NiCo(OH)_2RuAg$	10.09	76.80

As seen in Table 2, the OER efficiency of ruthenium doping is over 90%. As a result of silver precipitation, OER efficiencies in iridium silver and ruthenium silver were determined to be over 70%.

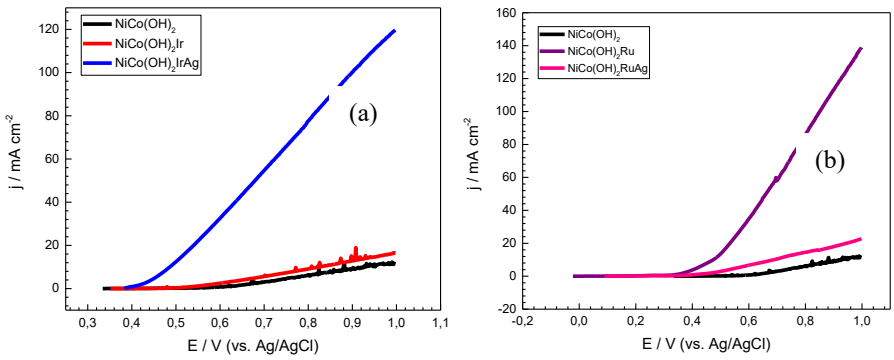

Fig. 3. Anodic current-potential curves of $NiCo(OH)_2$, $NiCo(OH)_2Ir$ and $NiCo(OH)_2IrAg$ (a), $NiCo(OH)_2$, $NiCo(OH)_2Ru$ and $NiCo(OH)_2RuAg$ (b) electrodes in 1.0 M KOH

In Fig. 3(a)., to determine the OER activities of $NiCo(OH)_2$, $NiCo(OH)_2Ir$ and $NiCo(OH)_2IrAg$ electrodes, anodic tests were performed in 1.0 M KOH solution at a scan rate of 1 mV s^{-1}. From these curves, the oxygen evolution efficiency of the electrodes were determined. The potential at which oxygen evolution begins was determined as 0.57 V, 0.55 V and 0.47 V for $NiCo(OH)_2$, $NiCo(OH)_2Ir$ and $NiCo(OH)_2IrAg$, respectively. It is observed that iridium doped and silver precipitation on the oxyhydroxide structure reduces the OER overvoltage. When OER efficiencies are compared, high current and low overvoltages are seen in the $NiCo(OH)_2IrAg$ electrode. In Fig. 3(b)., to determine the OER activities of $NiCo(OH)_2$, $NiCo(OH)_2Ru$ and $NiCo(OH)_2RuAg$ electrodes. The potential at which oxygen evolves for $NiCo(OH)_2$, $NiCo(OH)_2Ru$ and $NiCo(OH)_2RuAg$ was observed at 0.57 V, 0.39 V and 0.48 V, respectively. Examination of the curves indicated $NiCo(OH)_2Ru$ electrode had the lowest OER overvoltage potential. Although the OER efficiency of the electrode $NiCo(OH)_2RuAg$ is lower than that $NiCo(OH)_2Ru$, it is higher than that of the $NiCo(OH)_2$ electrode.

In Table 3, the oxygen release potential determined from the anodic current potential curves of the electrodes and the current densities obtained at 0.8 V are given.

Table 3. Electrochemical parameters of the electrodes determined from the current potential curves

Electrode	OER potential (V)	Current density at 0.8 V (mA cm^{-2})	Current Increase (%)
$NiCo(OH)_2$	0.57	6.35	-
$NiCo(OH)_2Ir$	0.55	9.17	44.41
$NiCo(OH)_2Ru$	0.39	87.68	>100
$NiCo(OH)_2IrAg$	0.43	76.88	>100
$NiCo(OH)_2RuAg$	0.48	14.61	>100

The catalytic activities of Ru and Ir, which have high OER efficiency, increased with silver (Table 3). In doping, conductivity, bond energies and structural features of the catalysts cause the number of active centers to increase and therefore the OER efficiency to be high.

4. CONCLUSIONS

Hydrogen is an interesting energy source due to its lack of waste, carbon neutrality and high energy density. In the electrolysis of water, which is the most used and most suitable method for hydrogen production, the anode material is as important as the cathode material. According to the experimental results of the study, the surface of the prepared electrode is an effective electrocatalytic surface for OER. According to EIS result OER efficiency of ruthenium doping was 98.41%. Considering the current values, it was found that ruthenium and iridium doping and silver precipitation on the surface increased the OER efficiency.

ABSTRACT
The work focuses on the research of three metal based electrocatalyst on a nickel coated nickel foam for its high HER efficiency and catalytic activity to be used as a cathode material in an anion exchange membrane (AEM) water electrolyzer. The developed ternary catalyst composed of nickel-iron-molybdenum (NiFeMo). Linear sweep voltammetry (LSV) and Electrochemical Impedance Spectroscopy (EIS) techniques were used in electrode efficiency examinations, while Scanning Electroscopy Measurement and Energy Dispersive Spectroscopy for the characterization and surface morphology. Significant increase in current density was obtained as seen from the LSV curve. Increased current density values for foam, nickel coated foam(#Ni) and NiFeMo#Ni were -14.89 mA cm^{-2}, -26.09 mA cm^{-2}, and -33.21 mA cm^{-2}, respectively calculated at -1.3 V for HER catalysis.

Keywords: HER, electrocatalyst, AEM water electrolyzer, ternary catalyst

1. INTRODUCTION
The focus to divert energy usage from fossil fuel sources to sources that are environmentally friendly and green is gaining much attention due to much concern over the sharp rise in environmental pollution and global warming. These concerns may also be attributed to the hike in energy usage especially considering the factor with which electric cars and other electric devices production has doubled. Instead of carbon based fuels, hydrogen studies have got much attention and consideration due to its properties. Natural availability of hydrogen helps with its studies and utilization in several methods [1]. Water electrolysis is considered the method for about 2-4% of the world's H_2 production [2]. In water electrolysis there is the necessity to develop more cost effective and naturally available electrocatalyst in place of platinum. In this case the reduction of overpotential must be considered. Nickel foam is considered a positive exchange in AEM studies with much consideration of thermodynamic stability and passivation ability [3]. Expansion of contact area between electrode and nanostructure catalytic layer which is to decrease in ohmic resistance is one factor considered for the development of our NiFeMo#Ni electrode. Therefore, a tenary NiFeMo alloy bifunctional electrocatalysts development is vital, being scientifically important and easily applicable [4].
The HER performance of the catalyst produced by electrodeposition was studied in this work. Energy dispersive X-ray spectroscopy (EDX) analysis and scanning electron microscopy (SEM) were used to accomplish the characterization. In a 1 M KOH solution, electrochemical behaviour was examined using linear sweep voltammetry (LSV) and electrochemical impedance spectroscopy (EIS).

2. EXPERIMENTAL
Synthesis of Catalysts; The electrodes to be studied were prepared from W300 x L1000mm Ni foam and cut to approximately 1 x1 cm. The nickel foam was cleaned in an ultrasonic bath for half an hour in acetone. The nickel mesh electrodes were left in the ultrasonic bath for 1 h in 3.0M HCl to make them electrically conductive. The foam was electrochemically coated with nickel at 10mA cm^{-2} for 60s, dried and later proceeded with the coating of NiFeMo at 50mA cm^{-2} for 30s using the bath compositions in Table 1.

Table 1. Coatings bath composition

	Bath composition	Conditions
Ni Coating	30% $NiSO_4.7H_2O$ 1.25% H_3BO_3 1.0 % $NiCl_2.6H_2O$ pH=3.5	60s, 10mA cm^{-2}, 25^0C
NiFeMo Coating	$NiSO_4.6H_2O$ = 6.4g $FeSO_4 \cdot 7H_2O$ = 1.6g $Na_2MoO_4.2H_2O$ = 0.96g $Na_3C_6H_5O_7 \cdot 2H_2O$ = 5.28g pH = 9.8	30s, 50mA cm^{-2}, 25°C

Gamry Interface 1000 potentiostat/galvanostat was used in performing the electrochemical experiments. A three electrode system with Ag/AgCl (3M KCl) as a reference electrode, 1 cm² Pt sheet as a counter electrode and 1 cm² nickel foam as a working electrode. Electrochemical measurements were done in 1 M KOH solution at room temperature. EIS

was taken in the frequency range of 10^5 -0.01 Hz, 5 mV and at -1.3 V. HER efficiency of electrodes was determined by LSV in the cathodic direction from open circuit potential to -1.5 V at 1 mV s^{-1} scan rate.

3. RESULTS AND DISCUSSION

Figure 1 is a representation of surface characteristics of foam (a), #Ni (b) and NiFeMo#Ni (c). In (a) fine roughness of struts were observed in the foam, indication of increased surface area which is an important tool for electrochemical performance. Image (b) displays a characteristic rough and porous structure which is common to foam substrates therefore, the increase in surface area for HER studies. Deposition quality is also observed from the uniformity that's the evenness. In Fig.1(c), co-deposition of NiFeMo on #Ni may have resulted in the significant roughness observed.

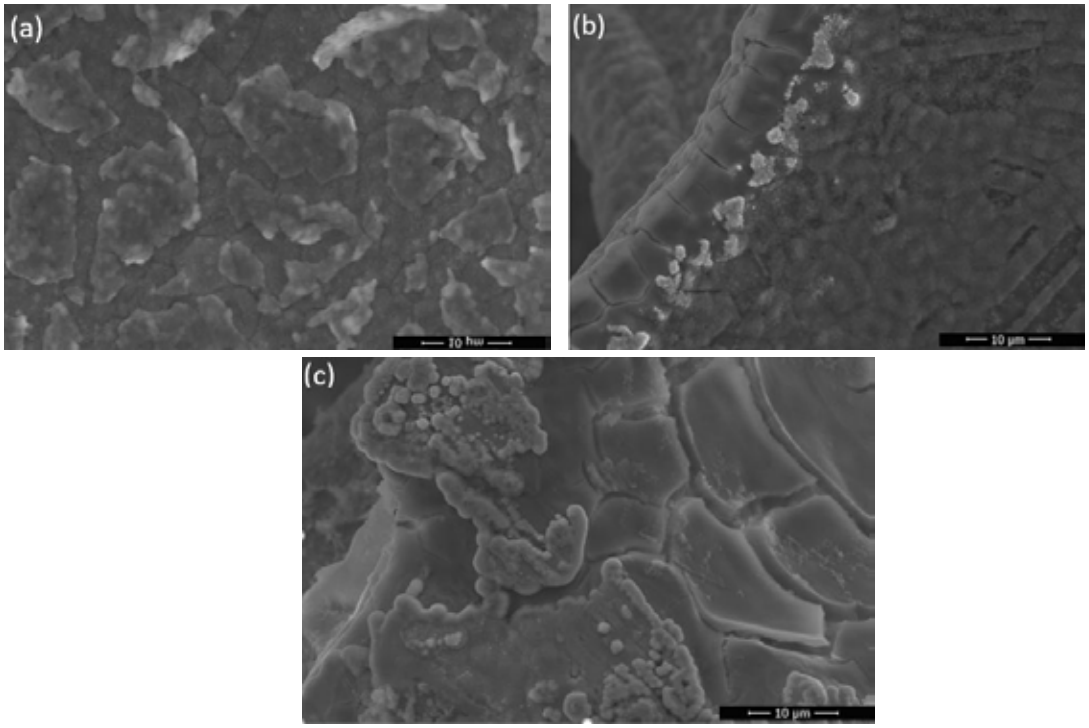

Fig.1. SEM images (scale bar: 10 µm) of foam (a), #Ni (b), and NiFeMo#Ni deposited (c) electrodes (Mag: x5000)

There may be good ion transport due to the highly porous and interconnected network observed. This roughness is enhanced by the active surface area. It's highly possible that the co-depositiion of NiFeMo caused the small granular formations seen and these lead to an increase in active surface area vital for electrochemical reactions, HER studies for example. The deposition created by the multi-metal layer deposition improved the ion transport and gas release in the HER process.

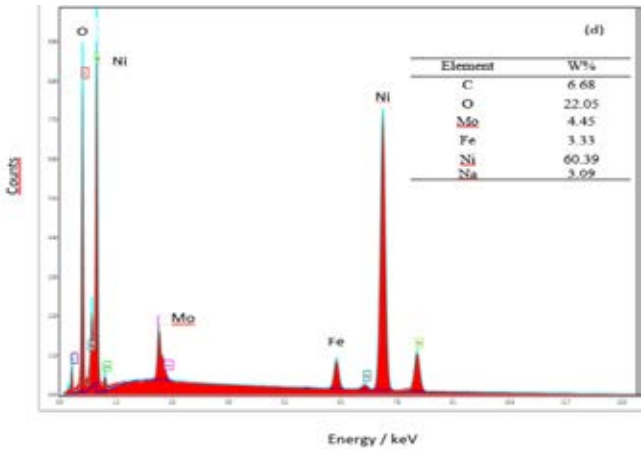

Fig. 2. EDX analysis representation of NiFeMo#Ni electrode (inset: Table shows % elemental composition of Ni, Mo, Fe, O, Na and C).

Compositional observation necessary for HER studies were seen in the NiFeMo#Ni electrode's EDX results with the most abundant being nickel. Nickel providing high electrical conductivity important for HER catalysis serves as a basic substrate. Creation of synergistic effects with nickel and molybdenum to improve catalytic performance and stability by iron (Fe) was also present at 3.33 wt%. Molybdenum (Mo) also contributing to active sites that improves HER kinetics, particularly in alkaline media, by facilitating electron transfer and reducing hydrogen evolution overpotential was found to be 4.45 wt%. surface oxides formed during deposition or sample exposure, which can influence catalytic activity by modifying electronic properties possibly contributed to oxygen at 22.05 wt%. Environmental contaminations or bath solution residuals count contribute the detection of lower concentrations of carbon(C) and sodium (Na) at 6.68 wt% and 3.09 wt%, respectively.

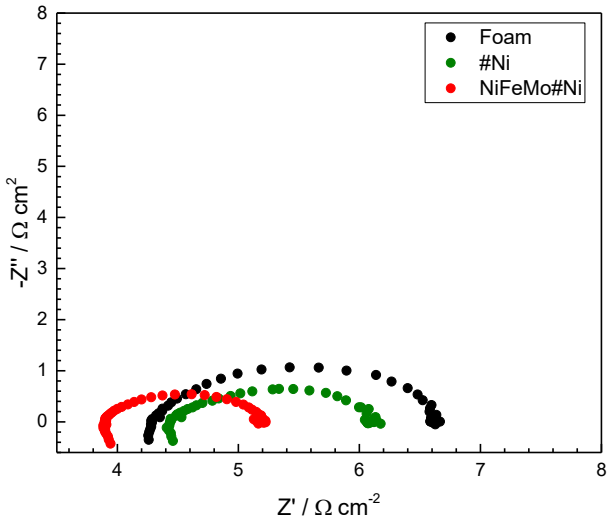

Fig. 3. Nyquist diagrams of foam(black), #Ni (green) and NiFeMo#Ni (red) electrode at -1.3 V 1 M KOH.

The EIS measurements at -1.3 V of the different electrodes for HER studies as seen im fig.2 gives key observations about their charge transfer properties and catalytic performances. The foam is seen to have the largest semi-circle signifying the highest charge transfer resistance and least efficient among the three due to poor conductivity and sluggish electron transfer. However, the coating of nickel on foam (NiF) tend to have decrease the semi-circle indicating a lower charge transfer resistance and thereby increasing its HER activity compared to the foam. NiFeMo#Ni exhibited the lowest charge transfer resistance meaning it was the best with a catalytic effect for HER studies amongst the three as seen with it having the smallest semi-circle. The shift in solution resistances may be attributed to the readiness of the surface at the applied potential. We could therefore conclude that NiFeMo increased the active surface area, reduced the charge transfer resistance and thereby increasing the catalytic activity for the HER stuies.

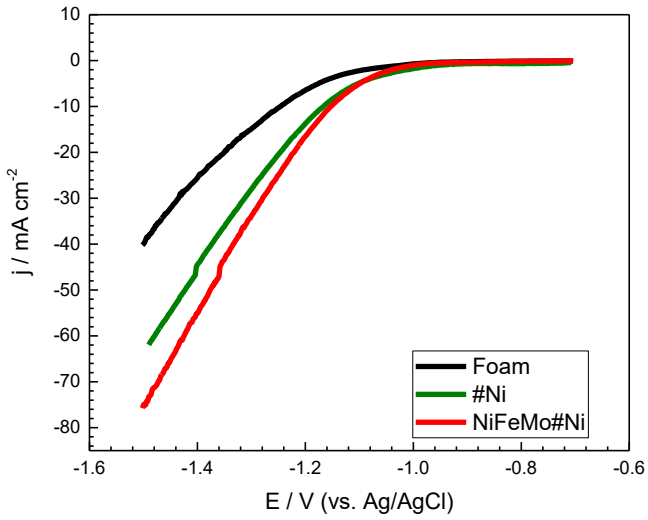

Fig. 4. Cathodic current-potential curves of foam (black), #Ni (green) and NiFeMo#Ni (red) deposited electrodes in 1.0 M KOH.

The cathodic current measurements were taken from the open circuit potential to -1.5 V at 1mV s^{-1} scan rate in 1.0 M KOH solution. with specific focus on a nickel-iron-molybdenum (NiFeMo) composition electrodeposited on nickel-coated nickel foam (#Ni), the performances of different electrode materials for the (HER) were compared in Fig. 4 above. Compared to #Ni and bare foam, the NiFeMo#Ni exhibited significant increase in current density as well as a decrease in the onset potential. A more negative potential (E) is required for the foam and #Ni to achieve equivalent current densities as NiFeMo#Ni, indicating higher overpotentials for HER. electrocatalytic efficiency was enhanced by lowering the energy barrier for hydrogen evolution. This property of our material as in the increase in current density and the lowering of onset overpotential could be attributed to the synergistic effect of our multi-metal (NiFeMo) layer coating, which likely optimize the adsorption and desorption steps in the HER mechanism. This is another factor of evidence that the incorporation of NiFeMo in our HER cathodic material studies, enhances catalytic activity and increases efficiency. Moreover, NiFeMo composition on Ni@F showed a unique morphology and inherent conductivity that improves electron transfer and catalytic site availability.

4. CONCLUSIONS

As a better alternative source of energy with the great advantages, it is important to focus on the best way to increase the production of hydrogen. The preparation of an ideal electrocatalyst to boost up the cathodic reactions in AEM water elecytrolyzer is vital. Our experimental results showed the electrocatalytic efficiency and activity of the prepared NiFeMo#Ni on hydrogen evolution reaction in 1 M KOH. Increased in current density and the decrease in charge transfer resistance as proof due to our synergistic NiFeMo#Ni electrode were observed in our LSV and EIS measurements respectively.

ABSTRACT
The increasing global energy demand and efforts to reduce environmental impact have accelerated the search for sustainable energy solutions. Hydrogen energy has emerged as a key player in achieving net-zero greenhouse gas emissions, with Proton Exchange Membrane (PEM) electrolyzers being a promising technology for clean hydrogen production. However, their long-term durability remains a critical challenge, especially after extended periods of inactivity. This study investigates the degradation effects in a PEM electrolyzer that was initially operational but remained idle for approximately 15 years. Experimental analyses were conducted to evaluate key performance parameters, including voltage loss and current density variations. The results indicate a significant increase in overpotential, suggesting membrane degradation, catalyst sintering, and increased internal resistance over time. A 15% efficiency loss was observed, highlighting the need for advanced materials and maintenance strategies to extend the operational lifespan of PEM electrolyzers.
The findings provide valuable insights into the long-term reliability and degradation mechanisms of PEM electrolyzers, contributing to their future development and commercialization.

Keywords: PEM electrolyzer, degradation, hydrogen production, long-term performance, electrolysis.

1. INTRODUCTION

In recent years, global energy consumption has been steadily rising due to factors such as population growth and improved living standards. This increase has led to a greater dependence on fossil fuels, contributing significantly to environmental pollution, intensifying global warming, and causing a range of other crises. Furthermore, the sharp rise in fossil fuel costs over the past few years has brought renewable energy solutions, particularly green hydrogen production through electrolysis [1-3]. Among the various electrolysis technologies, PEM water electrolysis is one of the most used method, along with alkaline electrolysis. Although alkaline electrolysis is a mature and reliable technology with lifespans of over 30 years, PEM electrolysis is also a commercially viable technology that boasts a high readiness level. One of its primary advantages is its quick and dynamic response, making it ideal for integration with fluctuating energy sources [4].

The efficiency and performance of PEM electrolyzers are directly influenced by the seamless integration of several advanced components. The Proton Exchange Membrane plays a crucial role in ensuring proton conductivity while preventing gas crossover. The anode, composed of iridium oxide, is responsible for oxygen evolution, whereas the platinum-based cathode acts as an efficient hydrogen production catalyst. Additionally, electrodes with large surface areas facilitate gas diffusion, improving overall efficiency. Bipolar plates contribute to electron conductivity and enhance the mechanical durability of the system. Meanwhile, seals and gasket materials play a critical role in preventing gas leakage and ensuring operational safety, all of which are essential for optimizing performance [5-6].

Despite these advantages, the long-term durability of PEM electrolyzers remains a significant challenge, especially after extended periods of inactivity. Over time, various degradation mechanisms can impact system efficiency and reliability. This study investigates the degradation effects observed in a PEM electrolyzer following nearly a decade of idle operation. Through experimental analysis, key performance parameters such as voltage and current density are evaluated. The findings will provide valuable insights into the long-term reliability, maintenance strategies, and potential improvements necessary for the future development and commercialization of PEM electrolyzers.

2. MATERIALS AND METHODS

This study investigates the long-term degradation effects in PEM electrolyzers by employing a structured experimental approach. The methodology encompasses material selection, experimental setup configuration, and data collection techniques to ensure accurate and reproducibility. The experimental framework is designed to assess key degradation parameters by analyzing performance changes over time. The system was equipped with thermocouples placed at the anode, cathode, and water outlet to monitor temperature variations. A digital data logger recorded real-time voltage and current density variations during operation.

In the PEM electrolyzer system, fine titanium meshes and sintered porous titanium serve as current collectors and diffusion media, while stainless steel is used for the end plates. A single cell utilizes a 100 cm² circular-shaped MEA supplied by Giner Inc. This MEA incorporates a Nafion 110 membrane and features catalyst loadings of 2 mg/cm² Pt and 2 mg/cm² Ir on the anode side, whereas the cathode side contains 4 mg/cm² Pt. The experimental conditions and assessment techniques are structured to provide insights into the durability and performance of PEM electrolyzers over extended periods of inactivity.

2.1. Experimental Setup

A schematic representation of the test setup is shown in Figure 1. In the setup, an adjustable peristaltic pump (12V) is used to supply water. Portable thermocouples (Ordel) and a data logger (Elimko 680) are used to control both water and stack temperatures. To provide the stack with the energy needed to split the water into hydrogen and oxygen, a 3 kW (30V-100 A) power supply (AlphaWorld) is used. All of the data have been recorded on a computer to analysis.

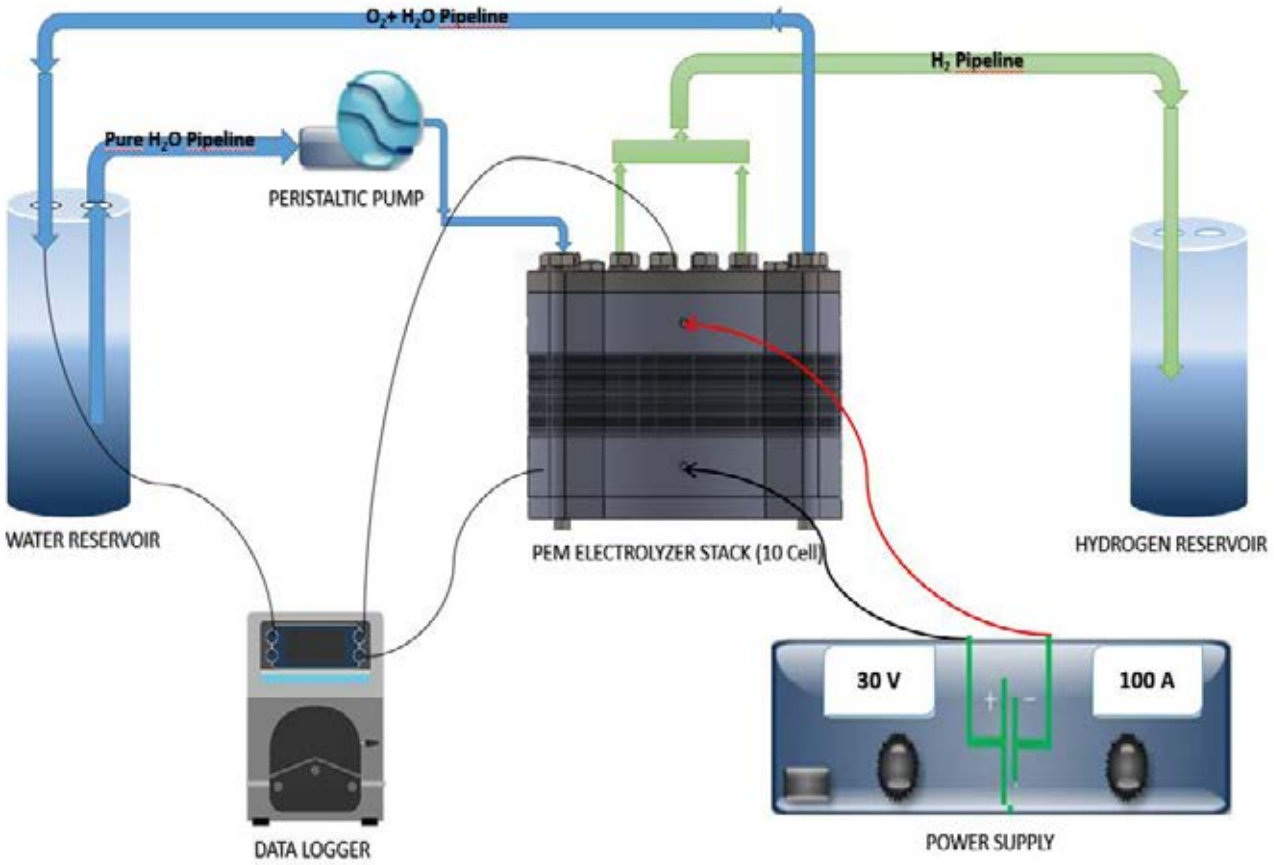

Fig. 1. Schematic representation of the experimental setup

When testing the performance of the stack, it is crucial to measure the temperature correctly. Temperature data were recorded using three thermocouples, each connected to a data logger. Two thermocouples were placed at the top of the stack and at the bottom of the end plates, while another thermocouple was placed at the water and oxygen outlets. Therefore, temperature changes in the system were checked with measurements at various points simultaneously.

2.2. Performance Measurement

Voltage losses, polarization curves, and electrochemical surface area (ECSA) measurements were conducted to assess performance degradation. The degradation rate was quantified using the following equation**:**

$$\text{Degradation rate}(\%) = \frac{V_{initial}_V_{final}}{V_{initial}}\ x\ 100 \quad (1)$$

where represents the initial stack voltage, and is the voltage measured after long-term inactivity.

3. RESULTS AND DISCUSSION

Voltage loss and polarization curve measurements were performed to assess performance degradation. The data taken from the same PEM electrolyzer at the initial condition and at the final condition are shown in Figure 2. The initial condition represents the performance of the electrolyzer 15 years ago, while the final condition reflects its performance after being operated intermittently and then idle for approximately 10 years prior to testing. Each graph shows the tests performed separately at 30, 40, 50 and 60 degrees, respectively.

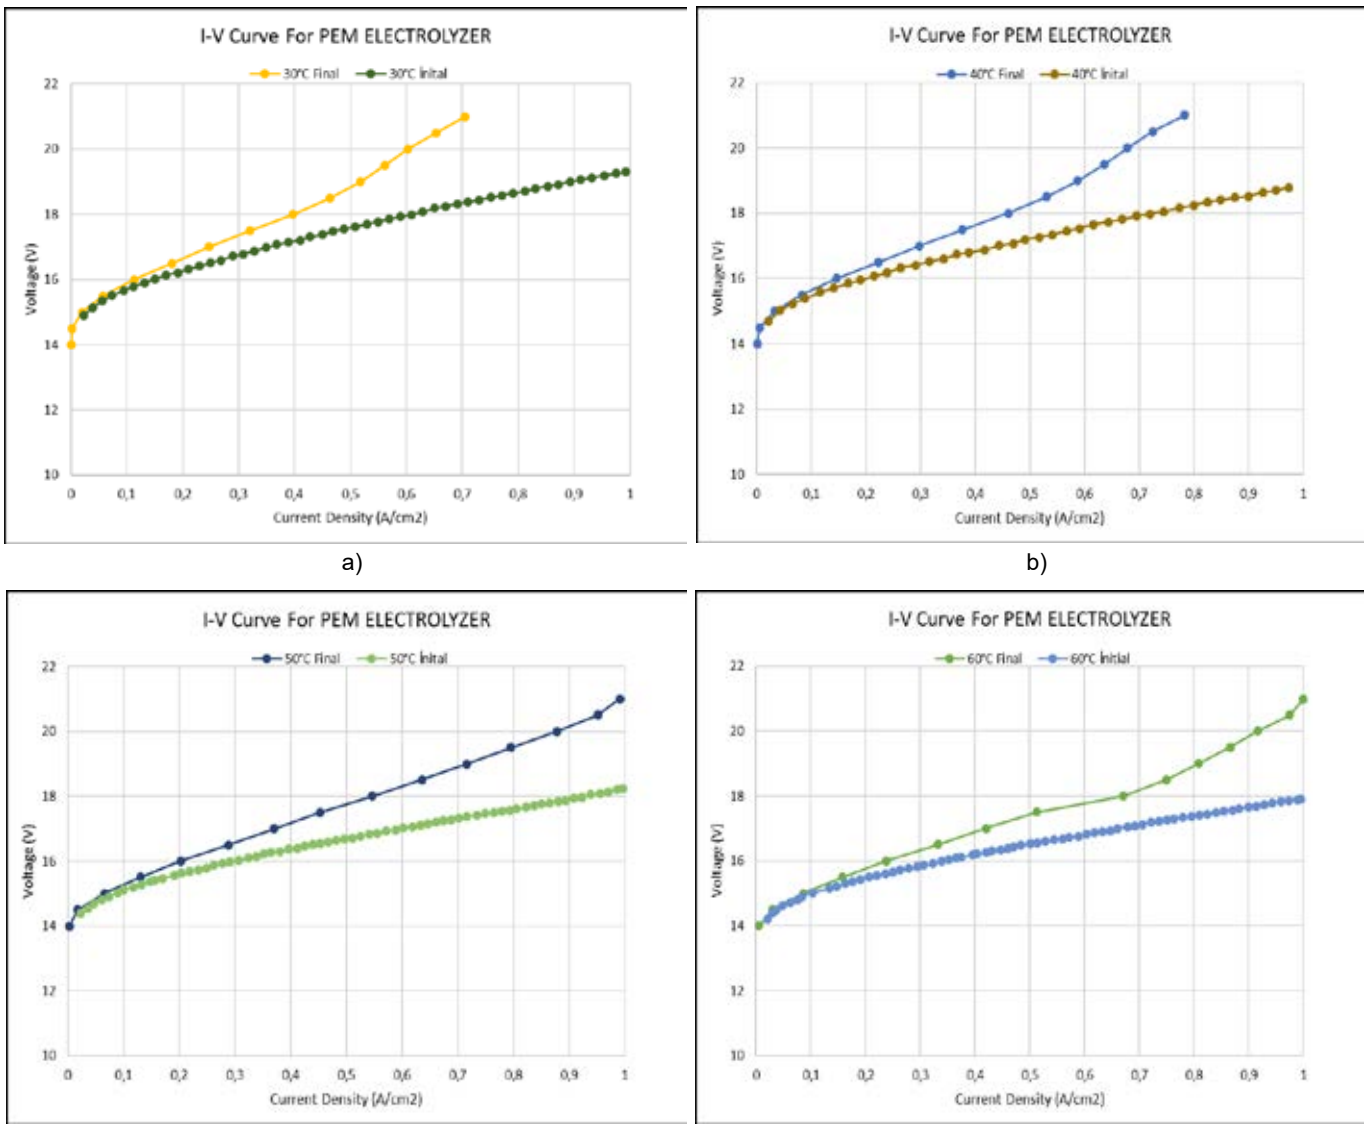

Fig. 2. Graphical representation of the degradation of the pem electrolyzer after 15 years at different temperatures a) 30°C b) 40°C c) 50°C d) 60°C

In all graphs, the final I-V curves show significantly higher voltage values at the same current densities compared to the initial curves, indicating increased overpotential and that the system requires more energy to achieve the same hydrogen production rate. This suggests membrane degradation, catalyst layer degradation, or increased internal resistance due to aging effects such as electrode delamination, membrane thinning, or catalyst sintering.

The experimental results revealed a notable increase in voltage losses and a decline in current density over time. A 15% decrease in overall efficiency was observed after ten years of inactivity. The performance measurements indicated an increase in membrane resistance, suggesting ionic conductivity deterioration. Figure 2 presents the polarization curve shifts, highlighting performance decline. Material degradation, particularly catalyst sintering and membrane thinning,

contributed to efficiency losses. The findings align with previous studies on PEM electrolyzer aging mechanisms [7,8]. The polarization curves demonstrated a significant shift towards higher voltage requirements at equivalent current densities. This shift is indicative of increased overpotential, which can be attributed to both catalyst deactivation and membrane resistance increase. The initial operational voltage at 1 A/cm² was recorded at approximately 1.8 V, whereas after ten years, it rose to nearly 2.1 V, marking a 16.7% increase in voltage loss. This trend is consistent with previous findings in literature, where long-term exposure to fluctuating operational conditions accelerates catalyst sintering and ionomer degradation [9].

4. CONCLUSIONS

This study investigates the long-term degradation effects in a PEM electrolyzer that remained idle for approximately 15 years while being continuously exposed to a water-filled environment. The prolonged exposure to moisture contributed to additional degradation mechanisms, including membrane hydrolysis, electrode delamination, and catalyst layer deterioration. These effects were reflected in the significant performance losses observed during testing.

The experimental results revealed a notable increase in voltage losses and a decline in current density over time. A 15% decrease in overall efficiency was observed, with the operational voltage at 1 A/cm² increasing from approximately 1.8 V to nearly 2.1 V, marking a 16.7% increase in voltage loss. The polarization curves demonstrated a significant shift toward higher voltage requirements, indicative of increased overpotential, which can be attributed to catalyst deactivation and increased ohmic losses due to aging effects such as electrode delamination, membrane thinning, and catalyst sintering.

While higher operating temperatures enhance efficiency by improving reaction kinetics and ion conductivity, they also accelerate degradative processes such as membrane degradation and catalyst deactivation. The findings emphasize the necessity for periodic maintenance, proper storage conditions, and refurbishment strategies to extend the operational lifespan of PEM electrolyzers.

To further understand the observed degradation, future studies will focus on advanced material characterization techniques such as X-ray diffraction (XRD) and scanning electron microscopy (SEM). These analyses will be conducted on both electrode materials and porous flow plates to investigate structural and chemical changes, including catalyst degredation, membrane thinning, and porosity alterations. Additionally, alternative electrode materials, improved membrane compositions, and enhanced flow plate designs will be explored to mitigate performance losses. The insights gained from this study will contribute to the development of more durable and commercially viable PEM electrolyzers with extended operational lifetimes exceeding 50,000 hours.

ABSTRACT
Polymer Electrolyte Membrane Water Electrolysers (PEMWEs) efficiently produce high-purity, compressed hydrogen, with bipolar plate design playing a key role in performance. This study proposes a novel flow channel inspired by vine leaf patterns from various plant species. The design, featuring a 13.85 cm² circular cross-section, is analyzed using COMSOL Multiphysics, integrating key physical and fabrication factors. Results show improved velocity uniformity, lower pressure drop, and enhanced mixture homogeneity compared to conventional serpentine models.

Keywords: bio-inspired, plant leaves, bipolar plates, PEM water electrolysis, flow channel design.

1. INTRODUCTION
The global shift toward clean energy has made hydrogen a key solution for decarbonization. Proton Exchange Membrane Water Electrolysis (PEMWE) is a promising technology for producing high-purity hydrogen due to its efficiency and compact design. However, high costs, especially for bipolar plates (BPPs), limit its widespread adoption [1,2].

This study introduces a novel bio-inspired flow-field design for BPPs, inspired by natural structures like leaf veins. These designs aim to improve fluid distribution, reduce pressure drops, and enhance water management. Preliminary results show significant improvements in performance compared to traditional flow fields, such as serpentine and parallel channels, paving the way for more efficient and cost-effective PEMWE systems [3,4].

2. METHODOLOGY
A 3D computational model of a PEMWE half-cell was developed in COMSOL Multiphysics shown in Fig.1. The model solved conservation equations across seven regions, including catalyst layers, gas diffusion layers, and membranes. Five bio-inspired and three traditional flow-field designs were analyzed. Assumptions included steady-state laminar flow, isothermal conditions, and negligible contact resistance. A mesh independence study ensured accuracy, and the model was validated against experimental polarization curve data [5].

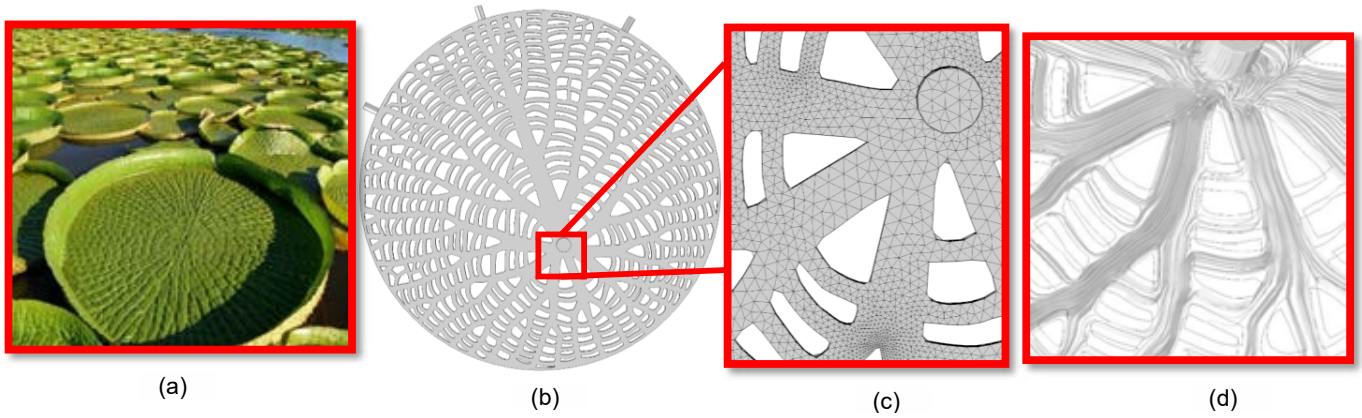

Fig. 1. Model process Victoria Amazonica Water Lily (L2V): (a) The real leaf selection (b) Design and extract the exact vein geometry (c) Mesh the model (d) Flow streamlines.

3. RESULTS AND DISCUSSION
The Victoria Amazonica Water Lily (L2V) model demonstrated superior performance compared to the serpentine model (SR8) across multiple metrics:

- Polarization Curve: The L2V model achieved lower voltages (1.9751–2.5173 V) at current densities ranging from 200 to 15,000 A/m², outperforming SR8.
- Pressure Drop: L2V exhibited a significantly lower pressure drop (8.05 Pa) compared to SR8, ensuring more efficient water management and uniform reactant distribution.
- Mixture Distribution: L2V showed better oxygen concentration and water mole fraction uniformity,

reducing reactant density inconsistencies and enhancing current density stability.

- Velocity Distribution: L2V achieved a more uniform velocity profile, improving water removal and reactant delivery compared to SR8.

These results highlight the L2V model's potential to optimize PEMWE performance, surpassing traditional serpentine designs like SR8 shown in Fig.2.

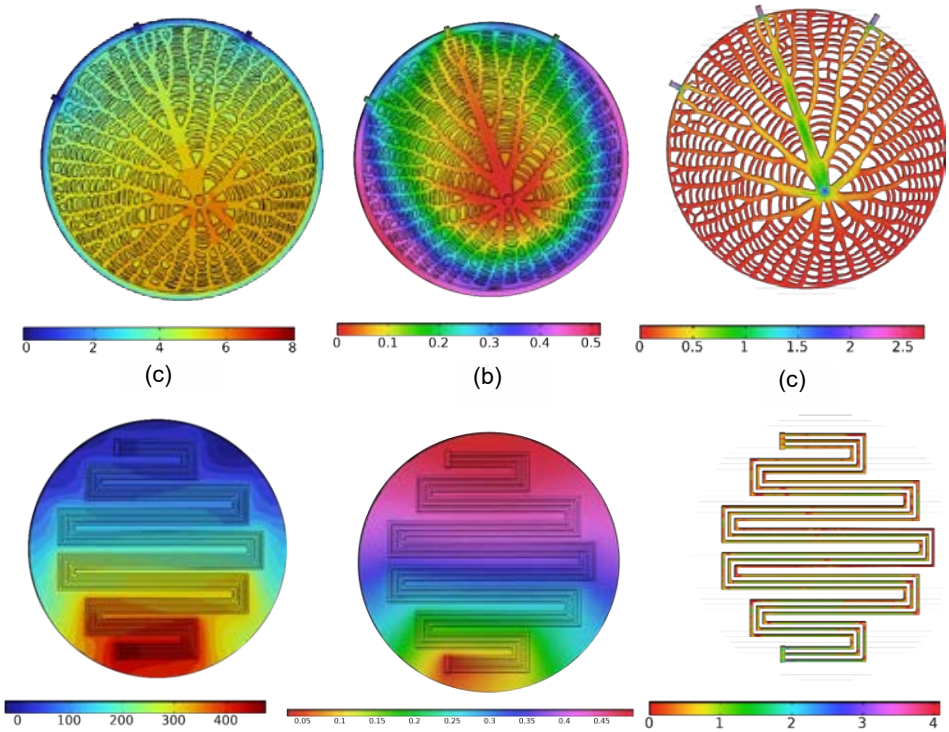

Fig. 2. Results Comparison Between the Victoria Amazonica Water Lily (L2V) and the Serpentine Model (SR8): (a) Pressure distribution (Pa) (b) Oxygen Mole Fraction distribution (c) Water Channels Velocity distribution (m/s)

4. CONCLUSION

This study demonstrates the remarkable advantages of bio-inspired designs in PEMWE performance, with the L2V Victoria Amazonica Water Lily model emerging as the most efficient design. At a current density of 15,000 A/m², L2V achieved up to 5%, 4.1%, and 4% lower voltage than parallel, serpentine, and point flow channels, respectively. It also exhibited the lowest pressure drop (8.05 Pa), outperforming traditional models by 97.9%, 98.6%, and 79.3%.
Additionally, L2V provided the most uniform water and velocity distributions, with homogeneity improvements of 40.8%, 40.1%, and 33.6% compared to parallel, serpentine, and point flow channels. Optimization studies revealed that increased exchange current density and active specific surface area, along with lower operating temperatures, enhanced polarization curve performance without significantly impacting pressure drop or velocity.
These results underline the superiority of bio-inspired designs, particularly L2V, in achieving efficient, durable, and sustainable PEMWE systems.

ABSTRACT
Zero-dimensional modeling is a practical approach for analyzing the internal processes of Direct Methanol Fuel Cells (DMFC). Mathematical models play a crucial role in efficiently assessing fuel cell system performance. In this study, the Engineering Equation Solver (EES) was utilized to evaluate key performance parameters, including flow rate, voltage, and current density, based on the semi-empirical equations developed by Meyers and Newman. The results indicate that under ideal conditions, the maximum power density is approximately 0.166 W/cm², achieved at a voltage of 0.44 V and a current density of 0.38 A/cm². The effect of varying current density on system efficiency was examined, and the methanol flow rate was determined as 0.753 mL/min, calculated using both the higher heating value (HHV) of methanol and Faraday's law. The findings suggest that optimizing operating conditions and design parameters can significantly enhance the efficiency and performance of DMFC systems.
Keywords: Direct methanol fuel cell, semi-empirical modeling, mathematical analysis, power density, methanol flow rate.

1. INTRODUCTION
Direct Methanol Fuel Cells (DMFC) have attracted significant interest in recent years as a promising technology for various small-scale energy system applications, such as portable electronic devices, with their design combining small size and high efficiency. Particularly, the ease of transportability of methanol fuel in liquid form contributes to wider application areas. The performance of Direct Methanol Fuel Cells is affected by certain electrochemical events and various processes occurring within the cell. To better understand and improve this situation, simplified modeling approaches, such as zero-dimensional semi-empirical formulas, serve as important tools. By using these models, the need for extensive experimental data or computationally intensive simulations is reduced. In this study, the zero-dimensional modeling of a direct methanol fuel cell system was performed using the EES (Engineering Equation Solver) program. This modeling approach is a significant method used to estimate the performance and losses of fuel cells. During the modeling process, the semi-empirical equations developed by Meyers and Newman [1] were utilized. These formulas are simplified equations validated with experimental data and aligned with electrochemical principles. With this approach, dimensional details within the cell are neglected. By using semi-empirical formulas instead of complex computational methods, fast and practical analysis results are obtained. This reduces the need for costly and time-consuming experimental studies. In this context, existing studies on the zero-dimensional modeling of DMFC systems have been reviewed. Ince et al. (2019) developed a thermodynamic model for the system components of an active direct methanol fuel cell system. The modeling equations were implemented using the Engineering Equation Solver (EES) program. This model provides the heat and work transfer between the system components and their surroundings, as well as the electrical efficiency of the system. They investigated the effects of methanol concentration (between 0.5 to 1.25 M) and air flow rate (between 20 to 30 mL cm−2 min−1) on the net power output, electrical efficiency, and condenser outlet temperature of the system. As a result of their findings, they identified the maximum value for the system's electrical efficiency [2]. Chiu et al. (2011) stated that theoretical approaches in a direct methanol fuel cell (DMFC) are complex and less practical, while experimental processes are time-consuming. As a result, they proposed a semi-empirical model incorporating many parameters to evaluate DMFC performance. In the proposed model, the power density and efficiency of the DMFC were studied in relation to parameters such as operating temperature, fuel concentration, and current density. Performance indices and operating variables were presented in a diagram. They concluded that a semi-empirical model is generally necessary for practical scenarios [3]. Yang et al. (2011) modeled the relationships between operating parameters and performance measurements for a single-stack direct methanol fuel cell (DMFC). To consider both modeling accuracy and simplicity, a semi-empirical model was developed in this study by integrating theoretical and approximate models. As a result of error analyses, they concluded that the semi-empirical model is effective for predicting the performance of DMFC. Furthermore, the potential applications of the semi-empirical model in the optimal control of fuel cell systems were discussed [4].

2. MATERIALS AND METHODS
This section elaborates on the steps involved in the zero-dimensional modeling of the DMFC system in detail. The semi-empirical models used provide a foundation for analyzing the system's behavior under different conditions. Computational methods for the anode, cathode, and overall cell structure of the DMFC system, as well as the relationships between current density, voltage, and power, and flow rate calculations, are presented below.

2.1. Anode and Cathode Modeling

The anode and cathode behaviors in the DMFC system were modeled using Meyers and Newman's semi-empirical equations. In this context, the equations defining the current-voltage (I-V) characteristics through theoretical modeling are provided below.

Anode:

The current density (i) is calculated as:

$$i = \frac{i_* C_M \, a \exp\,(2.303\eta/b)}{C_M + K \, a \exp\,(2.303\eta/b)} \tag{1}$$

The anode overpotential (η_{an}) is expressed as:

$$\eta_{an} = f_1 + f_2 \ln(i) + \, f_3 \exp\left(\frac{f_4}{C_M}\right) \tag{2}$$

Cathode:

$$i_{perm} = m_1 + m_2 \tag{3}$$

$$m_1 = 4.65 \, x \, 10^{-2} \frac{d}{d_{ref}} \frac{c}{1M} \exp\big(0.01329\,(T - 273.15K)\big) \frac{A}{cm^2} \tag{4}$$

$$m_2 = -0.4 + 0.27 \frac{n_{drag}}{n_{drag}^{ref}} \frac{c}{c_{ref}} \tag{5}$$

The cathode overpotential (η_C) is given by:

$$\eta_C = \frac{RT}{aF} \ln\left[\frac{i}{l_{cat} i_*}\left(\frac{c_{O2,ref}{}^{\gamma}}{c_{o2}{}^{\gamma}}\right)\right] + k(i) i_{perm} \tag{6}$$

Cell potential:

The total cell voltage, E_0 (open circuit voltage), is calculated using Eq. (7) and Eq. (8):

$$E = E_0 - \eta_C - \eta_{ohm} \tag{7}$$

Ohmic losses (η_{ohm}) are defined as:

$$\eta_{ohm} = \frac{l_{mem}}{\sigma_{mem}} \, i \tag{8}$$

Using these equations with the EES application, fundamental parameters such as flow rate, voltage, and current density were calculated to analyze the performance of the direct methanol fuel cell system.

2.2. Current Density and Voltage Relationship

Graphs showing the relationship between current density (A/cm²) and voltage (V) for different operating temperatures were created using EES. These are shown in Figure 1. It can be observed that as the current density increases, there is a change in the cell voltage. Thus, as current density increases, the effect of polarization losses in the system can be discussed.

2.3. Power Output

In the power density graphs, the maximum power density and the current density at which this value is obtained were determined. These are shown in Figure 2. This value represents the optimal performance point of the system. Beyond this point, a decrease in power density was observed due to potential losses on the electrodes and reactant limitations.

2.4. Current Density, Voltage, and Power Relationship

The I-V (current-voltage) and P (power density) curves of the DMFC are key parameters in understanding the overall performance of the system. The intersection point of the I-V and P curves determines the maximum power point. This is shown in Figure 3. This point represents the optimal performance of the DMFC in terms of efficiency and energy output. It is the point at which the balance between reactant consumption, energy production, and losses is best achieved.

2.5. Flow Rate Calculation

2.5.1. Methanol Flow Rate Calculation with Faraday's Law

Methanol flow is calculated by taking Faraday's law into consideration:

Basic Parameters:

- Current density: $0.38\ A/cm^2$
- Active area: Approx. $50\ cm^2$
- Number of cells: 10

As a result of the calculations, the methanol flow rate for the 3% methanol mixture was found to be 0.796 mL/min. Considering the 97% water fraction and a 1.5 stoichiometric safety factor, the total flow rate was calculated to be 39.782 mL/min. Yücel et al. (2015) developed a direct methanol fuel cell charger unit for 40W military wireless. The methanol flow rate for the developed fuel cell charger unit was calculated to be 40 mL/min [5].

2.5.2. Methanol Flow Rate Calculation with Power Balance and Efficiency

In this method, methanol flow is calculated by taking into account the total power and energy efficiency of the fuel cell.

Basic Parameters:

- Power per cell: $P = i\,V$ (i: current density, V: cell voltage)
- Total power: $\dot{W}_{for\ 10cell}$ (for 10 cells)
- Energy efficiency (η): %42
- High heating value of methanol: $HHV_{\text{methanol}} = 5540\ Wh/kg$
- Density of methanol: $0.792\ g/mL$

As a result of the calculation through EES, the methanol flow rate was found to be 0.753 mL/min. The lack of significant differences between the results from the two methods indicates that the calculations are generally consistent.

3. RESULTS AND DISCUSSION

The performance of the Direct Methanol Fuel Cell (DMFC) system was analyzed using a zero-dimensional modeling approach. The Engineering Equation Solver (EES) was employed to evaluate the relationships between current density, voltage, and power density under varying operating conditions.

Current Density and Voltage Relationship

The relationship between current density and cell voltage was examined for different operating temperatures, as illustrated in Fig. 1. The results indicate that voltage decreases non-linearly as current density increases, which is a typical behavior in fuel cells due to polarization losses. Higher operating temperatures generally improve reaction kinetics and reduce activation losses, leading to an increase in cell voltage. However, excessive temperatures may result in performance degradation due to membrane dehydration and increased methanol crossover. This trade-off highlights the importance of determining an optimal temperature range to ensure efficient fuel cell operation.

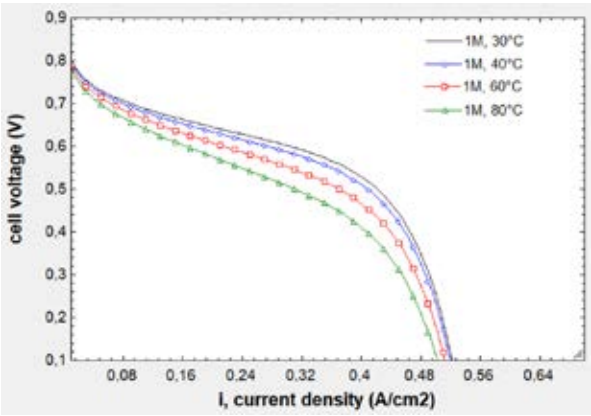

Fig. 1. Current density (A/cm^2) and voltage (V) graph for different operating temperatures

Power Density and Maximum Power Point

The power density curve, shown in Fig. 2, was analyzed to determine the maximum power output conditions. The findings reveal that the maximum power density of 0.166 W/cm² is achieved at a current density of 0.38 A/cm². Beyond this point, power density decreases due to increased ohmic and mass transport losses, which limit the effective utilization of reactants.

The intersection of the I-V and power density (P) curves represents the **maximum power point**, which is crucial for optimizing DMFC performance. Operating the fuel cell at or near this point ensures a balanced trade-off between power output and efficiency. These results underscore the necessity of precise control over fuel cell operating parameters to maximize energy efficiency while minimizing performance losses.

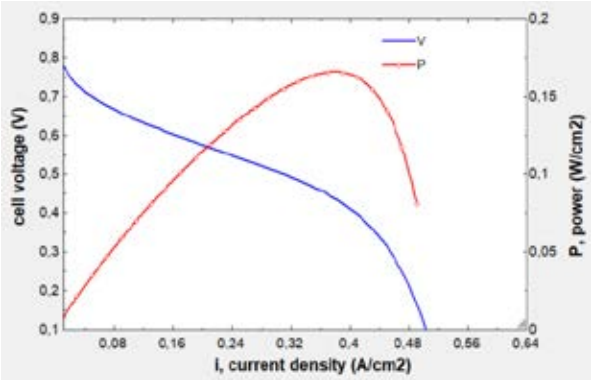

Fig. 2. Current density (A/cm²), voltage (V), and power density (W/cm²) graph

The study demonstrates that semi-empirical modeling is a reliable method for evaluating the performance of DMFCs. The observed trends in Fig. 1 and Fig. 2 confirm that optimizing key parameters such as current density, methanol concentration, and operating temperature is essential for enhancing overall system efficiency.
Future research can focus on refining these models to incorporate additional electrochemical and thermal effects. Additionally, integrating real-time monitoring and control strategies could further enhance the stability and operational longevity of DMFCs, making them more viable for portable energy applications.

4. CONCLUSIONS

This study presents a performance analysis of Direct Methanol Fuel Cells (DMFC) using a zero-dimensional modeling approach based on Meyers and Newman's semi-empirical equations. The results demonstrate that the system reaches its optimal power density of 0.166 W/cm² at a current density of 0.38 A/cm². The analysis of I-V and power density curves indicates that this operating point provides the best balance between energy output and efficiency, with an overall system efficiency of approximately 42%. The methanol flow rate was calculated as 0.796 mL/min using Faraday's law and 0.753 mL/min through energy balance equations, showing consistency between different estimation methods. These findings highlight the effectiveness of zero-dimensional modeling in evaluating DMFC performance, providing valuable insights for optimizing fuel cell operation in portable applications.

ABSTRACT

This study aims to develop, simulate, and validate different microchannel designs for a micro-sized direct methanol fuel cell (μ-DMFC). Inspired by the structure of mitochondria, novel membrane channels were designed for fuel cell applications. Mitochondria are organelles responsible for energy production within the cell and their structure is curved to increase surface area. The primary goal is to examine how variations in microchannel geometry influence the efficiency and performance of μ-DMFCs. Five different models were developed and simulated to analyze flow behavior and performance characteristics. After the design and simulation phase, microchannels were fabricated using the polydimethylsiloxane (PDMS) method, a widely used technique for microscale applications. Validation is crucial to ensure the reliability of the simulation tools and the accuracy of the predicted results. The outcomes of this study provide significant insights into the impact of microchannel design on μ-DMFC performance. This research highlights the role of advanced manufacturing techniques and optimized channel designs in enhancing micro fuel cell technology. In the simulations, it was observed that the 4th design, inspired by mitochondria, created a 42.76% better power density compared to the classical serpentine design. Considering that this structure provides efficient material transport, a similar principle was adopted in the micro channel design of the micro fuel cell in the study. The aim is to increase cell performance by optimizing fuel and oxidant flows.

Keywords: Micro Direct Methanol Fuel Cell (μ-DMFC), mitochondria-inspired design, microchannel optimization, polydimethylsiloxane (PDMS) fabrication, portable energy systems

1. INTRODUCTION

Among the many green energy sources, fuel cells are one of the most essential technologies that need to be developed worldwide. Fuel cells and hydrogen energy are low-cost carbon-free energy sources. A fuel cell is an electrochemical system that uses two redox processes to transform the chemical energy of an oxidizing agent (usually oxygen) and fuel (usually hydrogen) into electrical energy. In contrast to most batteries, which typically derive their chemical energy from materials already present, fuel cells require a constant supply of fuel and oxygen, typically air, to maintain the chemical reaction. When fuel and oxygen are available, fuel cells constantly generate power. Fuel cells are renewable energy sources with low carbon emissions that do not require a specific place or location for production. The development of direct methanol fuel cells (DMFC) is crucial for the production of green energy resources. DMFC is a type of polymer electrolyte membrane fuel cell that can operate at room temperature. High energy conversion efficiency, low weight, safe fuel storage, and easy refueling are only a few advantages of DMFC. Methanol has additional benefits over hydrogen, including easy handling, storage, and transportation methods, similar to gasoline. In the development of future sustainable energy conversion devices, DMFC has demonstrated superior performance in comparison to traditional internal combustion engines and batteries [1-3]. Fuel-cell technologies are used globally in various applications. Stationary power systems, transportation, space exploration, military applications, radar, communications, portable devices, submarines, fuel cars, and other fields are applications of hydrogen technology and fuel cells [4-7]. Various fuel-cell studies have been performed by different researchers. Ke *et al*. investigated recent developments in noncarbon support materials for advanced and direct methanol fuel cell development [5]. These materials are notable because of their synergistic mechanisms that can prevent Pt poisoning during the reaction process. The use of non-carbon material supports has advantages, such as increased chemical stability, corrosion resistance, and enhanced electrical conductivity. Massing *et al*. developed a novel heating system to accelerate the start-up timing in microfluidic direct methanol fuel cells [6]. The indium tin oxide heating layer helps the cell reach the desired temperature within 25 s, which is an important development of fuel cells in this work. Shen *et al*. developed a monolithic microfluidic proton exchange membrane (PEM) fuel cell by integrating a narrow strip of Nafion into the polydimethyl siloxane (PDMS) structure [2]. The PDMS/Nafion assembly was sandwiched between a glass chip and catalyst-coated Au electrodes to achieve rapid prototyping and sealed fuel cells. The effectiveness of various oxidant solutions and methanol fuel was studied, and the effect of the flow rate on the cell performance was analyzed. This work makes a significant contribution to research on the design and performance of microfluidic PEM fuel cells.

However, most studies did not consider and address the significant impacts and limitations of the technology arising from the design and models of different types of fuel cells. Therefore, in this study, we focused on the design and simulation of different cell models for a micro-sized direct methanol fuel cell (μ-DMFC), each containing different microchannel configurations. Our model was developed based on an impressive mitochondrial cell structure. Mitochondria have different shapes, sizes, and dynamics according to the cell type, energy status, and environment. Several mitochondrial functions are linked to their morphology, which is maintained by fission and fusion. Mitochondria are central to cellular metabolism [7, 8]. For this work, we chose a general structure of mitochondrial organelles. The primary objective is to investigate how changes in the microchannel geometry affect the performance and efficiency of μ-DMFCs. To increase the fuel delivery and cell efficiency, five unique cell models were initially developed, focusing on microchannel layout optimization. Numerical simulations were conducted to predict the flow behavior and performance features of each design. Following the design and simulation stage, the polydimethylsiloxane (PDMS) method, which is a technique known for its sensitivity and adaptability for microscale applications, is used to create microchannels. The fabricated microchannels were then integrated into μ-DMFCs, and a series of performance tests were performed to measure key parameters, such as power output, fuel usage efficiency, and overall cell stability. To verify the models and identify any differences, the simulation data and experimental results were compared. To ensure the accuracy of the anticipated results and reliability of the simulation tools, this verification process is essential. The results of this study provide important information on how microchannel design improves μ-DMFC performance. This study emphasizes the contributions of creative manufacturing techniques and optimized cell channel designs to the field of MFC technology. Ultimately, this effort seeks to advance the development of more effective and efficient μ-DMFCs, while opening the way for their wider use in small-scale and portable generation systems.

2. MODEL DEVELOPMENT

The aim of this model development is to identify the effects of channel design and shape on fuel cell activity with different numbers of inlets and outlets of the fuel cell system. We are inspired by the nature of mitochondrial organelles, and we plan to design a μ-DMFC channel based on the structure of mitochondria (Fig. 1A). A direct methanol fuel cell performs an electrochemical reaction with a mixture of methanol and water fed directly by the anode and oxygen fed by the cathode. The working principle of the electrochemical system based on our model is shown in Fig. 1B. It is known that the membrane structure of mitochondrial organelles provides the energy needs of the cell. Single-, double-, and multiple-channel designs can be created to develop a channel structure that is similar to that of the mitochondrial membrane. Considering the function of the mitochondria, we designed a model based on the structure of this organelle. The general membrane structure was drawn as a channel structure for application in solid works. Therefore, we developed five different designs in two categories (one inlet/outlet, two inlets/outlets, and four inlet/outlet channels). A schematic illustration of the different designs for the two categories is shown in Fig. 2. Design 2, 3, and 4 have two inlets and outlets, whereas Design-5 has four inlets and outlets.

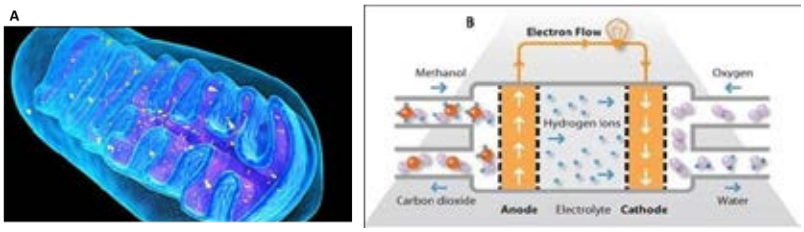

Fig. 1. General view of mitochondria cell structure (A) Credit: science photo library. Working principle of DMFC (B).

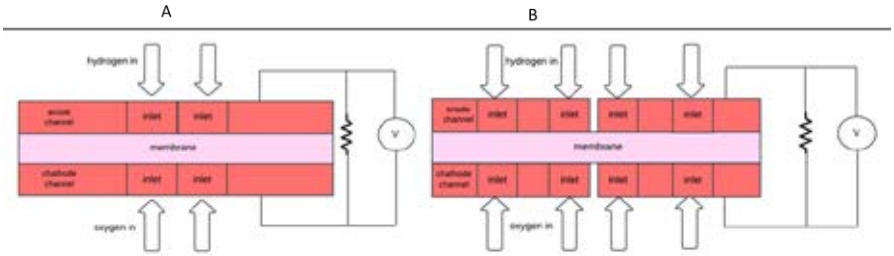

Fig. 2. Schematic illustration for different designs. A. The schematic represents the designs with two inlets (Design 2, 3 & 4). B. The schematic represents the designs with two inlets (Design 5).

3. RESULT AND DISCUSSION

The fuel cell channel designs were developed on a 5 mm × 5 mm square plate, resulting in a total working area of 25 mm^2. The first design includes a commonly used serpentine channel design. The purpose of designing a serpentine channel is to observe the efficiency of new designs compared with a classic design with the same active area of a fuel cell, such as Nafion. The channel bend numbers and bend lines differ from each other. In the designs, the maximum channel length that can fit into the same active area of the fuel cell is the priority of this study. The fuel cells were established based on each design. All schematic channel designs are shown in Fig. 3A. We have showed the demonstration of fuel cells for all designs. However, in this paper, we only showed for design 5 as shown in Fig. 3B.

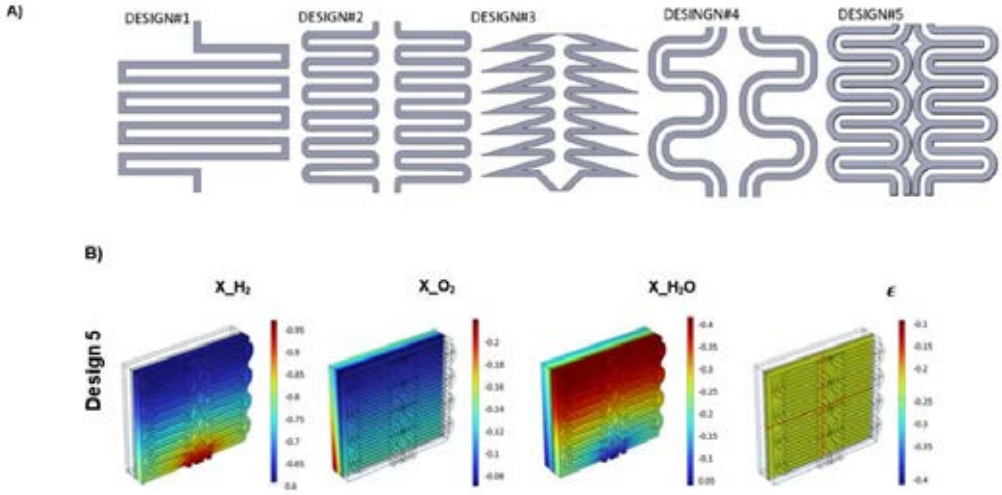

Fig. 3. A) Schematic showing the individual designs (Design 1, 2, 3, 4 & 5) B) Demonstrations of the fuel cell for Design-2 with mole fractions of H_2, O_2 & H_2O, respectively including the electric potential needed (ϵ).

Following the designed channel, it is possible to establish the fuel cell system using each five type channels by incorporating other component such as gas/sample inlet and outlet, power supply, reaction chambers and other constituents of the fuel cell set up. The thicknesses of the gas diffusion layers and reaction layers have set by considering and refereeing various studies and literatures. Each design channel has its specific area and perimeter as shown in Table 1.

Table 1. Perimeter and area dimensions of channel designs

Parameter	Channel				
	Design 1	Design 2	Design 3	Design 4	Design 5
Area (mm^2)	8.69	11.14	12.10	8.20	9.64
Perimeter (mm)	86.58	115.04	123.14	83.48	96.44

Our model development is carried out based on COMSOL 6.1 simulation program. It is known that the COMSOL software is used worldwide as an indispensable tool for various computer simulations for research and development and for multiple types of learning related to model and design development. It is a general-purpose simulation software package for modeling designs, devices, and processes in all fields of engineering, manufacturing, and scientific research. This study uses a hydrogen fuel cell (methanol oxidation) module and free and porous media to analyze the performance of fuel cells with different channel designs. For the design, channels and layers we have done as best as possible in a way suitable for simulation. The fuel cell designs will be simulated in two different types i.e. PEM and DMFC. The designed model channel setup includes H_2, O_2, H_2O mole fractions and electric potential analysis. This model is planned to observe the distribution of H_2, O_2, and H_2O in the cell and the electric potential distribution. The module created in the COMSOL simulation program was run and simulation results were obtained for the 5 fuel cell designs indicated in Fig. C and D. Results are recorded in the context of the values of the applied potential, mole fractions of H_2, O_2 and water. When the analyses are examined, channel designs must have a certain channel area to produce voltage. Although there is 0.96 mm^2 between Design-2 and Design-3, the power density in Design-3 is 19.91% higher than the power density in Design-2. Although the area of Design-2's channel is higher than the area of Design-4 and Design-5, high current is generated using Design-4 and Design-5 fuel cells. Design-3 has the highest channel area in which it generates the highest electricity. However, increasing the channel area does not necessarily increase the energy produced. Using each design, the simulation of voltage versus current density, power versus current density and power versus voltage is shown in Fig.4. When the simulation analysis is carried out, channel designs must have a certain channel area in order to produce

voltage. Although Design-1 has 0.49 mm^2 more area than Design-4, the fuel cell using Design-4 produced a power density of 17.62 mW/m^2 more than the fuel cell using Design-1. Although the channel area of Design-2 is more than the channel area of Design-4 and Design-5, the fuel cell used in Design-4 and Design-5 produced more electricity. The graph shows that the amount of electricity produced by the fuel cell depends on the channel design and shape.

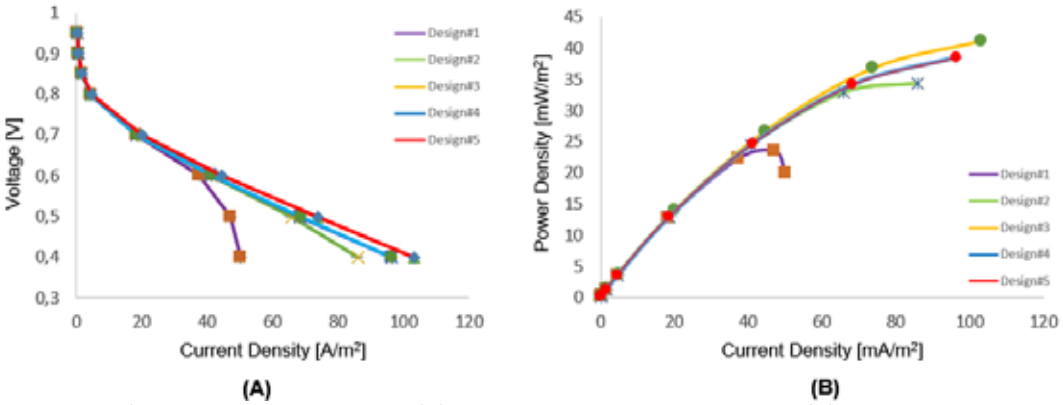

Fig. 4. Simulation results of voltage vs. current density (A), power density vs. current density (B) and power density vs. voltage using each design channel (Desing-1 to Design-5).

4. CONCLUSION

The development of single and multiple inlet/outlet channel designs demonstrated a significant impact on micro fuel cell performance. Among the channels of five designs 1, 2, 3, 4, and 5 were obtained to be suitable for fuel cell applications, with channel of Design-3 yielding the best power. To enhance manufacturability and ensure ease of assembly, modifications were made for the inlet and outlet configurations of channel of Design-1. Additionally, the complexity of channel of Design-5's structure was simplified to improve production feasibility. Future studies will focus on analyzing DMFCs with different channel designs and comparing their performance with PEM fuel cells. Inspired by the natural structure of mitochondria, this research contributes to the development of new μ-DMFC models with improved efficiency. These advancements aim to optimize fuel cell performance for portable and small-scale energy applications, paving the way for more practical and effective designs in the future. In the simulations, current density and power density values for five different designs are measured at eight different voltage levels: 0.95V, 0.90V, 0.85V, 0.80V, 0.70V, 0.60V, 0.50V and 0.40V. The highest current density for Design-1 was determined as 50.03 mA/m² at 0.4V, while 85.94 mA/m², 103.05 mA/m² and 96.28 mA/m² values were obtained for Design-3, Design-4 and Design-5 at the same voltage, respectively. The highest current density of Design-2 was measured as 96.31 mA/m² at 0.4V. In terms of power density, the highest value of Design-1 was recorded as 34.38 mW/m² at 0.5V; while for Design-2, Design-3, Design-4 and Design-5, the values were found as 41.22 mW/m², 38.51 mW/m², 38.52 mW/m² and 38.51 mW/m² at 0.4V, respectively. According to the simulation results, the best performance in terms of both current density and power density was obtained in Design-3.

ACKNOWLEDGEMENT

This research was funded by TÜBİTAK under the 2209-A Program (Project No: 1919B012323797). The authors sincerely thank TÜBİTAK for its support.

ABSTRACT
Hydrogen can be a key player in the global transition to cleaner energy, offering a sustainable and versatile solution to reduce carbon emissions across various sectors such as transportation, industry, and power generation. However, the development of the hydrogen market differs widely across countries and regions, shaped by the energy structure, resources, and goals of the countires. This study aims to compare the hydrogen market developments in China, Europe, and the USA by exploring the differences in national targets, regulatory frameworks and support mechanisms, and project pipelines. The findings of the study suggest that in Europe, hydrogen market development is slow but steady, with firm steps taken to ensure long-term growth and sustainability. In contrast, in China developments occur at a rapid pace, positioning the country as a frontrunner in the hydrogen market. Meanwhile, in the USA, the Inflation Reduction Act was initially seen as a game changer, and expected to have a significant positive impact on hydrogen market development. However, following the recent elections and the transition to a new administration, the outlook for hydrogen market development in the USA has become uncertain since the implementation of key acts lingers in a state of ambiguity.

Keywords: Clean hydrogen market, Regional analysis, China, Europe, the USA

1. INTRODUCTION

Clean hydrogen is seen as a key element in achieving the energy system transition. As countries all over the world have formulated emission reduction targets to mitigate climate change, viable and cost-effective decarbonization pathways are needed to support these strategies. Produced via zero or low carbon methods, clean hydrogen offers cross-sectoral opportunities to cut the carbon footprint. With more than 99% of current hydrogen production based on high emission production methods, a transition to clean hydrogen has the potential to decarbonize both existing applications, e.g. in industry and refineries, as well as new applications such as aviation, shipping or energy generation and storage [1].
While still an emerging market, the clean hydrogen industry is gaining traction. Based on project announcements, clean hydrogen production can reach 48 Mt p.a. by 2030. As of 2024, USD 75 billion have been invested in clean hydrogen projects in committed stages, the amount having almost doubled within a year [2]. However, several obstacles are hindering faster market development. To close the cost gap, stimulate demand and production, and reduce regulatory uncertainty, action is necessary. Against this background, hydrogen roadmaps have been formulated worldwide, highlighting different goals and strategies and providing insights into intended market-building efforts. Additionally, several countries and regions have started implementing policies and support mechanisms tailored to their individual hydrogen strategies. Thus, the clean hydrogen industry is currently characterized by high dynamics and regional disparities, and therefore warrants careful analysis.This paper provides an overview of recent developments in three frontrunners of the industry, China, Europa and the USA. By reviewing hydrogen strategies, implemented regulations, support mechanisms, and project pipelines, it offers an in-depth understanding of the hydrogen market status and outlook in these regions.

2. MATERIALS AND METHODS

This study provides an analysis of the hydrogen markets in China, the USA, and Europe by examining multiple sources to highlight the status of the key developments in these regions. First, national roadmaps and strategy documents from each region are reviewed to identify their main targets and strategic goals related to hydrogen market development. Next, the analysis explores the regulations and policies enacted by each region to support hydrogen market growth, focusing on the legal frameworks and incentives designed to meet their hydrogen targets. Additionally, news articles and media coverage are included to gather general insights into public reactions and industry sentiment surrounding the regulations and market developments.Finally, the study incorporates recent reports from the International Energy Agency (IEA) and the Hydrogen Council to assess the progress of hydrogen project pipelines in each region. This multi-source approach enables a comprehensive understanding of the evolving hydrogen landscape in China, the USA, and Europe.

3. REGIONAL ANALYSIS

The national hydrogen roadmaps and strategies for hydrogen market development differ significantly across countries and regions, primarily due to differences in their energy structures, resource availability, and future energy needs. As a result, each region sets distinct goals for hydrogen adoption, targeting various sectors and transition strategies. To meet these strategic goals, regulations and policies focus on different priorities, such as creating demand, mitigating investment risks, supporting domestic manufacturing of hydrogen technologies, and encouraging innovation and research. Additionally, the support mechanisms utilized, such as grants, competitive bidding schemes, contracts for difference, and tax incentives, can vary significantly from one region to another [1]. These differences make direct

comparisons between regions challenging, but this study aims to provide a concise overview of the national strategies and regulatory frameworks in China, Europe, and the USA. Morevover, the examination of the hydrogen project pipeline in each region might offer insights into how these varying strategies and support mechanisms may influence the development of the market. The following sub-sections will explore each region's hydrogen market in more detail, focusing on national strategies, key regulatory drivers, and developments in the project pipeline.

3.1. China

The Medium- and Long-term Plan for the Development of the Hydrogen Energy Industry (2021-2035), published by China's National Development and Reform Commission in March 2022, outlines the strategic direction for the country's hydrogen energy sector through 2035. The document sets specific targets for 2025, including the deployment of 50,000 fuel cell electric vehicles (FCEVs) and the production of 0.1 to 0.2 million tons of green hydrogen annually. The supply strategy emphasizes not only green hydrogen but also the use of industrial by-product hydrogen, particularly in the short term, given its wider availability. However, the plan does not address the role of Carbon Capture, Utilization, and Storage (CCUS) technologies, leaving them out of the hydrogen development strategy [3]. Although the central government's targets may seem modest, the primary driving force in China comes from regional strategies. A range of provincial hydrogen development frameworks, each designed to align with local resources, capabilities, and specific requirements, supports the national plan. In some provinces, hydrogen development plans can be more ambitious than the national plan. For instance, Inner Mongolia alone plans to produce nearly 0.5 million tons of green hydrogen per year by 2025, a target that greatly exceeds the national goal of 0.1 to 0.2 million tons [4]. When the production goals of other provinces are summed up, the total hydrogen production target reaches up to 1.2 million tons annually, demonstrating the crucial role of regional initiatives in propelling China's hydrogen market development [1].

China's approach to foster the hydrogen market demonstrates collaborative characteristics between central and regional governments. The central government sets the main framework and serves as a role model by promoting technological advancements, research activities, strategic initiatives, and pilot projects. Additionally, it provides financial rewards to regional governments that achieve their targets. For example, USD 109 million was awarded for the first phase of FCEV pilot programs to provinces that met their goals [1]. Meanwhile, regional governments handle the implementation and management of specific targets, offering financial incentives and support mechanisms that are specifically tailored to the needs of the region, to drive local hydrogen market development. As an example, Inner Mongolia is a favorable location for green hydrogen production due to its abundant renewable energy sources, and the region provides subsidies to support production. In Ordos City, which is located in the province, green hydrogen production is supported with subsidies ranging from USD 0.28 to 0.57 per kilogram of hydrogen based on sales volume from 2022 to 2025. In Hebei province, where FCEVs are prioritized, both CAPEX subsidies of up to USD 280,000 for hydrogen refueling stations and OPEX subsidies of USD 2.8 per kilogram of hydrogen for stations selling hydrogen below USD 4.2 per kilogram are offered. In the Ningdong region, to boost the demand, companies utilizing green hydrogen receive subsidies of approximately USD 0.79 per kilogram of hydrogen over a three-year period [1],[4].

The division of responsibilities between regional and central governments in China appears to be effective, as the rapid pace of developments in the hydrogen market is unparalleled anywhere else in the world. Hydrogen production projects in China which have passed final investment decision (FID) and are expected to be operational by 2030, have reached 1.4 Mt p.a., accounting for 30% of the committed global capacity of 4.6 Mt p.a.. More than 95% of this production capacity is dedicated to renewable hydrogen. Moreover, China is leading in terms of installed electrolyzer capacity. As of May 2024, installed electroylzer capacity in China has reached 1150 MW, which accounts for 65% of the installed capacity worldwide. Additionally, the scale of projects in China is larger than in the rest of the world. For instance, the Ningxia Solar Hydrogen Project, with a 150 MW electrolyzer installation, and Sinopec's Kuqa plant, with a 260 MW installed electrolyzer capacity, set records for the largest hydrogen plants in 2021 and 2023, respectively [2]. These achievements position China as the frontrunner in the global hydrogen economy.

3.2. Europe

In July 2020, the European Commission published the hydrogen strategy for the European Union. The strategy's main focus was on green hydrogen, which is produced through water electrolysis powered by renewable energy sources. The strategy set an initial target of installing 6 GW of electrolyzer capacity in the EU by 2024 to produce 1 million tonnes (Mt) of green hydrogen. The next step in the strategy is to increase the installed electrolyzer capacity to 40 GW by 2030, with the goal of securing the production of 10 Mt of green hydrogen. Moreover, the strategy aims to support the installation of an additional 40 GW of electrolyzer capacity in the neighboring regions of the EU, showcasing the EU's ambition to lead the global hydrogen economy beyond its own borders [5]. EU member states also published their own hydrogen roadmaps in alignment with the EU strategy, further strengthening the coordinated efforts toward developing a hydrogen market in Europe.

In June 2023, to bring regulatory clarity to what counts as green hydrogen, the European Commission adopted two delegated acts. These acts introduced the term renewable fuel of non-biological origin (RFNBO), which refers to fuels produced from renewable electricity. The main objective of these acts was to define renewable hydrogen based on the calculation of life-cycle greenhouse gas emissions, and categorize it under the term RFNBO [6]. Following this, in October 2023, the European Union increased the share of renewable energy target to 42.5% by 2030 with Renewable Energy Directive III (RED III). To reach this target, the directive defines separate sub-targets for the use of RFNBOs in the

transport, industry, and building sectors. As an example, for the industry sector, the directive mandates that 42% of hydrogen used should come from RFNBOs by 2030 and 60% by 2035, excluding by-product hydrogen. There is a possibility to discount the contribution of RFNBOs in industry use by 20% if the expected overall contribution of the member state is realized and the share of hydrogen from fossil fuels does not exceed 23% in 2030 and 20% in 2035. Furthermore, the directive addresses the slow permitting process for renewable energy solutions (RES) projects. Member states should determine renewables acceleration areas that allow for simplified and faster processing of permits. According to the directive, the maximum allowed permit-granting time for RES projects should not exceed 12 months, with an exception for offshore wind projects, which can take two years due to their higher complexity [7]. In addition to regulations, several hydrogen projects receive subsidies as Important Projects of Common European Interest (IPCEIs) and benefit from investment aids. For example, the IPCEI projects Hy2Tech and Hy2Use, funded with a total of EUR 10.6 billion, include the development of electrolyzer and hydrogen infrastructure technologies, as well as the advancement of technologies for various end-use applications [8], [9].

Considering these regulations and subsidies, it can be stated that the European Union addresses both the production and consumption side of the hydrogen market with concrete targets and with very detailed specifications. However, this level of detail might be hindering project realisations. In terms of number of announced hydrogen projects and total investments, Europe leads the world with 617 projects and USD 199 billion, respectively. However, the actualization of projects has been relatively slow. As of May 2024, the installed electrolyzer capacity in Europe is only 250 MW, which falls significantly short of the 6 GW target set for 2024. When considering the hydrogen production target for 2030, the announced 13 Mt p.a. production capacity has exceeded the 10 Mt target. However, only 0.3 Mt p.a. is currently committed, with around 2.9 Mt p.a. at the Front-End Engineering Design (FEED) stage. This means that the majority of the projects are still in the announcement phase or undergoing feasibility studies [2]. Under these circumstances, it is still in question whether Europe will manage to speed up the development of the hydrogen market in the upcoming years. The answer to this might lie in how member states implement the binding consumption targets and the faster processing of permits defined by the RED III directive.

3.3. USA

The official U.S. National Clean Hydrogen Strategy and Roadmap came into force in June 2023. According to the roadmap, the USA aims to achieve a clean hydrogen demand of 10 Mt by 2030, 20 Mt by 2040, and eventually 50 Mt by 2050. Additionally, the strategy specified cost reduction targets for clean hydrogen production. The USA aims to reduce the production cost of hydrogen via electrolysis to USD 2/kg H_2 by 2026, and USD 1/kg H_2 before 2035 [10].

In the USA, two key support mechanisms target the development of the clean hydrogen market: the Bipartisan Infrastructure Law, and the Inflation Reduction Act (IRA). As part of the Bipartisan Infrastructure Law, USD 8 billion has been allocated to establish hydrogen hubs in various regions across the country. These hubs differ in production methods, end-use applications, and funding levels. For example, the California Hydrogen Hub and the Pacific Northwest Hydrogen Hub focus on producing hydrogen solely from renewable energy sources. In contrast, the Appalachian Hydrogen Hub leverages the extensive natural gas resources in the West Virginia, Ohio, and Pennsylvania region. The Heartland Hydrogen Hub aims to decarbonize the agricultural sector by using clean hydrogen in fertilizer production, while the Midwest Hydrogen Hub targets supplying clean hydrogen to steel and glass producers. Additionally, USD 1 billion of the allocated funding is designated for end-users to boost demand for clean hydrogen within these selected hubs [11]. With the Inflation Reduction Act (IRA), introduced in August 2022, nearly USD 400 billion was allocated to clean energy investments through tax incentives, grants, and loan guarantees by the Biden administration. The IRA positively impacted hydrogen projects in the USA by providing incentives for solar and wind power facilities, clean fuel production, and tax credits for hydrogen production and CCUS deployment. Following the introduction of the IRA, both green and clean hydrogen production projects gained momentum in the USA, as the act's technology-neutral approach ensures that tax credits for hydrogen production are based on emission levels. For example, green hydrogen, with emissions lower than 0.45 tons of CO_2 per ton of hydrogen qualifies for the full tax credit of USD 3.00/kg H_2. In contrast, hydrogen with emissions of 4 tons of CO_2 per ton, the maximum eligible threshold set by the Department of Energy (DOE), receives a reduced tax credit of USD 0.60/kg H_2 [12].

The availability of vast natural gas and renewable energy resources, combined with these powerful acts, makes the USA a favorable location for a hydrogen economy. However, as of May 2024, only 110 MW of electrolyzer capacity has been installed in the USA. The share of blue hydrogen projects is higher than that of renewable hydrogen projects in the country. Blue hydrogen, produced from natural gas with CCUS, is more prevalent in the region due to the availability of natural gas resources and the relative easiness of converting existing SMR plants, while renewable hydrogen projects usually require the new installation of solar or wind infrastructure. This also increases the share of projects that have reached the maturity stages in the USA compared to Europe and China. Based on projects that have passed the FID stage, around 1.6 Mt of clean hydrogen production is committed in the USA by 2030, with approximately 85% being blue hydrogen [2], [12]. Yet the future of the project pipeline remains uncertain under the newly elected administration, as the disbursement of funds from the IRA and bipartisan infrastructure law has been paused in January 2025. [13].

4. CONCLUSION

The clean hydrogen industry is evolving rapidly, driven by distinct strategies and regulatory frameworks across different

regions. Table 1 compares the main factors discussed above for China, Europe, and the USA. In China, the collaborative efforts between central and regional governments have led to swift advancements in the hydrogen market. This positions the country as a frontrunner in the clean hydrogen market. In Europe the pace of market development remains slow. How member states will implement the robust but very specific regulations will impact the future of the market growth. Yet it can be stated that increased synergy between the EU-level directives and country-level implementations is essential for achieving cohesive progress. In the USA, with its abundant resources and the momentum gained from announced policies, the market was on track to become a clean hydrogen industry leader. However, recent political developments have put a brake on this progress by creating uncertainty regarding the implementation of the announced acts.

Table 1. Summary of Key Hydrogen Market Findings by Region

	China	Europe	USA
Main Roadmap Target	0.1 -0.2 Mt p.a. clean H_2 production capacity and deployment of 50 000 FCEVs by 2025 [3]	40 GW installed electrolyzer capacity by 2030 to produce 10 Mt green H_2 [5]	10 Mt clean H_2 demand by 2030 and reduction of cost of hydrogen with electrolysis to USD 2/kg H_2 by 2026 [10]
Key Regulatory Drivers & Funding Opportunities [1]	Provincial hydrogen targets and subsidy policies	Renewable Energy Directive (RED) III Important Projects of Common European Interest (IPCEIs)	Bipartisan Infrastructure Law Inflation Reduction Act (IRA)
Clean H_2 production capacity past FID until 2030 as of May 2024 [2]	≈ 1.4 Mt p.a (>95% renewable)	≈ 0.30 Mt p.a (≈ 60% renewable)	≈ 1.6 Mt p.a (≈ 15% renewable)
Installed Electrolyzer Capacity as of May 2024 [2]	1150 MW	250 MW	110 MW

ABSTRACT
This study evaluates the performance and durability of various Aquivion® membranes for PEM electrolysis, focusing on different configurations: bare cast polymers, polymers with radical scavengers and reinforced ones. Membrane-electrode assemblies (MEAs) were produced and tested for hydrogen production by means of polarization curves, electrochemical impedance spectroscopy (EIS) and long-term durability tests. Microscopic and physico-chermical analyses (TEM, SEM, optical microscopy, XRD, XRF,) were used to understand the membrane and ionomer structure and its impact on performance. The goal was to identify optimal membrane strategies for enhancing PEM water electrolysis efficiency and stability in green hydrogen production.

Keywords: Water electrolysis, Hydrogen, proton exchange membrane

1. INTRODUCTION

The transition to clean energy is crucial for sustainable growth and climate change mitigation. However, challenges exist in developing efficient energy vectors and integrating them with renewable energy sources and existing infrastructure. Water electrolysis, using surplus renewable electricity to produce green hydrogen, presents a promising solution. [1]

Green hydrogen from electrolysis offers advantages in energy storage, transportation, and diverse applications across energy and industrial sectors. Proton exchange membrane (PEM) electrolysis is particularly attractive due to its high efficiency, purity, rapid response times, compact design, and direct high-pressure hydrogen production, reducing downstream compression costs. [2, 3] These factors support the development of hydrogen market, given hydrogen's transportability and broad applicability in fuel cells, chemical synthesis, and industrial processes.

Nevertheless, large-scale PEM electrolysis implementation requires advancements in membrane technology. PEM membranes must provide high proton conductivity while maintaining chemical and mechanical stability under demanding operational conditions. [4, 5] Membrane degradation negatively impacts system lifespan, maintenance, and production costs. Developing robust and efficient PEM membranes is therefore vital for widespread adoption of PEM electrolysis. High-performance, stable ionomers are critical for efficient PEM water electrolysis. This study compares three membrane types a bare cast membrane, a membrane incorporating a radical scavenger (RSP-50) and a reinforced membrane to assess their performance and stability. Membrane-electrode assemblies (MEAs) were subjected to polarization tests, electrochemical impedance spectroscopy (EIS), and long-term (2000 hour) stability testing. Microscopic and physico-chermical analyses analyses (XRD, XRF, TEM, SEM, optical microscopy) were employed to correlate membrane properties with MEA performance. The findings aim to identify strategies for optimizing membrane characteristics to enhance PEM water electrolysis.

2. EXPERIMENTAL

2.1. Membrane-electrode assemblies (MEAs) - preparation

Four distinct Aquivion® membranes composed of the same polymer, Aquivion® perfluorosulfonic acid (PFSA), with an equivalent weight of 720 g/eq, were examined for the single cell characterizations: reinforced membrane R720, reinforced membrane NR720, cast membrane C720, and cast membrane with radical scavenger C720-RSP-50.

Two distinct grades of expanded PTFE fibers were used as support to create reinforced Aquivion® membranes. The primary distinction between the two e-PTFE grades is based on the characteristics of ePTFE in NR720, which exhibit greater thickness and mechanical qualities in comparison to grade ePTFE in R720.

Membrane-electrode assemblies were made using the catalyst-coated technique, in which the ionomer ink of the catalyst was sprayed directly onto the membrane. With the help of an automated equipment (Sono-Tek, model Exacta Coat), which has an ultrasonic nozzle (AccuMist, 128 kHz) that enables the nebulization of the ink based on the catalyst, the catalyst coated membranes (CCMs) were produced using a spray coating approach.

2.2. Electrochemical characterization

To assess the electrolysis performance at various temperatures (30 to 90 °C), electrochemical studies were conducted in a single cell with an active area of 5 cm^2. More in detail, polarization curves (voltage vs. current density) and electrochemical impedance spectroscopy (EIS) were carried out obtaining, the series resistance, Rs, by using the Nyquist plot as the high-frequency point where a curve intersection occurs on the real axis. Conversely, the difference between the low and high frequency intercepts on the real axis was used to infer the polarization resistance, or Rp.

3. RESULTS AND DISCUSSION

Both reinforced and radical scavenger-based membranes achieved excellent electrolysis performance, 1.87 V at 5 A cm^{-2}, and 79% voltage efficiency at 90°C. High voltage efficiency minimizes renewable energy consumption and green hydrogen cost, while high current density reduces capital costs due to increased production rates, this is essential for reducing the use of critical raw materials (CRMs).

Both CeO_2 (radical scavenger) and PTFE (reinforcement) fillers slightly improved proton conductivity, likely by altering membrane morphology and ionic pathways. Both reinforced and radical scavenger membranes exhibited similar stability over 2000 hours, with initial degradation attributed to increased series resistance (Rs) possibly due to initial impurity release. The test was carried out at 1 A cm^{-2} for 100 h at the beginning and there after a switch to 5 A cm^{-2} was carried out. The voltage loss was 39 μV/h and 46 μV/h for the R720 and CAST-RSP-50-based MEAs, respectively over 2000 h at 5 A cm^{-2}.

Polarization resistance (Rp), primarily related to the catalytic layers, increased slowly, minimally affecting initial degradation.

Post-mortem analysis (XRD, TEM and SEM) revealed negligible changes in the catalytic layers and minimal membrane thinning, suggesting excellent long-term durability. The reinforced membrane showed the lowest temperature dependence of Rs, and Rp was the dominant factor influencing performance at high current densities.

4. CONCLUSIONS

Due to their improved crystallinity, stronger protonic conductivities, and higher glass transition temperature compared to traditional Nafion® equivalents, Aquivion® membranes and associated ionomer dispersions are achieving popularity in PEM electrolysis. These increased characteristics allow them to function in a broad temperature range and provide better performance in PEM electrolysis. The possibility of modifying these membranes by adding reinforcing fillers or radical scavengers can provide further insights into improved chemical stability and mechanical tolerance against peroxide radical threat. These characteristics are crucial for electrolysers that offer a longer lifetime than traditional Nafion® electrolyte-based electrolysis systems.

ABSTRACT: In today's world of ever-increasing energy dependency, fossil fuels are still the primary source of energy. However, the environmental pollution and global warming caused by these resources have led countries to look for new sources. For this reason, the use of hybrid renewable energy is increasing day by day in many developing countries. Wave, wind, solar, hydro and similar sources are the most preferred renewable energy sources. In addition, hydrogen fuel, which is gaining popularity today, is another storable, clean renewable energy source that can be easily produced by electrolysis of water. This study aims to estimate the amount of emission-free hydrogen that can be produced by an electrolysis process using wave energy. An innovative adaptive model using data parsing and deep learning architectures is proposed. The prediction results show that high regression and low error values are obtained.

Keywords: Hydrogen production, Wave energy, Electrolysis, Renewable energy

1. INTRODUCTION

Since the last quarter of the twentieth century, the reduction of developing technologies to individual use and the increase in their diversity, and the accompanying increase in urbanization and population have made the need for energy important. However, a significant portion of energy is still obtained from fossil resources. The more important problem than the scarcity of these resources is that they cause climate change with their carbon emissions [1]. For this reason, many studies have been carried out to regulate the use of renewable energy sources found in nature for the utilization of energy resources. Renewable energy sources include wave energy, wind energy, solar energy, biomass energy, hydrogen energy, hydroelectric energy, tidal energy and geothermal energy. Wave energy is a renewable energy source that aims to generate electricity using the kinetic and potential energy of waves moving on the surface of oceans and seas. This energy is a clean and sustainable alternative with the potential to reduce dependence on fossil fuels [2]. Therefore, with the increasing demand for wave energy, different fields of study have emerged in the literature. Considering the stochastic nature of waves, it is important to accurately predict the wave height for efficient energy production [3]. At the same time, the many advantages of hydrogen fuel as an alternative to energy sources increase the interest in the product. Hydrogen fuel is considered an energy carrier and is an excellent energy source that can be used to replace traditional fuels [4]. An important feature that makes hydrogen fuel unique is that it can be stored. Therefore, it can be used as an energy provider anytime, anywhere [5]. This advantage is very useful in renewable energy sources where it increases system efficiency during periods when electricity generation is intermittent as a result of the demand-supply balance in the grid [6]. Therefore, excess electricity generated from renewable energy sources can be used to produce hydrogen as a clean fuel and stored for later supply during peak times when demand is high [7].

In this study, an adaptive innovative model (Iterated Frequency Decomposition (IF) - Multiple Fractional Generalized Fluctuation Analysis (NF-DFA) - Bidirectional Long Short-Term Memory Network (BI-LSTM)) is proposed for hydrogen quantity forecasting. For this purpose, firstly, the wave height, which is the most important input of the wave energy system, was estimated. Using the obtained results, the electrical power required for the catalyst process was calculated. Finally, the amount of hydrogen likely to be obtained through the necessary conversions was determined.

2. METHODOLOGY

In this section, the definition of the study area and obtaining the wave height data, decomposition of the wave height data, construction of the wave height prediction model, calculations required for the electrolysis process according to the wave energy power, and estimation of the amount of hydrogen likely to be produced are presented in detail.
In this study, the province of Samsun, Turkey was selected as the reference for the case study to show the potential wave energy on the southern coast of the Black Sea. The data set used was obtained from the SAMSUN Offshore Buoy (E:41.4375 W:36.475834) of the General Directorate of Meteorology. The data set consists of 35040 hours of standard meteorological data. The dataset includes the parameters Significant Wave Height (SWH), Dominant Wave Period (DPD), Average Period (APD), Mean Wave Direction (MWD), Water Temperature (WTMP). These data were used for the analysis. Missing data were filled using a linear interpolation method that gives greater weight to the nearest available value. From these data, a dataset of 35040 units was created using data from 2020-2023. Iterated Frequency Decomposition (IF) was used to decompose this data set. IF is a decomposition technique that provides a complete reconstruction of the original signal and a better spectral separation of the intrinsic mode functions (IMFs) [8].
The obtained IMFs were combined according to their dominant fractal properties with the MF-DFA method and a new

data was obtained. This method is used to analyze multiple fractal properties of time series. **MF-DFA** is especially preferred for analyzing data with intrinsic scaling properties in fields such as finance, biology, climate sciences and engineering [9]. The Bidirectional Long Short-Term Memory Network (BI-LSTM) deep network model was used in the prediction process. LSTM is a type of **recurrent neural network (RNN)** model that can learn long-term dependencies. However, the standard LSTM only processes data from the past to the future. The **BI-LSTM, on the other hand, processes data both from the past to the future and from the future to the past**, thus learning **contextual information better. When BI-LSTN is analyzed, it has been reported that it provides better accuracy in applications such as speech recognition, text processing, time series prediction, and can learn long-term dependencies** more effectively than standard LSTM [10]. The power of the wave energy was determined by using the parameters in the data set, especially the wave height and period. Depending on the determined wave power, the necessary calculations used in the hydrogen production stages were made and the amount of hydrogen expected to be produced according to the estimated wave height was determined.

3. RESULTS AND DISCUSSIONS

The graph of the wave height change measured by the buoy off Samsun between 2020-2023 is shown in Fig. 1. Of these, 24528 data were used as training data, 8760 data as test data and 1752 data as validation data for the prediction process.

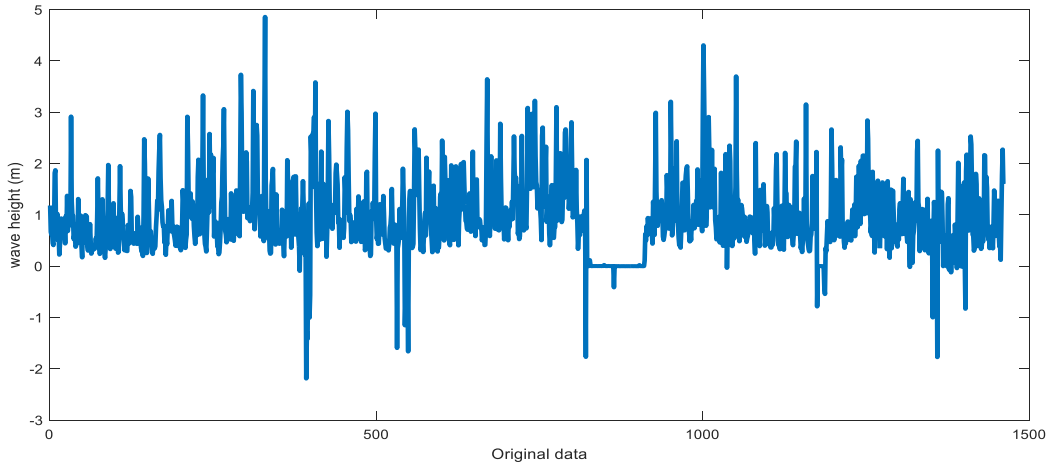

Fig. 1. Wave height variation

The data set used was subjected to decomposition by the IF method and 7 internal mode functions were obtained. The variations of the obtained internal mode functions are shown in Fig. 2.

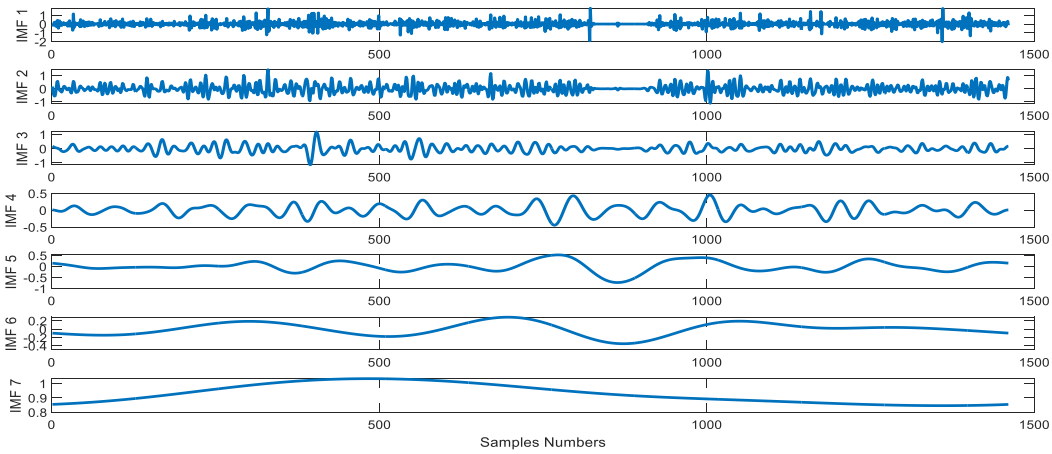

Fig. 2. Internal Mode Functions (IMF1-IMF7)

Each of the IMFs was analyzed by MF-DFA, and the IMF series showing dominant fractal characteristics (IMF2-IMF3-IMF5) were collected and a new data was generated and shown in Fig. 3.

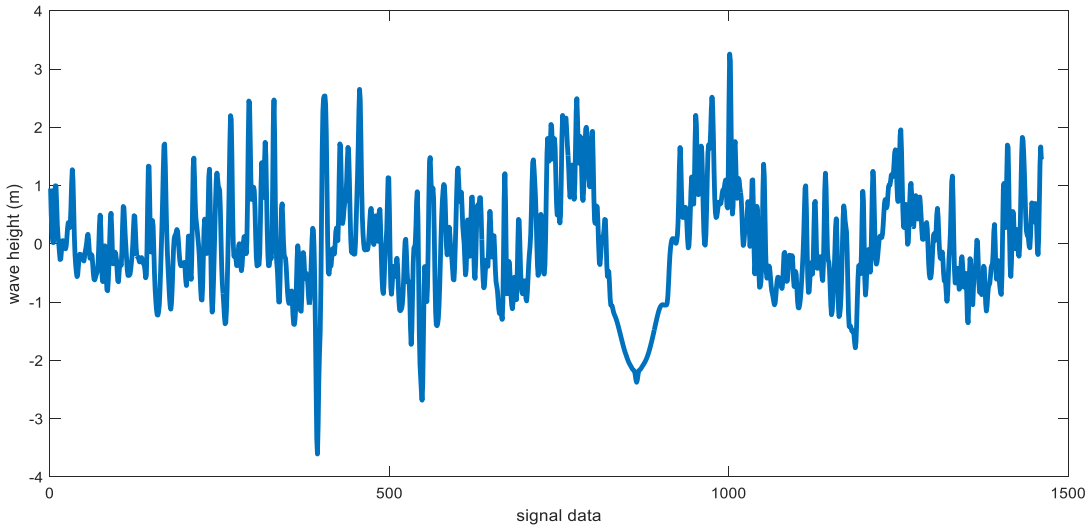

Fig. 3. Data graph obtained as a result of MF-DFA analysis

According to the prediction model, the proposed adaptive model (IF - MF-DFA - BI-LSTM) performed more accurately and reliably than the other methods compared in Table 1.

Table 1. Performance Metrics

Models	MAPE	R^2	RMSE
IF - MF-DFA - CLSTM	1.650	0.930	1.447
IF - MF-DFA – LSTM	46.482	0.079	1.400
IF - MF-DFA - BI-LSTM	1.313	0.953	0.859
IF - MF-DFA - CGRU	2.171	0.896	1.475
IF - MF-DFA – GRU	101.138	0.012	4.265
IF - MF-DFA - CRNN	1.373	0.869	1.404
IF - MF-DFA – RNN	70.383	0.018	2.198

On the basis of the obtained estimation results, the necessary calculations for the electrolysis process using wave energy in the region selected for the case study were performed and the daily amount of hydrogen production for one year was estimated for the proposed and other models. The difference between the calculated amount of hydrogen that can be produced and the estimated amount of hydrogen that can be produced is shown in Fig. 4. In addition, the total estimated amount of hydrogen energy for one year is shown in Table 2.

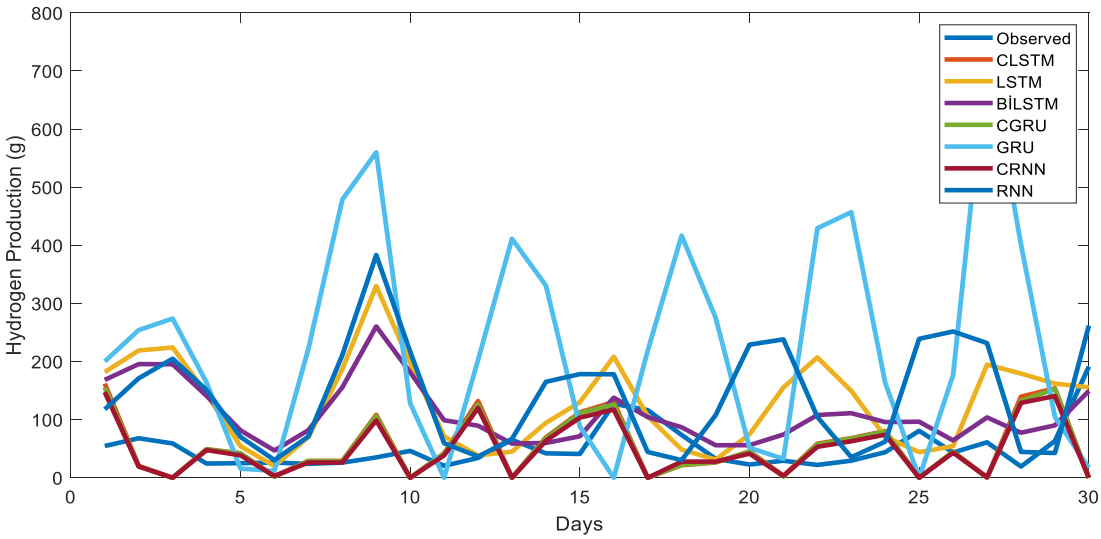

Fig. 4. Determined hydrogen production for all models in 30 days

Table 2. Hydrogen production

Models	The Amount of hydrogen produced per day (Gr)	The amount of hydrogen produced per year (kg)
TEST DATA SET	60.337	21.84
IF - MF-DFA - CLSTM	65.412	23.68
IF - MF-DFA – LSTM	129.769	46.98
IF - MF-DFA - BI-LSTM	62.044	22.46
IF - MF-DFA - CGRU	64.428	23.32
IF - MF-DFA – GRU	278.677	100.88
IF - MF-DFA - CRNN	64.281	23.27
IF - MF-DFA – RNN	172.713	62.52

4. CONCLUSIONS

In this study, 1-year hydrogen production is estimated. Wave energy is used as the source for hydrogen production. Wave height, which is the most important input of wave energy, is estimated using the proposed innovative adaptive model. Thus, using the system parameters, the actual amount of hydrogen energy to be produced by the proposed model was estimated with an accuracy of 97.32%.

ABSTRACT
Hydrogen is a potential alternative solution for ejection systems that separate stores from air platforms. In this study, Hydrogen powered ejection system is developed instead of conventional ejection systems. This system contains hydrogen production and storage equipment. Ignition of the mixture of gases which contains onboard produced Hydrogen in the combustion chamber. In-cylinder pressure reaches to 350 bar and pistons push to eject the external stores from air platform.
In this study, the ejection system performance characteristics were examined using the laws of thermodynamics and ideal gas equations. For this purpose, previously tested conventional ejection system performance data are collected for a wide range of stores. Aircraft compatibility issues are considered to determine the usage concept of a hydrogen-powered ejection system. Then, sizing and rating calculations are carried out on these configurations. Engineering Equation Solver and Comsol Multiphysics software are used to compute performance predictions of the system and compare them to previous system data. The design of the electrolyzer and storage equipment depends on the calculated amount of hydrogen required.
It has been found that hydrogen is a very suitable and clean alternative for ejection systems, and the practical costs of maintenance are very low compared to other systems.
Keywords: Store Separation, Hydrogen, Bomb Rack Unit, Ejection System, Aircraft

1. INTRODUCTION
Bomb Rack Units are used to launch external stores from aircraft. The most widely used ejection systems use electrically ignited impulse cartridges or a compressed air vessel. The unit's ejection pistons are touching to store and always ready-to-launch. In this study, MAU-12 ejector rack's ejection system will be replaced with hydrogen powered ejection system. Hydrogen is less corrosive for bomb rack units rather than cartridge explosive system since it only emits water vapor when it burns. Air platform and maintenance personnel are also at risk when carrying the compressed air vessel on board.

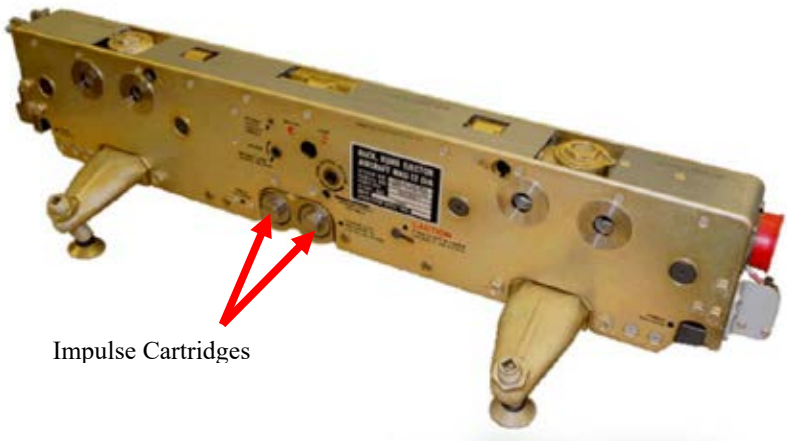

Fig. 1. Bomb Rack Unit (MAU-12)

Researchers are studying ejection systems for air platforms; however, they haven't looked into hydrogen-powered ejection systems yet. This system has never been integrated on an air platform and has no current applications. For this reason, conventional ejection systems are being studied. Hydraulic, Pneumatic, Thermal Controlled and Cold Gas systems are also developed for ejection in the literature.
This study is driven by the belief that using Hydrogen as an alternative to other systems in ejection on the air platform will prevent maintenance costs from increasing and degradetion of ejection system. System development is carried out and the ejection system performance is calculated. Zero dimensional simulations are run for verification of calculations.

2. SYSTEM MODELING
System model is developed based on conceptual usage of F-16 aircraft which is considered as air platform. Hydrogen is produced onboard by a water electrolyser. All water splitting technologies are examined and PEM water electrolyser is

selected to produce Hydrogen from water. Usable volume in the bomb rack unit is constraining the dimensions of PEM electrolyser and water tank dimensions. Unit is examined for external dimensions of electrolyser is maximum 50x50x80 mm. Bomb rack unit's explosive cartridge slots are used as combustion chamber in this system. Produced Hydrogen can be storaged in metal hydrides in the Unit or directly filled in the combustion chamber and ignited by the pilot's signal.

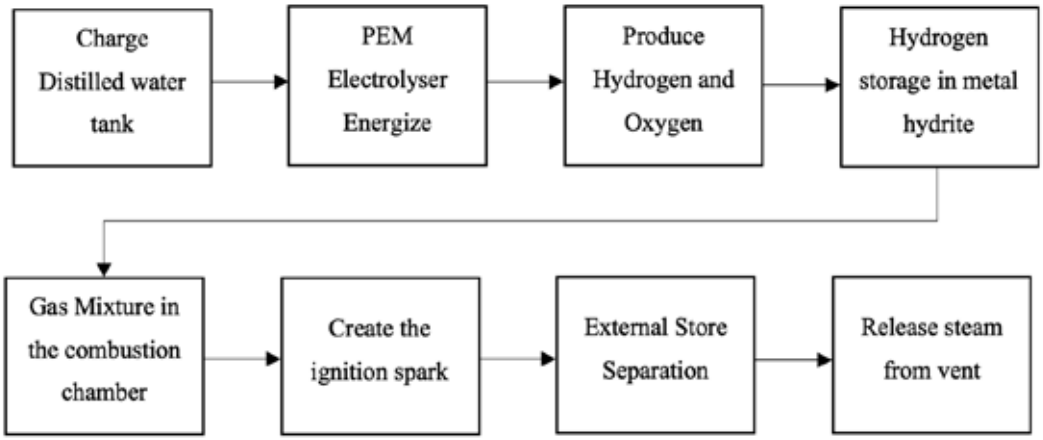

Fig. 2. System Functional Flow

Electrical power for Hydrogen production could be supply from the aircrafts power distribution system or an external battery. There is a usable volume in the aircraft's pylon for battery placement.

2.1. PEM Water Electrolysis

Proton exchange membrane (PEM) water electrolysis has emerged as a major technique for the creation of hydrogen, because of its great efficiency and small size [1]. PEM electrolysers are superior to traditional alkaline electrolysers in that they can run at pressures greater than 100 bars and reach higher current densities, which increases both the overall efficiency of the system and the purity of the hydrogen produced[2].

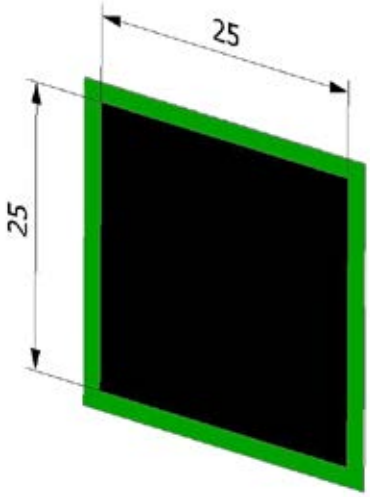

Fig. 3. Proton Exchange Membrane Dimensions

The solid polymer electrolyte membrane is the fundamental part of PEM electrolysers. It blocks gases such as hydrogen and oxygen and only permits protons to pass through. As shown in **Error! Reference source not found.**, gas crossing is avoided and high-purity hydrogen output is guaranteed by this feature[3].
Designed electrolyser contains 12 cells and each cell has 25x25 mm Proton Exchange Membrane surface.

2.1. Required Piston Force

The ejector performance requirement can be figured out by applying ground tests to MAU-12 ejector with different weights of the external stores under investigation. Test data obtained regarding the performance of the MAU-12 ejector with explosive cartridges were added to the literature by Carter . As shown in **Error! Reference source not found.**4, experimental data regarding the single piston forces in lbf obtained using different weights are shown. The unit of piston forces is lbf. Required piston forces and in-cylinder pressure values for each weight of external store given in Table 1.

Table 1. Required piston force and in-cylinder pressure values

Heaviest External Store [lb]	Piston Force [N]	In-Cylinder Pressure [bar]
4800	34500	358,6

MAU-12 ejector has pistons to eject external store. Given performance datas is for aft and forward single pistons applied force. The thrust-generating mechanism in the pistons is separated into four states as shown in Fig.5, for the purpose of simplifying design calculations. Assumptions for each state are done and mathematical models set in the Engineering Equation Solver program. The calculations are based on these assumptions.

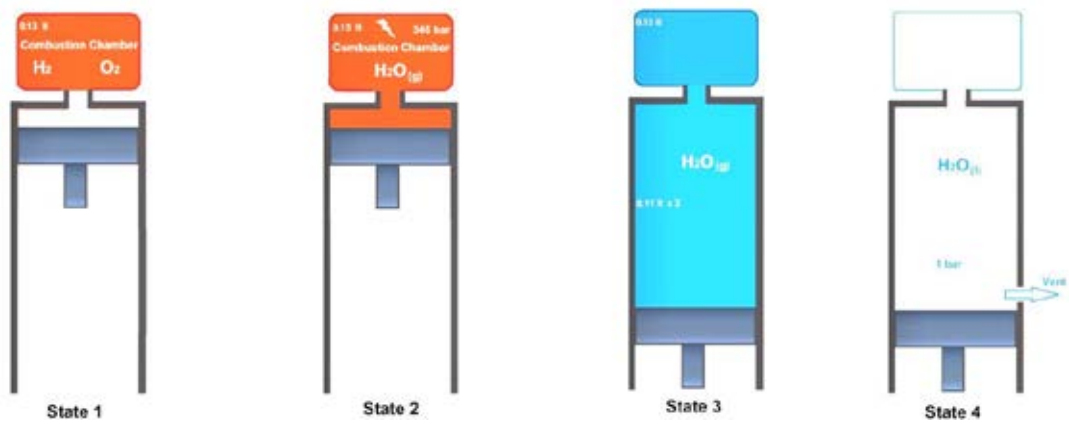

Fig. 4. Four States of Ejection

In the first state, required Hydrogen mass which was produced in PEM electrolyser and stored in metal hydrite is sent to combustion chamber. Gas mixture is ready to ignite in chamber. In this state, the temperature of the gas mixture assumed is 27° [C]. In the second state, an ignition spark is created when the pilot of the air platform pushes the pickle button. The gas mixture is burned immediately and in-cylinder pressure increases. There is no displacement of the pistons in this state, so volume is assumed to be constant. This process is assumed to be adiabatic because burning is completed in miliseconds[4]. The third state is the expansion of the aft and forward pistons affected by in-cylinder pressure. External store reaches the end of stroke velocity after expansion. When stroke is completed in fourth state, a ventilation line is opened, and in-cylinder pressurized steam is vented to the atmosphere.

2.2. Required Hydrogen Mass

In this study, required Hydrogen mass calculations are carried out for combustion with pure oxygen and dry air. Stoichiometric combustion reaction equations are calculated and solved in Engineering Equation Solver. Adiabatic flame temperature of Hydrogen when combusted with dry air is 2400 [K][5]. P[1] is the initial pressure in the first state and P[2] is the in-cylinder pressure. Required Hyrdogen amount providing P[2] value 350 bar is approximately obtained.

$$H_2\,(g) + 0{,}5\,O_2(g) + 1{,}881 N_2\,(g) \rightarrow H_2O\,(g) + 1{,}881\,N_2\,(g) \quad (1)$$

Using pure oxygen as oxidizer increases the adiabatic flame temperature to 4920 [K][6]. As shown in Fig.6, approximately obtained Hydrogen amount combusted with pure oxygen is providing P[2] value 350 bar.

$$H_2\,(g) + 0{,}5\,O_2(g) \rightarrow H_2O\,(g) \quad (2),$$

3. RESULTS AND DISCUSSIONS

Comsol Multiphysics software is used to simulate zero-dimensional combustion reactions to obtain and verify in-cylinder pressure values as shown in Fig .5.

Designed PEM electrolyser placement in Bomb Rack Unit is shown in Fig. 6. Development and design process are in progress. Hydrogen production rate of electrolyser will be obtained and system ready to ejection times for each weight of store will be calculated. All component designs and technical drawings will be completed in the end of study.

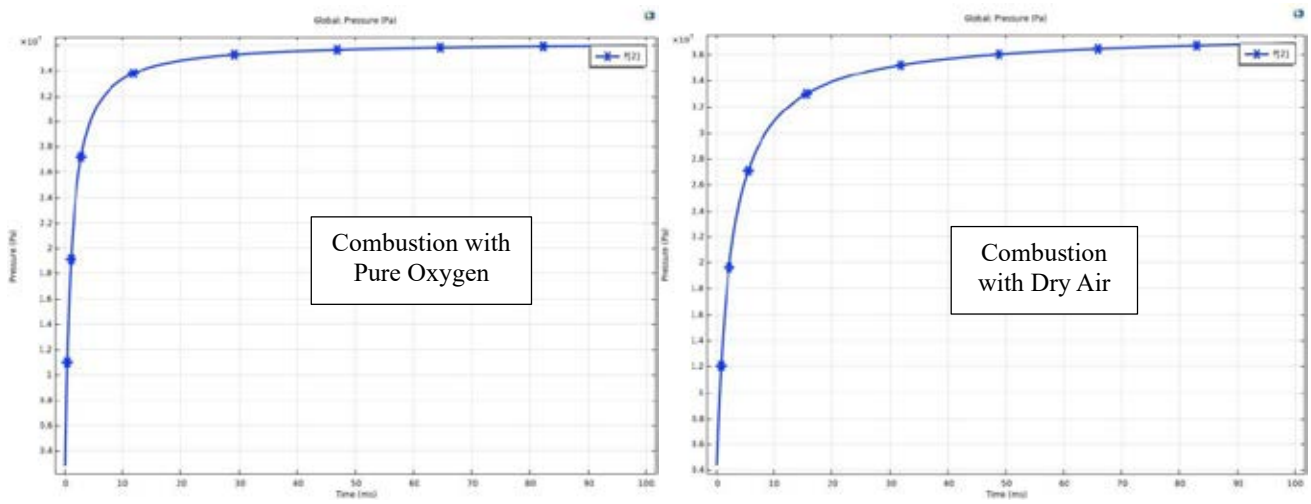

Figure 5. In-cylinder Pressure During Combustion

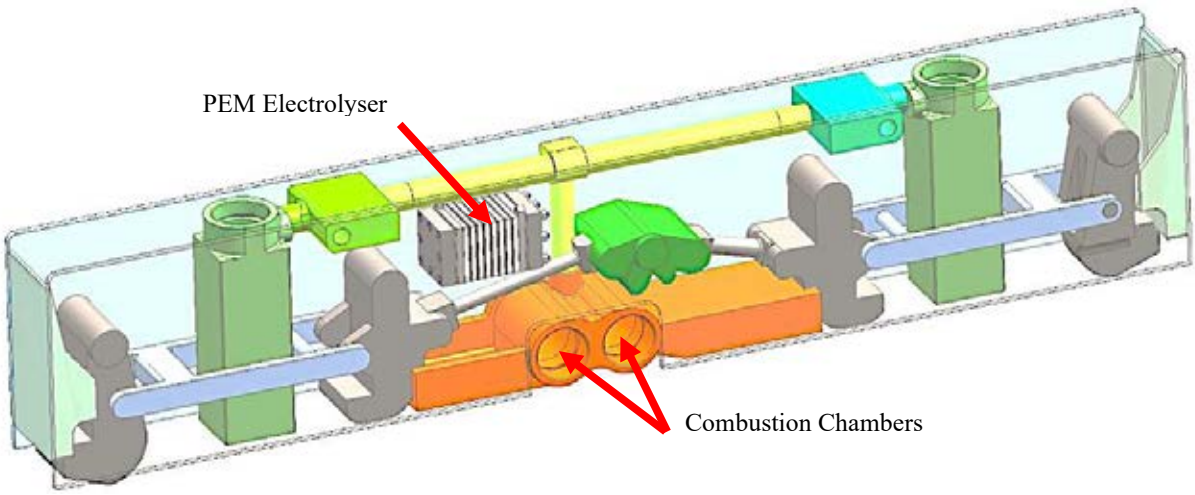

Fig. 6. PEM Electrolyser Placement in the Bomb Rack Unit

4. CONCLUSIONS

This study demonstrates the potential of Hydrogen as an alternative for conventional ejection systems. The PEM electrolyzer is designed and mounted in the bomb rack unit. The results of the calculations and analysis are provided. In order to evaluate the design, studies have been conducted based on conceptual alternatives. Moreover, this system can be designed for different air platforms for ejection of the external stores.

ABSTRACT
This study presents the geometric design of single-layer porous transport layers (PTLs) with strut-based lattice structures for proton exchange membrane (PEM) electrolyzers, aiming to enhance mass transport, electron conductivity, and gas removal efficiency. Conventional PTLs often suffer from high interfacial resistance and suboptimal water management, limiting overall electrolyzer performance. To address these challenges, this work explores novel lattice geometries with tunable porosity and superior fluid dynamics characteristics. Additive manufacturing is highlighted as a key fabrication technique, enabling precise control over structural parameters and scalability in production. Preliminary findings indicate that optimized lattice designs can effectively minimize mass transport losses and improve water utilization. This study establishes a foundation for further experimental validation and optimization, contributing to the advancement of high-efficiency and cost-effective PEM electrolyzers for sustainable hydrogen production.

Keywords: PEM electrolyser, lattice structure, porous transport layer, additive manufacturing, hydrogen production.

1. INTRODUCTION
Proton exchange membrane (PEM) electrolyzers are a key technology for green hydrogen production and experts emphasise that water electrolysis is the most effective zero-emission hydrogen production technology when a renewable energy source such as solar energy is used as an electricity source [1]. In the electrolysis of water, Proton Exchange Membrane (PEM) electrolysers are widely used to produce high purity hydrogen at high efficiency. PEM electrolysers, which are already commercially available, have a similar operating principle to fuel cells and can produce hydrogen with approximately 99.9% purity [2]. Although PEM electrolysers provide the advantage of high purity green hydrogen production, they also bring disadvantages such as high material cost, cross-permeability phenomena that increase with pressure, and the presence of water vapour that requires dehumidification with the produced hydrogen [3]. On the one hand, the possibility of high purity green hydrogen production increases the interest in PEM electrolyzers, and on the other hand, studies on the development of the system are continuing [4]. Web of Science [5] data, it is seen that the number of research on PEM electrolysers is quite low compared to fuel cells. This has generally been the case in the past, and studies on fuel cells have been at higher levels compared to electrolyzers [6].

The performance and durability of these systems are strongly influenced by the design and material properties of their internal components, particularly the porous transport layer (PTL). The PTL plays a crucial role in facilitating water distribution, gas removal, and electron transport while minimizing interfacial resistance and mass transport losses. The aim of this study is to increase the electrochemical reaction efficiency in the system by improving the fluid distribution with flow fields designed as a single piece using lattice structured porous material for PEM electrolysers.

Recent advancements in additive manufacturing have enabled the development of tailored PTL structures with enhanced transport properties. Strut-based lattice structures, in particular, offer a highly tunable architecture with optimized porosity, permeability, and mechanical stability. Unlike conventional sintered or fibrous PTLs, lattice-based designs can improve fluid dynamics, reduce pressure drop, and enhance water management within the electrolyzer. Additionally, additive manufacturing allows for precise control over geometric features, enabling the fabrication of complex PTLs with high reproducibility and scalability [7-9].

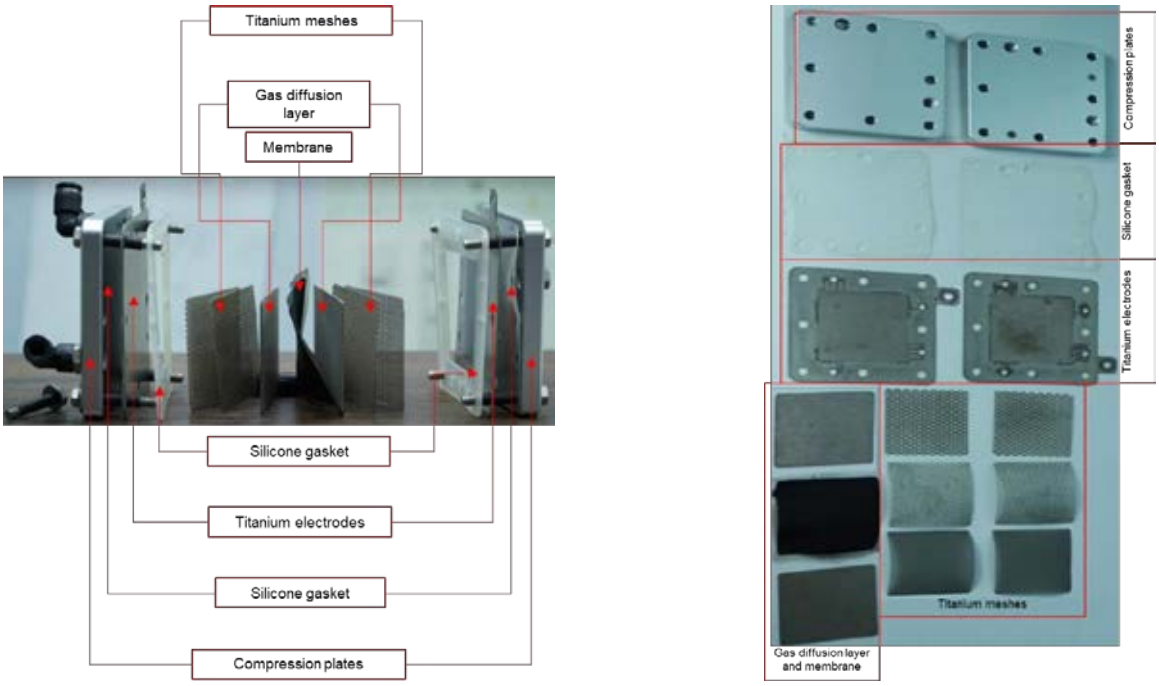
By integrating advanced lattice structures into PEM electrolyzers, the efficiency and cost-effectiveness of green hydrogen production can be significantly improved. This study explores the potential of single-layer PTLs with strut-based lattice geometries, laying the foundation for future experimental validation and optimization. Lesmana and Aziz [10] utilised porous material with lattice structure in a cell type called gyroid to increase heat transfer efficiency and consequently hydrogen storage capacity. As a result of the study, it was reported that the use of cage structured porous material with a wall thickness of 1 mm gave very good results in terms of volumetric capacity, material weight and thermal efficiency. Peng et al. [11] placed a high thermal conductivity lattice-structured porous material in the adsorbent bed to improve the system performance in an adsorption-based hydrogen storage system. As a result of the study, it was reported that the use of lattice-structured porous material allows lower average bed temperature, higher hydrogen fraction and larger adsorption amount compared to finned structures. However, studies on the use of lattice-structured porous materials in

hydrogen technologies are very limited in the current literature. At the same time, there are currently no studies on the use of these materials in PEM electrolyser flow fields. In this context, the use of cage structured porous materials as a single piece in porous flow fields consisting of multiple layers to improve electrochemical performance in PEM electrolysers is seen as a promising application.

2. MATERIALS AND METHODS

In this study, the effects of innovative flow field designs containing porous material with lattice structure on system performance will be investigated to increase electrochemical efficiency in PEM electrolyser. PEM electrolysers consist of a compression plate, bipolar plates, gas diffusion layer and membrane electrode assembly. The main components of a PEM electrolyser are shown in Fig. 1a and detailed views of the components are shown in Fig. 1b.

The compression plates are used to fix the PEM electrolyser cell and are manufactured from aluminium alloy. Bipolar plates are used to evenly distribute the voltage supplied by the power supply by connecting multiple electrolysis cells in series. These separator plates contain various flow field channels and are manufactured from materials with properties such as high thermal conductivity, high mechanical strength, high chemical stability and low resistivity to enhance the heat transfer mechanism. Titanium is generally considered to be the most suitable material to meet these properties and is widely used. The gas diffusion layer ensures efficient mass transfer by electrical conductivity and fluid flow between the membrane and the bipolar plate. At the anode, purified liquid water is transported from the bipolar plate through the current collector to the catalyst layer on the membrane, where it decomposes into oxygen and protons. The released oxygen diffuses in the direction opposite to the flow direction from the current collector. At the cathode, liquid water and hydrogen are transported from the membrane through the current collector to the bipolar plate gates. Electrons start from the catalyst layer on the anode side, pass through the current collector and bipolar plate and reach the cathode side. The membrane is the most basic component of the electrolyser process in which water is separated into hydrogen and oxygen by exposure to electric current. It is a material that conducts protons coated with porous flow areas on the anode and cathode sides. At the anode, water is split into oxygen and protons. Protons pass to the cathode, while electrons pass to the cathode through the external circuit. At the cathode, protons gain electrons to form hydrogen gas. This study focuses on the PTL obtained by stacking titanium meshes on the left and right sides of the membrane shown in Fig. 2. On both the anode and cathode side, the titanium meshes will be designed as a single piece of porous materials with a lattice structure. Thus, the additional resistances occurring at the interfaces of the stacked grid structures will be eliminated and the amount of material will be reduced. Thus, it is aimed to increase the system performance with the design of the flow field containing porous materials with lattice structure.



(a) (b)

Fig. 1. PEM electrolysers a) general and b) detailed views of the components (adapted from reference [12]).

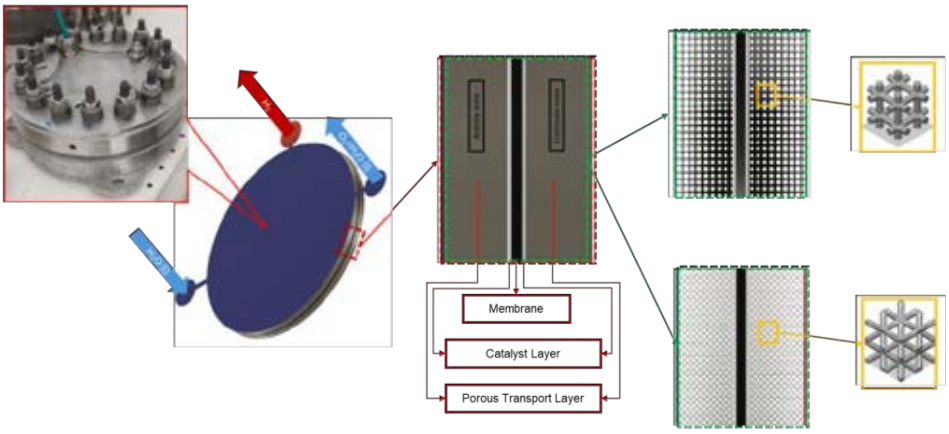


Fig. 2. PTLs containing strut-based lattice structured titanium material

Within the scope of this study, the results will be evaluated by comparing the performance parameters of the traditional structured PTL and the innovative lattice structured PTL containing porous material. In the hydrogen production process in PEM electrolysers, the chemical reactions that take place at the anode and cathode side are as follows.

Anode side:

$$2H_2O \rightarrow O_2 + 4H^+ + 4e^- \quad (1)$$

Cathode side:

$$4H^+ + 4e^- \rightarrow 2H_2 \quad (2)$$

Total reaction:

$$H_2O + electricity + heat \rightarrow H_2 + \frac{1}{2}O_2 \quad (3)$$

In the electrolysis reaction, the cell efficiency (thermodynamic efficiency) of the PEM electrolyser, in other words the voltage efficiency, is calculated as in Eq. (4).

$$\eta = \frac{V_{\text{neutral}}}{V_{cell}} \quad (4)$$

Where V_{neutral} is the smallest potential difference value at which neutral electrolysis can occur, V_{cell} is the potential difference of the electrolyser cell. For each innovative design, the cell efficiency will be calculated and the effects of porous materials with lattice structure on the system performance will be determined.

3. RESULTS AND DISCUSSION

As illustrated in Fig. 3, the PTL structure of the PEM electrolyser investigated in this study consists of low, medium and high titanium mesh layers produced by conventional methods. A review of the PTL structure reveals that overlapping meshes can cause additional resistances and adversely affect the electrochemical activity. The random stacking of titanium mesh layers on top of each other creates an unpredictable complex structure in the PTL. To address the challenges posed by this irregular PTL structure, the proposed strut-based lattice PTL designs are outlined in Fig. 4. The advent of additive manufacturing techniques has facilitated the fabrication of complex porous structures. The single PTL, as illustrated in Fig. 5, can be produced from SLA resin through the utilisation of additive manufacturing techniques. It has been demonstrated that a wide range of porosity, spanning from 20% to 80%, can be achieved by employing a singular layer PTL configuration. As a result, it has been demonstrated that single layer titanium PTLs in PEM electrolysers can be produced by additive manufacturing technique. It is considered that single layer PTLs, which have many advantages such as eliminating additional resistances between layers, can be evaluated as a new research field.

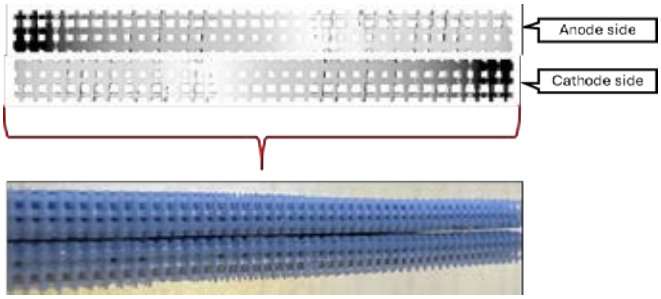

Fig. 5. Fabrication of a PTL designed using a strut-based lattice structure with SLA resin.

4. CONCLUSIONS

This study investigates the design and potential benefits of strut-based lattice porous transport layers (PTLs) in PEM electrolyzers. By integrating advanced lattice structures, it is possible to enhance mass transport, electron conduction, and water management while reducing interfacial resistance. The application of additive manufacturing enables precise fabrication of complex PTL geometries, offering improved structural integrity and performance. The preliminary results suggest that optimized lattice structures can contribute to increased electrolyzer efficiency and durability. Future studies will focus on experimental validation and further optimization to assess the practical viability of these designs in real-world applications.

ABSTRACT

The hydrogen economy has rapidly become a vital energy carrier, feedstock, and fuel in long-term climate action strategies, contributing to the achievement of affordable and clean energy goals and playing a critical role in decarbonization efforts for a net-zero economy. With this content, green hydrogen plays a critical role in achieving net zero in decarbonization of hard-to-abate sectors. Solar green hydrogen production is a promising approach to utilizing solar energy in hydrogen economy. However, further development of catalysts is still needed to achieve economic viability and high efficiency. In this study for solar-driven green hydrogen production, TiO_2@MoS_2 nanocomposites were synthesized via the sol-gel method owing to its ability to manipulate the nanostructure, and of high homogeneity. The effect of varying molybdenum disulfide (MoS_2) ratios in composites was investigated to determine its impact on hydrogen production yield. The crystal structure and morphology of the composites were confirmed using X-ray diffraction (XRD) and field emission scanning electron microscopy (FESEM) techniques. Hydrogen production performance was evaluated using a solar simulator, and hydrogen production profiles were analyzed. XRD analysis revealed that titanium dioxide (TiO_2) exhibited an anatase phase with a tetragonal crystal structure, while MoS_2 displayed a hexagonal crystal structure. FESEM images confirmed that the MoS_2 nanosheets were coated with agglomerated TiO_2 nanoparticles, leading to the absence of the MoS_2 c-plane. Based on the photocatalytic performance driven by solar energy, the TM1 (TiO_2@MoS_2 nanocomposite with 1% MoS_2 ratio) was identified as the most effective, outperforming the other catalysts (TM3, MoS_2, and TiO_2).

Keywords: Green Hydrogen, Solar Driven, TiO_2, MoS_2

1. INTRODUCTION

A result of the global energy crisis, the Paris Agreement established the importance of depleting the effect of climate change by reducing carbon emissions globally [1]. Furthermore, hydrogen stands out as a critical energy carrier, feed stock, and fuel due to its high energy density and low environmental impact in global energy demand and zero emission industry. Investments in hydrogen technologies are expected to grow significantly in the coming years, aligning with global sustainability goals and the vision of a net-zero carbon economy by 2053 due to Türkiye's Hydrogen Strategy and Roadmap [2]. One of the impeccable solutions to hydrogen production is photocatalytic water splitting since the most excessive, clean, and renewable energy resources on earth are solar energy and water [3]. Photocatalytic hydrogen production occurs in three steps which are photon absorption, transport of electron-hole pairs to active sites, and hydrogen and oxygen production in those sites, respectively [4]. Hence, it could prevent the side reactions causing instability in the materials and decomposition of photocatalysts [5].

One of the vital and most utilized semiconductor-driven photocatalysts in hydrogen production is titanium dioxide (TiO_2) due to its suitable conduction and valence positions, high stability, non-toxicity, and low cost. Improving the efficiency of TiO_2 has been studied via semiconductor heterostructure formation, doping, noble metal deposition, etc. Since the construction of semiconductor heterostructures effectively improves the separation and transfer of photogenerated electron-hole pairs while enhancing visible light absorption, it is a widely preferred method [6]. Having a 2D layered structure, good ion transport capacity, large surface area, layered structure held via weak Wan der Waals interactions, and ability to control the recombination of electron-hole pairs on TiO_2 surface makes molybdenum disulfide (MoS_2) a favorable choice for semiconductor heterostructure formation [7].

Several photocatalyst synthesis methods have been studied such as chemical reduction, hydrothermal synthesis, sol-gel method, chemical vapor deposition, etc. In studies on MoS_2 and TiO_2 composite photocatalysts used for hydrogen production, it has been observed that the hydrothermal synthesis method is the most employed. However, in this study, the sol-gel method was chosen to synthesize the TiO_2@MoS_2 photocatalyst for photocatalytic water-splitting hydrogen production. This method was preferred due to its ability to control the microstructure of the product, operate at low temperatures to save energy, ensure high homogeneity, avoid the need for complex systems, and produce catalysts with the desired properties [8].

2. MATERIALS AND METHODS

2.1. Nanocomposite Synthesis and Characterization

In terms of hydrogen production, TiO_2@MoS_2 composites were synthesized with 1% and 3% MoS_2 ratios by sol-gel method. For the synthesis method [9], molybdenum disulfide (MoS_2, Alfa Aesar, 99%, metals basis) at different amounts was added to distillate water (DW) – ethanol (EtOH, Honeywell) solution in order to prepare MoS_2 suspension. The solution was mixed for 30 minutes in an ultrasonic bath. While ethanol was mixed, tetrabutyl titanate ($Ti(O(CH_2)_3)_4$, Alfa Aeser, 99+%) was added. Then, 0.75 ml hydrochloric acid (Tekkim, 37%) was added to tertbutyl titanate-ethanol solution. Finally, MoS_2 suspension was poured into the solution. The final solution was stirred until gel formation was obtained. The gel was heated in the oven which's temperature was set to 180°C for 4 hours. The sample, which got dust formation, was then washed until its supernatant part did not contain any impurity. As a final step of photocatalyst synthesis, to dry the samples, they were kept in the oven at the temperature of 40°C for 12 hours (Fig. 1). The composites were named TM1 and TM3 concerning their MoS_2 ratios. The characterization of the composite photocatalyst was made by X-ray diffraction (XRD, Philips Panalytical X'Pert-Pro) with CuKα tube at 45 kV and 40 mA and Field Emission Scanning Electron Microscopy (FESEM, Thermo Scientific Apreo 2 S LoVac) analysis.

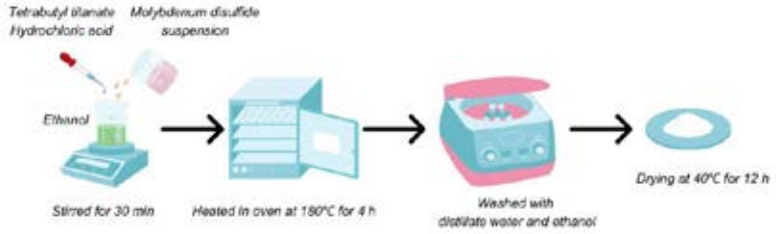

Fig. 1. TiO_2@MoS_2 Nanocomposite Synthesis with Sol-Gel Method

2.2. Solar-Driven Hydrogen Production Performance

Solar-driven hydrogen production (based on water splitting) was carried out in a batch type reactor set in solar simulator with a wavelength range between 400 and 1000 nm (FYTRONIX). In order to figure out the catalytic performance of composites under solar irradiation, hydrogen production was carried out using commercially available TiO_2 (Aeroxide, Fumed Metal Oxide), and MoS_2 as a catalyst. In a typical process, 200 mg of TiO_2, MoS_2, or TiO_2@MoS_2 was introduced to 120 ml water (25% methanol aqua solution) in hydrogen production. Methanol (Honeywell) was chosen as a sacrificial agent due to its capacity of limiting the formation of electron-hole pairs in the semiconductor via consuming valence band holes, hence increasing the H2 production efficiency of photocatalysts [10]. The photocatalytic performance was tested for 96 minutes, and hydrogen generation profile was plotted using evolved gas measured against to time.

3. RESULTS AND DISCUSSION

3.1. Characterization

The crystal structure of TiO_2@MoS_2 nanocomposites with different composition were determined by XRD analysis. XRD patterns are illustrated in Fig. 2. The peaks observed at 25.13°, 37.52°, 47.72°, and 54.27° are associated with (101), (004), (200), and (105) which are correlated to TiO_2's anatase phase and crystal plane of tetragonal, respectively (JCPDS card 04-014-0246) while corresponding peaks of MoS_2 are found at 14.39°, 39.58°, and 43.75° representing (003), (104), and (009) lattice planes. According to lattice planes, MoS_2 has a hexagonal crystal structure (JCPDS card 04-007-3026). The slight peak at 14.39° for TM3 and the absence of this peak in TM1 indicates the c-plane of MoS_2, which proves the successful formation of the layered S-Mo-S structure. The reason behind this might be due to the few layers and thinness of the MoS_2 nanosheets which makes it challenging to detect [11].

Additionally, the morphology of MoS_2, commercial TiO_2, and TM1 nanocomposite was evaluated by FESEM analysis (Figure 2). MoS_2 has nanosheet morphology (Figure 2b). When looking at similar FESEM results in the literature, it was observed that TiO_2 nanoparticles tend to agglomerate. Tang et al. (2022) noted that close interaction occurs between TiO_2 and MoS_2 nanoparticles due to TiO_2 agglomerations on the surfaces [9]. Furthermore, the study of Ciesielczyk et al. (2020) indicates that MoS_2 structures are covered by TiO_2 nanospheres owing to TiO_2's agglomeration affinity [12]. Considering these facts, Fig. 2.d demonstrates that agglomerated TiO_2 nanoparticles cover MoS_2 nanosheets.

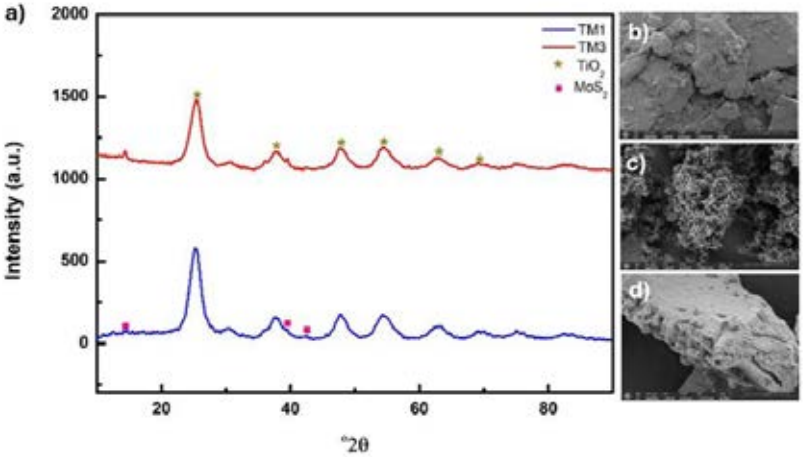

Fig. 2. a) XRD Patterns of TM1 and TM3, FESEM Images of b) Pure MoS_2, c) Pure TiO_2, and d) TiO_2@MoS_2 (TM1)

3.2. Solar-Driven Hydrogen Production Performance

The hydrogen production performance was evaluated under solar simulated irridation over 1.6 hours. The amounts of hydrogen produced in DW catalysize with MoS_2, TiO_2 and TM1 and TM3 coded TiO_2@MoS_2 composite photocatalysts are presented in μmol/$g_{catalyst}$ in Fig. 3.

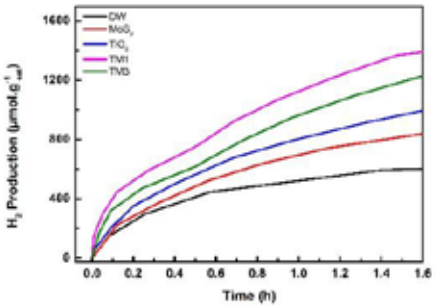

Fig. 3. Effect of MoS_2 Loading on Photocatalytic Hydrogen Production

According to Fig. 3, although the performance of the MoS_2 nanosheet is lower than that of TiO_2, its electrical, physicochemical, and mechanical properties have enhanced the rate of the water-splitting reaction when combined with TiO_2 in a composite form, resulting in hydrogen production that is 1.5 to 2 times greater in a shorter period. The highest hydrogen production (~1450 μmol.g^{-1}) was performed by TM1. While still, TM3 illustrated better hydrogen production (~1200 μmol.g^{-1}) than TiO_2 and MoS_2 which implies the importance of the inclusion of MoS_2.
To maximize hydrogen production, optimizing MoS_2 content in the composite has a substantial role. Depletion in hydrogen production efficiency may be due to excessive loading of MoS_2 in TM3 which could be as a result of aggregation or decreased light absorption. The hydrogen production profiles show a stable performance without major deactivation, suggesting good catalyst stability. On the whole, TiO_2@MoS_2 composites have been found to outperform the pure components, with the TM1 sample proving to be the most effective, emphasizing the potential of composite materials for efficient hydrogen production by water splitting.

4. CONCLUSIONS

In the study, TiO_2@MoS_2 nanocomposites at varying MoS_2 ratios (1% and 3%) were synthesized by the sol-gel method to generate green hydrogen via the photocatalytic water splitting method. Crystal structure, composite morphology, and hydrogen production performances were evaluated via XRD, FESEM, and solar simulator system. In accordance with XRD results TiO_2 particles showed an anatase phase with a tetragonal crystal phase while MoS_2 was revealed to be a hexagonal crystal phase. FESEM images illustrated that MoS_2 nanosheets were covered with agglomerated TiO_2 nanoparticles which was supported by the absence of a c plane of MoS_2. Finally, the most active catalyst was determined as TM1 due to the superb performance in the solar simulated irradiation in comparison to other catalysts.

ABSTRACT
Ammonia is increasingly being acknowledged as a versatile energy carrier, offering substantial promise for applications in low-carbon energy storage, transport, and electricity production. As a carbon-free fuel, ammonia offers several key advantages, making it a strong alternative for integrating renewable energy sources into existing energy infrastructures. The proposed methodology takes advantage of excess power generated during periods of high solar radiation or strong wind conditions to synthesize and store ammonia, which can then be used for power generation when energy availability is low. This approach enhances the flexibility and reliability of renewable energy systems by addressing the intermittency challenges associated with solar and wind power. A feasibility analysis was conducted based on the available energy sources, evaluating both the feasibility and cost-effectiveness of utilizing ammonia as a renewable energy storage and power generation solution. By leveraging its characteristics, ammonia can play a crucial role in enabling efficient long-term renewable energy storage, supporting grid stability, and facilitating a sustainable energy transition toward a low-carbon future. where ensuring a stable and secure, particularly during natural disasters and other emergency situations.

Keywords: Ammonia, Green hydrogen, Renewable, Feasibility

1. INTRODUCTION

The inevitable consequences of fossil energy sources have led to considerable damage to human health, well-being, and the environment. This situation has heightened the urgency for environmentally friendly and sustainable energy alternatives. According to the International Energy Agency (IEA), renewable energy sources are projected to account for 50% of the global primary energy supply by 2050, aligning with international efforts to mitigate these problems [1].Recent studies highlight the potential of hydrogen-based sources, which is widely regarded as an ideal synthetic source due to its clean combustion properties and versatility across various applications [2]. The most challenging problem to overcome in the adoption of hydrogen are storage and transportation requirements. Additionally, Hydrogen's high volatility, wide flammability range, and elevated explosion risk make it essential to implement rigorous safety protocols and advanced containment technologies [2]. As a result, over time, several alternatives have been proposed to serve as hydrogen carriers. Among these options, ammonia stands out as a promising candidate due to its high hydrogen content, ease of liquefaction, and existing global infrastructure. Its ability to store and transport large quantities of hydrogen in a stable form makes ammonia an attractive solution for addressing the challenges associated with hydrogen storage and distribution [1,3]. Projections indicate that over the next 10 years, the global ammonia market is expected to expand by approximately 3%, positioning ammonia as a viable alternative to conventional fuels [4]. Beyond its safety benefits, ammonia plays a crucial role in optimizing renewable energy utilization, particularly for intermittent sources like wind and solar power. By storing renewable energy in the form of chemical fuels, ammonia enables efficient long-term energy storage and facilitates transportation over extended distances, thereby supporting the development of a more sustainable energy infrastructure [3]. In the context of ammonia production, it is important to note that existing ammonia synthesis technologies are fully mature and widely deployed on an industrial scale. However, under current production pathways, ammonia cannot be classified as green, as the majority of its production still relies on fossil fuel-based hydrogen generation, primarily through steam methane reforming (SMR) [5].

Green ammonia is synthesized via the Haber-Bosch process, in which hydrogen, derived from electrolysis, is combined with nitrogen extracted from the air. Unlike conventional ammonia production, the entire process is powered by renewable energy sources, making it a carbon-free and sustainable alternative. This approach significantly reduces greenhouse gas emissions and aligns with global efforts toward achieving a net-zero carbon economy [6].

Numerous researchers have conducted techno-economic assessments to evaluate the viability of green ammonia production, analyzing its economic feasibility, energy efficiency, and potential role in the global shift towards sustainable energy systems [7–10]. These studies focus on various production pathways, cost factors, and integration strategies to determine how green ammonia can be scaled efficiently and competitively [11–13]

Some other studies explore the potential development as a fuel source by examining multiple fuel production plants, utilizing aggregated data, and modeling the entire energy system at a regional or national level. These studies aim to assess the feasibility, scalability, and impact of integrating synthetic fuels into existing energy and transportation infrastructures [14–16].

The decarbonization of the power and transportation sectors through green ammonia will require the development of strategic transition pathways that ensure its practical and economically viable implementation in real-world applications.

Successfully integrating green ammonia into the energy system involves overcoming several key barriers, which can be categorized into economic, technical, and political challenges [1]. Addressing these challenges through technological advancements, policy support, and economic incentives will be essential for unlocking the full potential of green ammonia in achieving a low-carbon energy future.
In regions susceptible to severe earthquakes, maintaining a reliable and resilient energy supply is crucial for emergency response and recovery efforts. In this study, green ammonia, as an energy carrier, serves as an effective hydrogen energy carrier in such disaster-prone areas due to its storage efficiency, transportability, and safety advantages over conventional hydrogen storage methods. When assessing the most efficient pathway for green ammonia production, it is essential to consider key factors that influence its economic viability and sustainability. By carefully evaluating these factors, the most cost-effective and scalable strategies for integrating green ammonia into the global energy transition can be provided [3]. The renewable power generation technologies analyzed in this study include onshore wind turbines and fixed-axis solar panels. By integrating location-dependent energy profiles into the analysis, this study provides a realistic assessment of how different renewable sources can be optimized for green ammonia production, ensuring cost-effective and reliable energy supply for large-scale applications [17].

2. MATERIALS AND METHODS

Ammonia is predominantly utilized in the agriculture sector as a fertilizer, playing a crucial role in crop production. Additionally, it is widely employed as a refrigerant due to its efficient cooling properties. Beyond these traditional uses, ammonia has gained attention as a potential fuel source, particularly in engines and fuel cells, where it is being explored for its feasibility in sustainable energy systems[4]. Ongoing research continues to investigate its viability as a carbon-free alternative for power generation and transportation applications. At present, hydrogen production for ammonia synthesis is predominantly achieved through the natural gas reforming process, which presents significant challenges due to its high costs and negative environmental impacts, primarily linked to fossil fuel dependency. One of the main drivers for innovation in this field is the effort to replace fossil fuels with renewable energy (RE)-based hydrogen production, enabling the creation of clean ammonia. Figure 1 highlights the various green ammonia production pathways powered by renewable energy sources [17].

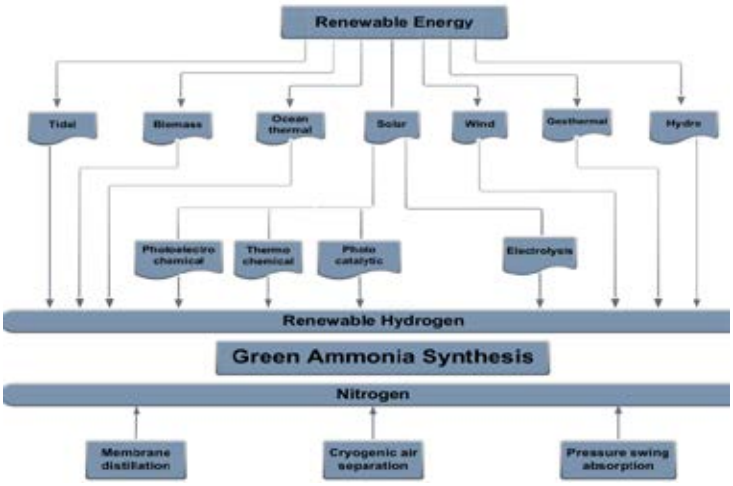

Fig. 1. Green ammonia production pathways [3]

In recent years, global ammonia production has experienced significant growth. Among the various techniques used in ammonia synthesis, the cryogenic air separation process is the most widely industrialized, allowing for bulk production of ammonia at a lower cost and higher efficiency. Another method called as Haber-Bosch process can be utilized method for large-scale ammonia production due to its well-established infrastructure and widespread adoption in the industry. However, ongoing advancements in cryogenic separation and alternative ammonia synthesis technologies continue to improve efficiency and sustainability in the sector [4]. The synthesis of ammonia follows an exothermic reaction between nitrogen (N_2) and hydrogen (H_2), which is represented by Eq. (1).

$$N_2 + 3H_2 \rightarrow 2NH_3 \quad (1)$$

Ammonia is classified as "green" when its production process is entirely carbon-free and relies 100% on renewable energy sources (excluding emissions from embodied systems). This method forms the basis of the Haber-Bosch process, which remains the primary method for industrial ammonia production. Ongoing researches focuses on identifying more sustainable alternatives to reduce carbon emissions and energy consumption in the process [18]. Haber-Bosch (H–B)

method differs in that the energy required for hydrogen production is derived from renewable energy sources (RES) rather than fossil fuels, as used in conventional centralized H–B technology. This transition significantly reduces carbon emissions, making ammonia production more sustainable and environmentally friendly. Additionally, the nitrogen (N_2) supply in this process is obtained using proven air separation technologies, such as cryogenic distillation or pressure swing adsorption (PSA), ensuring a reliable and efficient nitrogen source for ammonia synthesis. This approach supports the shift toward green ammonia production, aligning with global efforts to decarbonize industrial processes and promote sustainable energy solutions [19]. The general application framework of this method is illustrated in Figure 2.

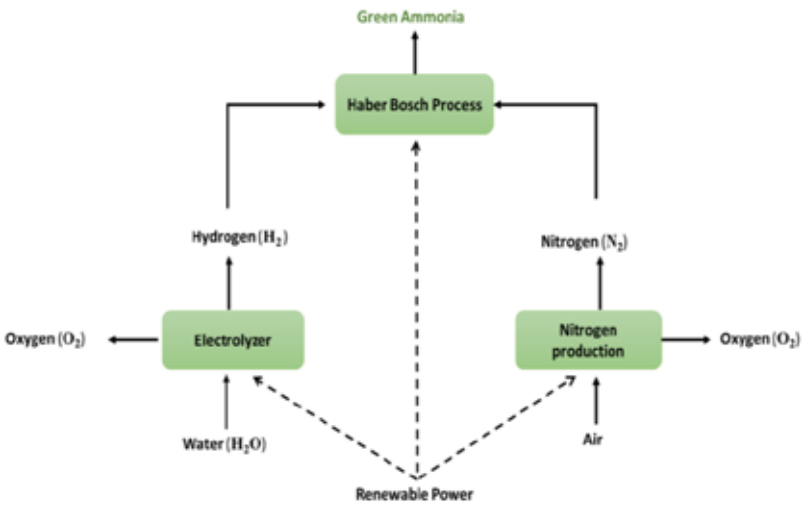

Fig. 2. The general application framework of green ammonia production [3]

3. RESULTS AND DISCUSSION

The technical and economic feasibility of green ammonia production depends on several key factors that influence its cost-effectiveness and long-term viability. One of the primary considerations is the production method selected, as different technological approaches impact both capital investment and operational efficiency. The initial costs of establishing green ammonia production facilities, including electrolyzers, renewable energy infrastructure, and synthesis units, play a significant role in determining financial feasibility. While green ammonia requires a high initial investment, particularly for infrastructure and technology deployment, it offers lower daily operational costs compared to conventional fossil fuel-based ammonia production methods. This is largely due to the absence of fuel costs associated with natural gas reforming and the potential for low-cost renewable electricity to power the process. When evaluating the most efficient pathway for green ammonia production, it is crucial to account for key factors that influence its economic feasibility and sustainability. Key factors factors encompass the accessibility of renewable energy sources, the development of infrastructure for ammonia storage and distribution, and the economic viability of hydrogen production via electrolysis. This study focuses on Elazığ, a city located in the Eastern Anatolia Region of Turkey, as a strategic location for the production and storage of green ammonia as an alternative energy source. Elazığ's geographical and seismic characteristics, along with its exposure to natural disasters, make it an ideal candidate for developing resilient energy solutions that can support disaster preparedness and emergency response efforts. The geographical location of the selected region, along with the system configuration for ammonia production, is illustrated in Figure 3.

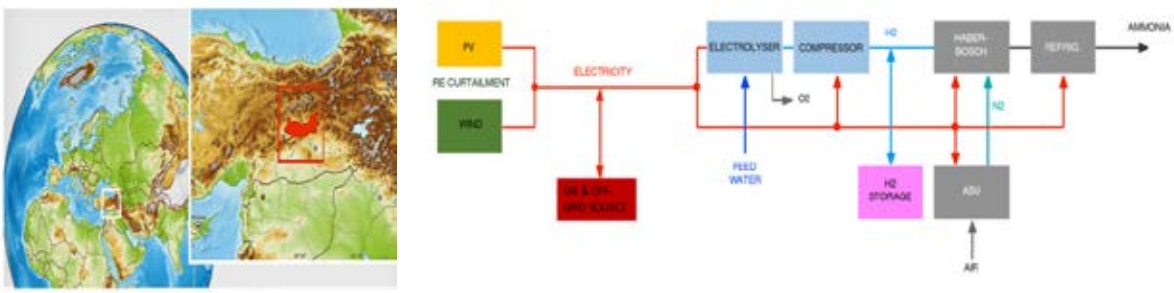

Fig. 3. The general application framework of green ammonia production

The figure provides a visual representation of how Elazig's regional characteristics align with the technical setup required for green ammonia production and storage**.** The selected location was chosen based on its potential for renewable energy integration, particularly from solar and wind resources, which are essential for powering the electrolysis process and

Haber-Bosch process. The economic viability of green ammonia production is influenced by several key factors, including initial capital investment, daily operational expenses, and long-term cost savings. Despite the high capital expenditure (CAPEX), the daily operational costs (OPEX) of green ammonia production are generally lower compared to traditional fossil fuel-based ammonia production. This is due to the elimination of natural gas dependence, as renewable energy sources (solar, wind, or hydropower) can be utilized to generate hydrogen through electrolysis. Additionally, maintenance costs for renewable-powered ammonia plants are expected to be lower than fossil fuel-based alternatives, contributing to overall cost efficiency in the long run.

4. CONCLUSIONS

The decarbonization of the transportation and power generation sectors and the reduction of fossil fuel dependency can be achieved by developing alternative green fuels derived from clean energy sources. Among these alternatives, green ammonia has recently emerged as a promising hydrogen energy carrier, offering a carbon-free solution for energy storage and utilization. While hydrogen is a promising clean fuel, its storage, transport, and distribution present significant technical and economic challenges. Ammonia, as a hydrogen carrier, offers key benefits that enhance the feasibility of hydrogen-based energy systems at both domestic and global scales. As advancements in production, storage, and transportation technologies continue, expected to play a significant role in energy transition initiatives, particularly in power generation, industrial applications, and the transportation sector. This study focuses on the production of ammonia as a key milestone in the transition to a hydrogen economy, analyzing its technical and economic feasibility across selected regions. The findings will contribute to the development of resilient cost-effective energy infrastructure in Türkiye and neighboring regions, where ensuring a stable and secure energy supply is essential, particularly during natural disasters and other emergency situations. Future research should focus on the cost analysis and feasibility of ammonia transportation and distribution via pipelines across different regions.

ABSTRACT
Induction machines are widely employed in industry due to their low cost, high starting torque, and minimal maintenance requirements. In contrast, synchronous machines, designed to operate either as motors or generators, offer advantages such as constant-speed operation and the relatively straightforward implementation of vector control methods, despite their higher expense and maintenance demands. Hydrogen energy, unlike other renewable sources, provides uninterrupted power generation independent of environmental conditions. In applications that demand both high starting torque and constant speed, particularly in remote installations with limited grid connectivity, the combined benefits of induction and synchronous motors become crucial. This paper investigates the conditions under which an induction motor can operate in synchronous mode, implements a hydrogen fuel cell model to power the system, and applies a vector control strategy. A simulation model incorporating both the detailed PEM fuel cell dynamics and the three-phase induction motor's phase-variable model is developed and analyzed.
Keywords: Hydrogen Fuel Cell, Synchronized Induction Motor, Vector Control, Phase Variable Modeling

1. INTRODUCTION

Induction motors are favored in industrial applications primarily due to their economical design and low maintenance requirements. However, these machines inherently operate below synchronous speed, which limits their performance in applications requiring strict speed constancy. In contrast, synchronous machines, although costlier and demanding continuous maintenance, provide stable rotational speeds and simplify the implementation of advanced control methods such as vector control.

Originally, the concept of synchronizing a wound-rotor induction motor was proposed by Danielson in 1901 [1] to improve power factor, and subsequent work in England led to the term "British Machine" [2]. Recent studies have focused on high-conductivity synchronized induction motors and self-excited variants [3]–[5]. Moreover, integrating hydrogen fuel cells—a renewable energy source capable of delivering continuous power regardless of ambient conditions—further enhances the applicability of such motor drives in isolated installations.

2. METHODOLOGY AND SYSTEM MODELING

This paper presents an in-depth analysis of the synchronization techniques for induction motors, with a particular emphasis on the Danielson rotor connection. It also details the development of a phase-variable model for the motor, the integration of a detailed PEM fuel cell model, and the implementation of a vector control strategy to regulate speed.

2.1 Phase Variable Modeling of the Induction Motor

A critical initial step in engineering analysis is the formulation of a mathematical model that closely represents the physical system. The phase-variable approach offers significant advantages since the variables directly correspond to measurable physical quantities (currents, voltages, and torque), thereby enabling the direct analysis of transient responses without the need for coordinate transformations [3].

In this study, the dynamic behavior of a three-phase wound-rotor induction motor is modeled using phase variables. The voltage equations for the stator and rotor can be expressed as:

$$[V_{s,r}] = [R_{s,r} I_{s,r}] + [L_{s,r}]\left[\frac{di_{s,r}}{dt}\right] + \left[\frac{dL_{s,r}}{d\theta}\right][i_{s,r}]\left[\frac{d\theta}{dt}\right] \quad (1)$$

Here, $[L_{s,r}]$ denotes the inductance matrix defined via flux linkages, while $[R_{s,r}]$ is the diagonal resistance matrix of the windings. Under the assumption of sinusoidal winding distribution, the effects of slot harmonics and air-gap variations are neglected.

The mechanical dynamics of the motor are given by:

$$\frac{d\omega_m}{dt} = \frac{1}{j}\left(T_d - T_y\right) \quad (2)$$

Furthermore, the rotor's angular position is defined by:

$$\omega = \frac{d\theta}{dt} \quad (3)$$

and the induced torque is calculated as:

$$T_d = -\frac{P}{2} M_{sr} \left((i_{ra} i_{sa} + i_{rb} i_{sb} + i_{rc} i_{sc}) \sin\theta + (i_{ra} i_{sb} + i_{rb} i_{sc} + i_{rc} i_{sa}) \sin\left(\theta - \frac{2\pi}{3}\right) + (i_{ra} i_{sc} + i_{rb} i_{sa} + i_{rc} i_{sb}) \sin\left(\theta + \frac{2\pi}{3}\right) \right) \tag{4}$$

Table 1 below summarizes the motor parameters used in the simulation [3]:

Table 1. Summary of IHTEC2025 formatting details

P_g = 150 W	U = 220 V	f = 50 Hz	p = 4
R_r = 211 Ω	R_s = 109.399 Ω	L_{ls} = 0.158 H	L_{lr} = 0.158 H
L_m = 1.579 H	J = 1.521e-3 kg.m/s^2	B = 0	

2.2. The Danielson Synchronization Technique

One effective method to achieve synchronous operation without modifying the motor's physical structure is the Danielson connection. In this technique, multiple rotor winding connection schemes are available; some require specific design modifications while others can be retrofitted to existing wound-rotor motors.

During startup, the rotor windings are connected through external resistors (referred to as "starting resistors") to provide a high starting torque. Once the rotor speed approaches the synchronous speed (typically around t=2t = 2t=2 s in simulations), the starting resistors are bypassed, and the appropriate excitation voltage is applied to the rotor windings following the Danielson connection scheme. This transition enables the motor to operate at synchronous speed while maintaining the high-torque characteristics of an induction motor [1],[3], [6-8].

A schematic of the rotor winding connection in the Danielson method is illustrated in Fig. 1.

a) **b)**

Fig. 1. Rotor winding connection in the Danielson method

a) Starting b) Synchronous Operation

3. MODELING THE HYDROGEN FUEL CELL

Hydrogen fuel cells convert the chemical energy stored in hydrogen directly into electrical energy through electrochemical reactions. In a Polymer Electrolyte Membrane (PEM) fuel cell, hydrogen is split at the anode into protons and electrons; the protons traverse a semi-permeable membrane, while the electrons generate current via an external circuit. At the cathode, oxygen reacts with protons and electrons to form water and heat.

3.1 Fundamental Equations

The overall reaction can be summarized as:

$$H_2 + \frac{1}{2} O_2 \rightarrow H_2O + heat \tag{5}$$

Subsequently, the Nernst voltage (E) is calculated by:

$$E = \begin{cases} K_c N \left(1.229 + K_z \frac{RT}{zF} \ln\left(p_{H_2} p_{O_2}^{\frac{1}{2}} \right) \right) - E_{\text{Tafel}} - E_{\text{conc}}, T < 373.15\text{K} \\ K_c N \left(1.229 + K_z \frac{RT}{zF} \ln\left(\frac{p_{H_2} p_{O_2}^2}{p_{H_2O}} \right) \right) - E_{\text{Tafel}} - E_{\text{conc}}, T \geq 373.15\text{K} \end{cases} \tag{6}$$

Here, the parameters defined based on nominal conditions of operation [9-12].

4. VECTOR CONTROL OF THE SYNCHRONIZED INDUCTION MOTOR

4.1 System Overview

For locations with limited grid access and where maintenance activities are severely restricted, powering motor drives with hydrogen fuel cells is an attractive solution. Such a configuration eliminates dependency on external energy sources while leveraging the maintenance-free operation of induction motors. Once synchronized, the motor benefits from the constant speed characteristics of synchronous machines, making it ideal for applications that require both high starting torque and precise speed regulation.

4.2 Implementation of Vector Control

A vector control method is directly applied to the phase-variable model to regulate motor speed. By comparing a reference speed with the measured rotor speed, an error signal is generated and used to compute the required reference currents. These currents are then transformed into three-phase (abc) signals via an inverse Park transformation to drive the inverter. The result is a synthesized stator voltage that enables rapid and precise speed tracking even under varying load conditions.

5. SIMULATION RESULTS

The motor, initially loaded with 0.1 Nm, undergoes a transition to synchronous operation at approximately 2 s when the Danielson method is activated. At 4 s, a load increase to 0.2 Nm is introduced, and at 6 s the vector control system adjusts the speed to a target of 120 rad/s. The simulation confirms that the hydrogen fuel cell supplies the expected electrical outputs, that the motor reliably achieves synchronous operation, and that the vector control ensures smooth torque and current responses.

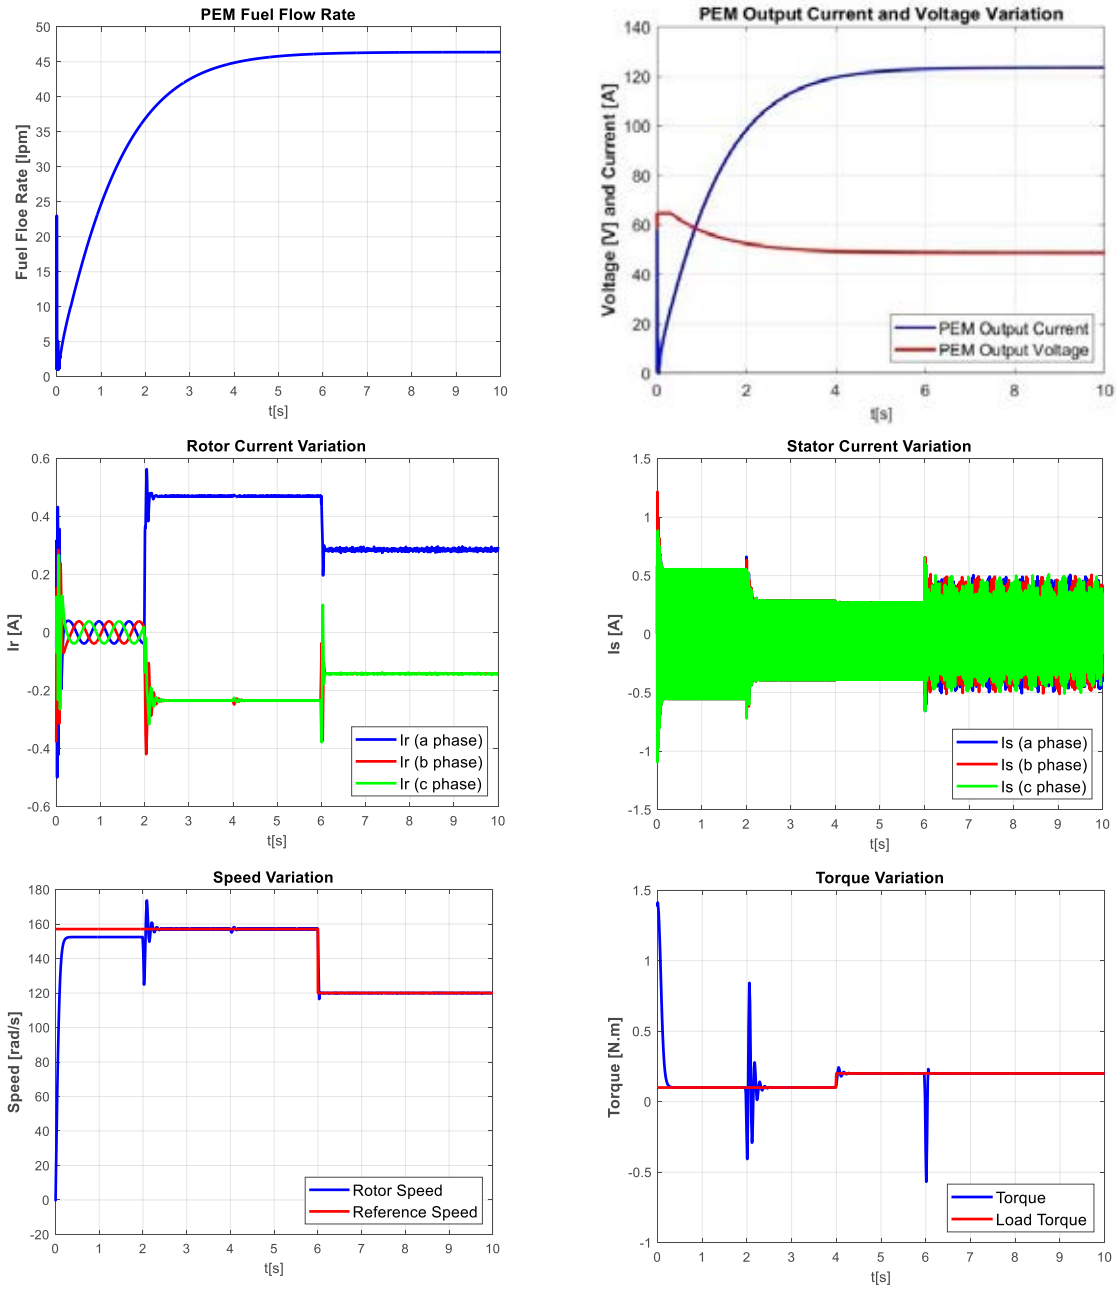

Fig. 4 Simulation results of the proposed model

6. CONCLUSION AND RECOMMENDATIONS

The study demonstrates that converting an induction motor to synchronous operation using the Danielson rotor connection is both feasible and effective. Coupling the motor with a hydrogen fuel cell offers a robust solution for off-grid applications, while the direct implementation of vector control on the phase-variable model guarantees accurate speed regulation. This integrated system is recommended for industrial applications requiring both high starting torque and precise, constant-speed performance in remote locations.

ABSTRACT
The negative environmental impact of transportation remains a critical challenge for urban areas, requiring a shift toward sustainable mobility solutions to reduce emissions and improve energy efficiency. In this context, the production, storage, and utilization of hydrogen have gained increasing importance in the global energy transition, providing a clean and viable alternative to conventional transportation system. This study focuses on the technical and economic evaluation of a hydrogen-fueled transportation system within a university campus, serving as a case study for urban transit applications. The analysis examines key performance metrics, including operational cost and infrastructure requirements, providing insights into the feasibility of hydrogen-based public transportation in controlled urban environments. The findings contribute to a broader understanding of how hydrogen mobility solutions can be effectively integrated into sustainable urban transport networks.

Keywords: Public transport, Hydrogen, Hydrogen Buses, transportation

1. INTRODUCTION

A logical and sustainable approach in the energy sector involves the increased adoption of renewable energy sources to reduce dependence on fossil fuels and mitigate environmental impacts. However, the pursuit of sustainability should not be confined solely to energy production but must extend to other high-emission industries, particularly transportation, which remains a major contributor to air pollution and greenhouse gas (GHG) emissions. A critical green solution in transportation is the replacement of conventional diesel- and petrol-powered vehicles with electric or hydrogen-powered alternatives. The transition to zero-emission transport technologies presents significant environmental and economic benefits. Advancing clean transportation technologies alongside renewable energy integration is essential for building a sustainable, low-carbon economy, ensuring energy security, and fostering long-term environmental resilience[1,2]. One of the most promising applications is hydrogen usage as a fuel for vehicles, offering an environmentally friendly transportation solution that supports the transition to low-emission mobility systems. Hydrogen-powered transportation not only contributes to carbon footprint reduction but also enhances energy security and efficiency [3]. The advantages of hydrogen energy position it as a highly viable option for urban transportation, particularly in areas where environmental noise pollution and traffic congestion are significant concerns. Given these, hydrogen-based transportation solutions can play a crucial role in developing cleaner, quieter, and more efficient urban mobility systems, aligning with sustainable city initiatives and climate action goals.

As transportation remains a major contributor to greenhouse gas (GHG) emissions, transitioning to clean mobility solutions is essential for achieving global sustainability targets. Numerous studies explore and analyze the concept of ecological and sustainable transportation, emphasizing its role in reducing carbon emissions, improving air quality, and enhancing energy efficiency. The transition toward sustainable mobility solutions is driven by the need to mitigate environmental impacts caused by conventional fossil-fuel-based transport systems [4–8]. In addition to technical, economic, and feasibility studies, research is also being conducted on the environmental sustainability of green ammonia production and utilization [9]. In contrast to the extensive body of research focused on electric-powered vehicles, the literature on hydrogen-powered vehicles remains relatively limited. Despite this, interest in hydrogen-powered buses has been steadily growing driven by advancements in hydrogen production, fuel cell technology, and policy incentives promoting low-emission public transportation. The identified research gap is the lack of a thorough techno-economic analysis regarding the investment in hydrogen-powered buses, especially within the context of a specific campus area. This gap encompasses critical aspects such as infrastructure requirements, investment and operational costs, and optimal bus routes that maximize the utilization of locally produced hydrogen. To analyze the prospects and key challenges associated with the increased adoption of hydrogen powered buses. The study places special emphasis on economic and technical performance, along with the environmental impact of these buses.

2. MATERIALS AND METHODS

Road transport accounts for the largest share of energy consumption within the transport sector, representing approximately 75% of global transport energy demand. Consequently, it is a major contributor to greenhouse gas (GHG) emissions, with road vehicles alone responsible for 15–20% of total global CO_2 emissions. This translates to an estimated 3 gigatonnes (Gt) of CO_2 emissions annually from passenger vehicles worldwide, significantly impacting climate change and air quality. [10]. The graph in Figure 1 illustrates the global changes in energy consumption and carbon dioxide (CO_2)

emissions based on different transportation technologies.

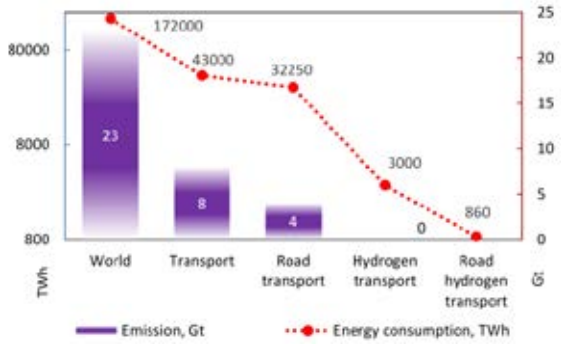

Fig. 1. Energy consumption and carbon emission values for different transportation technologies

This comparison underscores the environmental impact and efficiency of different vehicle technologies, emphasizing the need for sustainable alternatives in the transport sector. As illustrated in Fig. 1, hydrogen-based transportation technologies achieve the most favorable results in terms of both carbon emissions reduction and energy efficiency on a global scale. These findings highlight hydrogen's pivotal role in driving the transition toward a clean and sustainable transportation system. [10]. Furthermore, hydrogen-based transport systems have the potential to enhance energy security by reducing dependence on oil imports and leveraging locally produced green hydrogen from renewable energy sources such as solar and wind power. By integrating hydrogen refueling infrastructure with existing energy grids and mobility networks, the long-term scalability and feasibility of hydrogen-powered mobility solutions can be further optimized.

Although hydrogen and fuel cell technologies have a wide range of applications, they are increasingly emerging as a viable alternative to both conventional and battery-electric large vehicles, particularly for those requiring an extended driving range, such as buses. One of the key advantages of hydrogen-powered buses is their operational efficiency in urban transit systems. Since these buses regularly return to a central depot, their deployment can be achieved with minimal refueling infrastructure, making them a practical and scalable solution for public transportation networks. Additionally, they produce low or zero emissions, significantly improving their competitiveness compared to diesel-powered counterparts. By eliminating harmful pollutants, they help mitigate urban air pollution, contributing to healthier and more sustainable cities. Hydrogen-powered buses can be classified into three main configurations, each utilizing hydrogen as an energy source in different ways: Hydrogen-Powered Internal Combustion Engine (H2-ICE) Buses, Fuel Cell Buses, Hybrid Fuel Cell Buses. Fig. 2 illustrates the three primary configurations of hydrogen-powered buses.

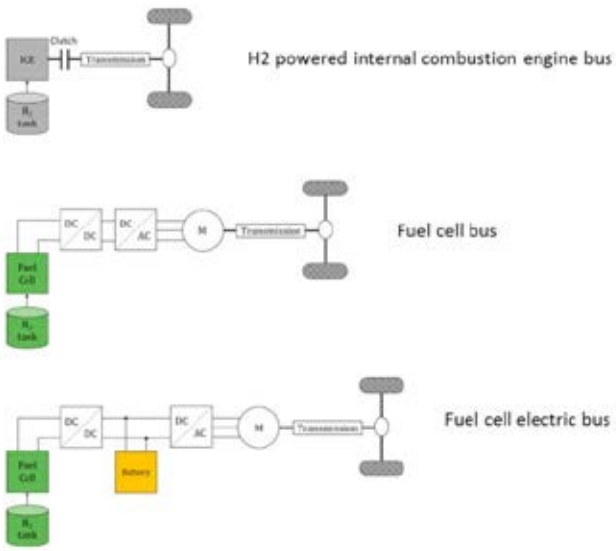

Fig. 2. Three configurations of hydrogen buses

Hydrogen-Powered Internal Combustion Engine (H_2-ICE) buses operate using modified internal combustion engines that burn hydrogen instead of conventional fossil fuels. While they still produce some NO_x emissions, they eliminate CO_2 emissions, making them a cleaner alternative to diesel buses.Unlike conventional battery-electric vehicles (BEVs), which

store energy solely in lithium-ion batteries, fuel cell electric vehicles (FCEVs) generate electricity on demand by converting hydrogen and oxygen into electricity through an electrochemical process [1]. Hybrid Fuel Cell Buses are a type of vehicle that utilize a fuel cell either as a standalone power source or conjunction with a battery or supercapacitor to power an onboard electric motor. Hybrid buses are particularly promising for urban and long-range applications, as they enhance fuel efficiency, reduce hydrogen consumption, and extend battery life, making them a sustainable and cost-effective solution for public transportation. Fig. 3 illustrates the process of producing hydrogen fuel to supply the buses.

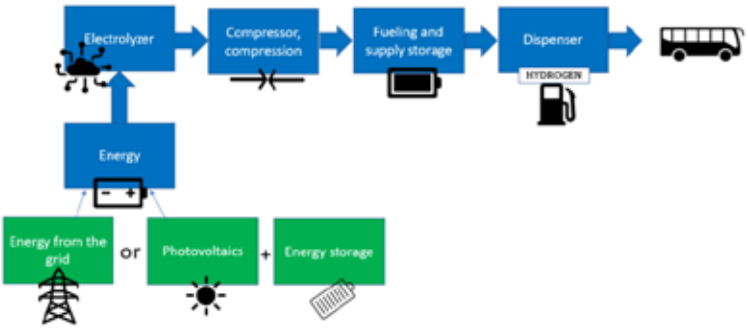

Fig. 3. Hydrogen fuel configuration supply

The integration of hydrogen technology with renewable energy sources (RES) enhances energy resilience and adaptability, ensuring the efficient utilization of renewable energy in both transportation and stationary applications. By coupling hydrogen production with RES, such as solar, wind, and hydropower, it is possible to store excess renewable energy and deploy it on demand, addressing the intermittency challenges of renewable generation [3]**.** In this study, the station infrastructure includes an electrolyzer, compressor, fueling supply and storage units, and dispensers, together forming a comprehensive hydrogen production and distribution system [11]. By combining hydrogen refueling and electric infrastructure, these hybrid stations can optimize energy distribution, improve grid stability, and support the decarbonization of mobility

3. RESULTS AND DISCUSSION

The high initial costs of Hybrid Fuel Cell Buses (HFCBs) compared to conventional diesel buses remain a major barrier to their widespread adoption. The total cost of mobility for buses is determined by evaluating investment costs (IC), annual distance traveled (d), energy costs (CE), and operating and maintenance costs (CO&M). The total cost per kilometer (TCK) is given by the following equation:

$$TCK = \frac{IC_{i,a}}{d}(C_{ei}) + \frac{CO\&Mi}{d} \text{ [\$/km]]} \quad (1)$$

where $IC_{i,a}$ represents the annualized investment costs, C_{ei} denotes the energy costs, and $CO\&Mi$ accounts for operating and maintenance expenses. The capital recovery factor (α) is calculated based on the discount rate (r) over the analysis period (n) using the formula:

$$\alpha = \frac{(1+r)^n \times r}{(1+r)^n - 1} \qquad C_{ei} = E_i \times P_{ei} \; [\$/km] \quad (2)$$

The energy cost (C_{ei}) depends on the average energy consumption of the buses (E_i) and the price of the corresponding energy source (P_{ei}) The cost analysis includes key financial factors such as investment costs (IC), annual driven distance (d), energy costs (CE), and operation and maintenance expenses (CO&M). The breakdown provides a comparative assessment of different bus technologies. It is evident that the investment costs of HFCBs remain significantly higher than those of diesel buses and battery electric buses (BEBs), making them less competitive in the current market. In addition to the high initial capital costs, HFCBs also face elevated fuel costs due to the high price of hydrogen, further impacting their overall economic feasibility. The departure and arrival routes of the hydrogen-powered bus operating within Fırat University's campus in Elazığ are illustrated in Fig. 4.

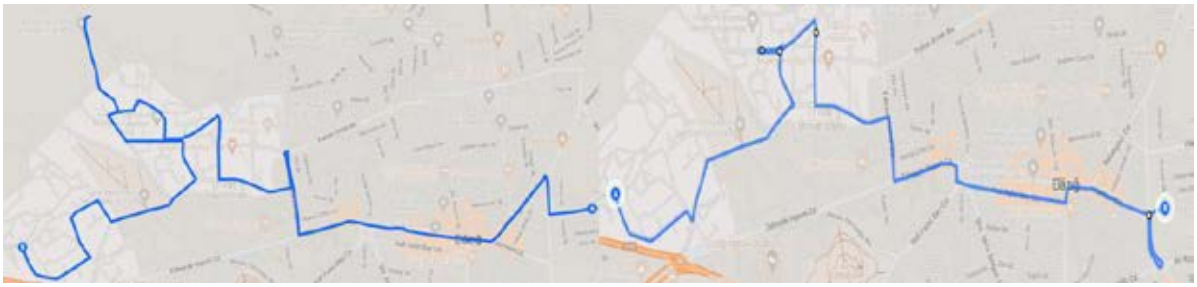

Fig. 4. The departure and arrival routes of the proposed study

The strategic location of the campus area, particularly in terms of existing energy infrastructure and accessibility to renewable energy sources, presents significant advantages for the implementation of hydrogen-fueled vehicles. A fuel station possibility integrated with both renewable energy sources and the electric grid further supports the feasibility of this clean transportation solution. The bus route spans approximately 10 kilometers, with most of the journey occurring within the university's campus boundaries. The two transportation routes include the number of stops, service frequency, and geographic positioning etc. These variations make them ideal for conducting a comparative analysis of vehicle performance under different real-world operating conditions. This controlled environment allows for optimized operational efficiency, making it an ideal case study for assessing the technical and economic feasibility of hydrogen-powered public transportation.

4. CONCLUSIONS

Public bus transportation is currently dominated by diesel-powered buses. Although these vehicles have seen considerable improvements over the years, they should ultimately be replaced by more environmentally friendly alternatives, such as hydrogen-powered buses and battery electric buses to reduce environmental impacts and support sustainable urban mobility. This study focuses on the technical and economic evaluation of a hydrogen-fueled transportation system within a university campus, serving as a case study for urban transit applications. By analyzing the feasibility, cost-effectiveness, and operational efficiency of hydrogen-powered public transportation, the research aims to provide insights into the potential advantages and challenges of integrating zero-emission vehicles into similar institutional and urban settings. As production methods improve, economies of scale and advancements in electrolysis and hydrogen storage are expected to lower hydrogen costs, making this technology more economically viable in the long term. The integration of renewable energy sources, particularly in hydrogen production, is also expected to have a catalytic effect in further reducing operational costs. Studies suggest that vehicles refueled from stations incorporating both electricity and hydrogen infrastructure will create even greater cost reductions over time. By utilizing green hydrogen, the transition toward low-carbon mobility can be accelerated while also supporting economic growth and energy security.

ABSTRACT

This research investigates the preparation of Ni-B, Ni-Co and Ni-Zn doped electrodes and the evaluation of their hydrogen production activity under alkaline conditions. The electrolyte compositions included nickel, cobalt, and zinc sulfates (10 wt.%) and chlorides (3 wt.%), with a constant boric acid concentration (1 wt.%). Electrode preparation was conducted under controlled conditions, maintaining an applied voltage of 4.5 V and a bath temperature of 60°C. The impact of doping agents on electrode efficiency and hydrogen evolution was systematically evaluated in a 20 wt.% KOH alkaline solution at an applied potential of 2.3 V. The findings indicated that Ni-Co doped electrodes exhibited the highest hydrogen evolution rate, achieving 0.08 mL/s at room temperature. The analysis revealed that electrodes doped with cobalt (Co) and zinc (Zn) demonstrated significantly enhanced hydrogen production activity compared to those doped solely with Ni. The results underscore the potential of doped electrode systems in enhancing membraneless alkaline electrolysis, offering a promising strategy for improving hydrogen generation in sustainable energy applications.

Keywords: Doping Agent; Nickel Electrodes; Hydrogen Production; Alkaline Electrolysis; Electrolyte Composition

1.INTRODUCTION

The global energy demand has become a critical issue in constructing a sustainable future. In this context, Green Deal policies play a pivotal role in transitioning towards clean energy sources, forming the cornerstone of climate change mitigation strategies [1]. The significance of the transition to green energy extends beyond merely reducing fossil fuel dependency; it also contributes significantly to mitigating environmental pollution. Within this framework, hydrogen energy emerges as one of the most promising components of the green energy transformation. In particular, alkaline water electrolysis (AWE) has gained considerable attention due to its potential to utilize electrical energy to dissociate water molecules, sustainably generating hydrogen gas. This process offers a revolutionary approach to energy storage and transportation, particularly when powered by renewable energy sources. Currently, hydrogen production holds a crucial position among sustainable energy solutions, serving as a cornerstone for environmentally friendly fuel alternatives. In this regard, intensive research is being conducted on both alkaline electrolysis and electrocatalyst development strategies to enhance efficiency and scalability. Alkaline water electrolysis involves the decomposition of water (H_2O) into hydrogen (H_2) and oxygen (O_2) through an applied electric current, making it a well-established and cost-effective method [2]. However, optimizing electrocatalysts is of paramount importance to improve electrolyzer performance, reduce energy consumption, and enhance reaction kinetics [3]. Advances in electrocatalyst materials, particularly those based on transition metal oxides, perovskites, and nanostructured alloys, have demonstrated significant potential in lowering overpotentials and increasing hydrogen production efficiency.

The focus of this research is to enhance the efficiency of the alkaline water electrolysis (AWE) by delving into the interplay between alkaline electrolysis and electrocatalyst engineering. By investigating the latest developments in catalyst design, electrode structures, and reaction mechanisms, this study aims to pave the way for advanced electrolyzers capable of significantly improving hydrogen production efficiency. Nickel, zinc, and cobalt were chosen for their unique properties that make them excellent candidates for nanostructured alloys in enhancing the efficiency of hydrogen production by water splitting [4]. These elements have shown promise in lowering overpotentials and increasing AWE efficiency, making them ideal for electrocatalyst engineering in alkaline electrolysis. By exploring the interplay between these materials and electrode structures, this research aims to advance the development of electrolyzers with improved hydrogen production efficiency. Ultimately, these advancements will play a crucial role in accelerating the transition toward a more sustainable and scalable hydrogen-based energy economy.

The ”election of nickel (Ni), zinc (Zn), and cobalt (Co) for electrochemical deposition In the fabrication of electrocatalysts for alkaline water electrolysis is based on their distinct electrochemical properties, catalytic performance, and environmental considerations. Nickel (Ni), zinc (Zn), and cobalt (Co) coatings are transition metals commonly used in electrocatalytic hydrogen production processes, each offering different electrochemical advantages. The selection of these metals has been made under the principles of electrocatalytic performance, chemical stability, and sustainability. Nickel is widely used in alkaline electrolysis systems due to its high electrical conductivity and effectiveness in alkaline

water electrolysis (AWE). Additionally, nickel coatings provide corrosion resistance, extending the lifespan of the electrocatalyst [5]. Zinc is an abundant and recyclable metal found in nature, and it is considered one of the environmentally friendly alternatives in electrochemical coatings [5]. Zinc coatings can improve the reaction mechanism by optimizing the binding energy of hydrogen on the electrocatalyst surface and stand out as a sustainable choice due to their low cost. Cobalt has high electrocatalytic activity for AWE and is preferred in electrocatalysis applications due to its electrochemical stability and ability to operate over a wide pH range [7]. However, its environmental impact can be reduced by using cyanide-free plating solutions. From the perspective of green electroplating, these three metals can be coated with cyanide-free solutions to minimize the formation of toxic waste, thereby producing sustainable and environmentally friendly electrocatalysts. The individual coating of nickel, zinc, and cobalt allows for the optimization of each metal's specific electrochemical properties compared to alloys. This choice has been made in line with the goals of developing low-cost, high-efficiency, and environmentally friendly electrocatalysts.

Table 1. Evaluation of Three Different Metals in Terms of Green Electroplating

Metal	Advantages	Disadvantages	Suitability for Green Electroplating
Ni	- Excellent electrical conductivity and catalytic efficiency. - Corrosion-resistant and widely used in industry[7].	- Potential health risks and allergenic properties. - May require advanced waste treatment due to toxicity concerns.	**Moderate to Low** (Sustainability can be improved using cyanide-free nickel sulfate or chloride-based solutions.)
Zn	- High corrosion resistance. - Abundant, cost-effective, and recyclable [5]. - Non-toxic and environmentally friendly. - Can optimize hydrogen binding energy in AWE.	- Requires specific electrolyte conditions for stable deposition. - May dissolve in acidic or neutral environments.	**High** (Eco-friendly sulfate or chloride electrolytes can be used for non-toxic deposition.)
Co	-High electrocatalytic activity for AWE.[6][8] - Strong electrochemical stability. - Capable of working in both acidic and alkaline media.	-Environmental and ethical concerns related to mining. -Requires non-toxic electrolytes for sustainable deposition.	**Moderate** (Sustainable cobalt sources and cyanide-free electroplating are required to align with green principles.)

2. MATERIALS AND METHODS

The experimental studies were conducted in two stages: (I) the preparation of separate Co and Zn doped and undoped nickel electrodes for alkaline electrolysis, and (ii) the evaluation of their hydrogen production performance. Ni-B doped electrodes were fabricated using Watts Nickel bath, a widely used industrial electrodeposition solution, composed of $NiCl_2 \cdot H_2O$ (15 g/L), $NiSO_4 \cdot H_2O$ (5 g/L), and H_3BO_3 (2 g/L) maintained at temperature of 60°C. Ni-Zn and Ni-Co electrodes were prepared based on Watts Nickel solution, with doping agents introduced via their respective sulfate and chloride salts while maintaining the overall composition. For electrode preparation, 316L stainless steel plates were utilized as the substrate, while 99% pure nickel strips served as the cathode during the electroplating processes. Prior to electroplating at 4.5V, the substrate underwent pre-treatment with hydrochloric acid in an ultrasonic bath acid to ensure surface cleanliness, surface activity and adhesion. To investigate the impact of different dopants on hydrogen evolution efficiency, electrolyte solutions of potassium hydroxide (KOH) were prepared. The experiments were conducted in a 20 wt.% KOH solution at 2.3V and room temperature (25°C). The hydrogen evolution rate of the electrodes was quantified in milliliters per second (mL/s) and measured using a graduated cylinder.

3. RESULTS AND DISCUSSION

The electrochemical hydrogen evolution performance of Ni-based electrodes doped with boron (Ni-B), cobalt (Ni-Co-B), and zinc (Ni-Zn-B) was evaluated by measuring the volume of hydrogen produced over time and calculating the hydrogen production rate. The results are presented in Figure (1a) and Figure (1b), illustrating the cumulative hydrogen volume as a function of time and the corresponding hydrogen production rates for each electrode composition. Figure (a) presents the cumulative hydrogen volume (mL) generated over time (minutes) for the three doped nickel electrodes. The trend shows a nearly linear increase in hydrogen production, indicating a stable electrochemical process throughout the duration of the experiment. Among the three samples, Ni-Co exhibited the highest hydrogen evolution, producing the greatest volume of hydrogen. Ni-Zn demonstrated a moderate performance, with slightly lower hydrogen evolution compared to Ni-Co but higher than Ni-B. The Ni-B electrode displayed the lowest hydrogen production, suggesting a lower catalytic activity for the alkaline water electrolysis (AEW). The improved performance of Ni-Co may be attributed

to the enhanced electrochemical conductivity and optimized hydrogen adsorption energy introduced by cobalt doping. Figure (b) compares the hydrogen production rate (mL/s) of the three electrode materials. The Ni-Co electrode exhibited the highest hydrogen production rate, surpassing both Ni-Zn and Ni-B. The enhanced catalytic activity of Ni-Co is consistent with previous findings, where cobalt incorporation in Ni-based electrocatalysts improves electron transfer kinetics and reduces activation energy for AEW. The Ni-Zn electrode also showed a significant enhancement in hydrogen production compared to Ni-B, likely due to the favorable impact of zinc on surface reactivity and charge distribution. However, slightly lower efficiency compared to Ni-Co suggests that cobalt doping provides superior active sites for AEW, contributing to a more efficient hydrogen evolution process. The observed trend aligns with existing literature, indicating that transition metal doping significantly influences the catalytic activity of Ni-based electrodes. Cobalt doping, in particular, enhances the electronic structure, surface area, and electrochemical stability, resulting in improved hydrogen evolution kinetics. On the other hand, zinc doping appears to provide moderate benefits, possibly by modifying the hydrogen adsorption energy and surface interactions without significantly altering the electronic conductivity. These variations highlight the crucial role of transition metal selection in optimizing the performance of Ni-based electrocatalysts. These results suggest that Ni-Co is the most efficient doped electrode for hydrogen evolution applications, making it a promising candidate for electrochemical water-splitting and green hydrogen production. Further investigations on electrode stability, overpotential, and Tafel slope analysis will provide deeper insights into the long-term performance and mechanistic understanding of these materials.

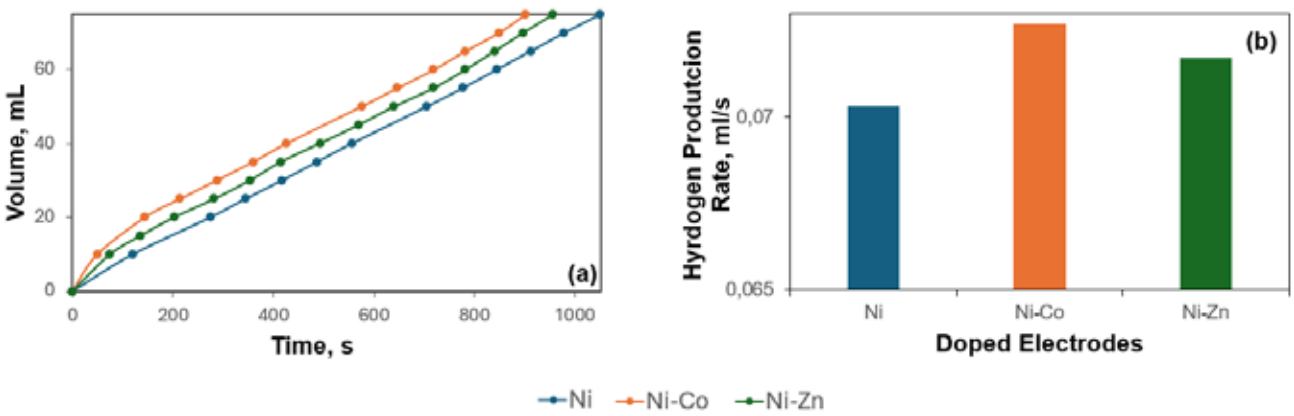

Fig. 1. (a) Time-Dependent Hydrogen Evolution Performance of Doped Stainless Steel Electrodes (b) Comparison of Hydrogen Production Rates for Different Doped Stainless Steel Electrodes

4. CONCLUSIONS

The results of this study highlight the significance of material selection and doping strategies in optimizing hydrogen evolution performance. While all three Ni-based electrodes demonstrated electrochemical activity, their effectiveness varied depending on the dopant introduced. Among the tested materials, certain modifications exhibited enhanced catalytic properties, suggesting that careful surface engineering and composition tuning play a critical role in electrochemical efficiency. Furthermore, the study aligns with the principles of green electroplating, emphasizing the potential of sustainable electrode fabrication techniques. By utilizing environmentally friendly deposition methods and avoiding hazardous chemicals, this approach contributes to the advancement of eco-conscious electrochemical systems. The findings suggest that strategic metal incorporation can lead to improved efficiency without compromising sustainability. Overall, these insights pave the way for further exploration of alternative doping elements and deposition strategies to develop efficient and environmentally responsible hydrogen evolution catalysts. Future work should focus on long-term stability, mechanistic studies, and large-scale applicability to bridge the gap between laboratory research and industrial implementation in green hydrogen production.

ACKNOWLEDGEMENT

ABSTRACT
Clean energy sources like hydrogen, solar, and wind are essential in combating global warming, but solar and wind energy face challenges due to weather dependency and grid integration. On the other hand, hydrogen offers a stable and reliable energy supply. The economic and environmental benefits of hydrogen fuel cell vehicles (HFCVs) make them a viable substitute for fossil fuel vehicles, particularly considering the transportation sector's impact on global warming. However, widespread use of these vehicles is possible through developing a well-designed hydrogen supply chain (HSC). Therefore, this study aims to design the HSC of the Central Anatolia Region of Turkey, which has huge hydrogen energy production advantages due to its flat terrain and renewable energy sources. The problem is modelled using mixed integer linear programming (MILP) to minimize the costs related to production, storage and distribution under carbon emission constraints. Obtained results can help policymakers proactively specify the most efficient configurations for hydrogen production, storage, and transportation systems, taking carbon emissions into account.

Keywords: Hydrogen Supply Chain, Carbon Emission, Mixed Integer Linear Programming, Central Anatolia

1. INTRODUCTION

Since various effects of global warming began to threaten the world, some policymakers and governments have taken several actions to mitigate its impact. For instance, one of the European Union's environmental and climate-related goals is to be climate-neutral by 2050, establishing an economy with net-zero greenhouse gas emissions defined as minimizing greenhouse gas emissions as much as possible [1]**.** Another significant action is the Paris Agreement which aims to limit global temperature rise, focusing on limiting the increase under 1.5°C to minimize climate change risks and impacts. After this agreement came into force in 2016, countries, including the Netherlands, Spain, Norway, France, the UK, Sweden, Denmark, and Ireland, declared that they plan to gradually terminate the sales of fossil fuel vehicles [2]. This commitment is crucial, since the transportation sector, one of the major causes of global warming, consumes 65% of the world's oil products, accounts for 28% of global energy consumption, and contributes to approximately 25% of greenhouse gas emissions [3]. In addition, the European Union's Carbon Border Adjustment Mechanism (CBAM) aims to put a fair price on the greenhouse gases (GHG) emitted during the production of certain GHG-intensive goods, including hydrogen, entering the EU, and by 2025, importers will be required to report emissions data and obtain "authorized CBAM declarant" status for customs clearance by 2026. Thus, the EU's climate objectives will not be violated and cleaner industrial production in non-EU countries will be encouraged [4].

All these measures and actions against global warming rely on clean energy resources, such as hydrogen, solar, and wind, which have lower carbon emissions [5,6,7]. However solar and wind energy generation depends on weather conditions and the time of day, also their integration into a grid is challenging. On the other hand, hydrogen production technology stands out by offering stable and reliable energy supply and storage options [8].

Considering the transportation sector's impact on global warming, it is inevitable to prefer vehicles that use clean resources rather than fossil fuel vehicles that are not sustainable [9]. Therefore, HFCVs powered purely by hydrogen gas are promising alternatives for carbon emission reduction targets. HFCVs are also more environmentally and economical than Battery Electric Vehicles [10]. Many countries already recognized the promising features of hydrogen energy, and they mapped their hydrogen energy strategies [11]. Turkey is one of the countries that reported its hydrogen technology strategy and roadmap [12]. It has nearly all forms of renewable energy and abundant water resources. Moreover, it is bordered by seas on three sides. These factors can make Turkey a potential leader in global hydrogen exports if these resources are utilized in hydrogen energy generation. Furthermore, not only coastal cities but also the cities in Central Anatolia have a high potential for hydrogen energy production [13].

Considering Turkey's hydrogen production potential, several studies [14,15,16] were conducted to handle Turkey's future HSC using mathematical optimization problems. Furthermore, optimal locations of hydrogen fuel stations in Istanbul, the most crowded city in Turkey, were determined in the studies [17,18] employing different approaches.
In this study, we aim to design the HSC of the Central Anatolia region of Turkey in 2050, minimizing production, storage and distribution-related costs, considering carbon emissions. According to the best knowledge of the authors, this is the

first study that considers specifically Central Anatolia which has a high potential for hydrogen production according to the report [13] conducted in 2021.

2. METHOD

In this study, we address the HSC design problem of Central Anatolia employing a MILP model formulated by Almansoori and Shah [19]. The model aims to minimize the total daily cost of the HSC considering capital and operating costs. In addition to that, we consider the total daily carbon emissions ($TDCO_2$) produced in the HSC. The HSC model obtains the optimal number and location of production plants and storage facilities to be established in each city, the necessary transportation links in the network, and the production rates and flows of hydrogen. The model includes demand, transportation, production, storage facilities, and carbon emission constraints. This single-period model differs from the previously developed models since it handles HSC integrating production, storage, and distribution.

The total daily carbon emissions ($TDCO_2$) produced in the HSC stem from production, storage, and transportation. It is calculated according to Eq. (1).

$$TDCO2 = PRCO2 + STCO2 + TRCO2 \quad (1)$$

We adapt the model for 2050, which is the earliest projected year, utilizing Turkey's energy potential [20]. Table 1 shows the forecasted number of automobiles and large vehicles in each city of Central Anatolia in 2050 and presents a projection for hydrogen energy demand based on the estimated number of vehicles. Since Ankara has the largest population among these cities, it also has the highest number of cars and large vehicles. As a result, it has the highest hydrogen energy demand. Whereas Çankırı is the least populated city in Central Anatolia, accordingly, the demand for hydrogen energy is the lowest among the cities in the region.

Table 1. A projection for the number of automobiles and large vehicles, and hydrogen energy demand

City	Forecasted Number of Automobiles	Forecasted Number of Large Vehicles	Forecasted Hydrogen Energy Demand (kg/day)
Ankara	4,056,964	953,003	4,347,471
Konya	901,915	370,675	1,641,481
Kayseri	604,580	191,497	858,164
Eskişehir	416,268	128,784	577,836
Aksaray	165,186	57,113	254,836
Sivas	211,438	72,791	324,858
Nevşehir	135,452	64,952	285,978
Niğde	118,934	57,113	251,451
Yozgat	115,630	40,315	179,813
Kırıkkale	93,426	24,737	112,486
Kırşehir	92,504	24,633	111,580
Karaman	89,200	33,596	149,320
Çankırı	52,860	22,397	99,063

The MILP model is solved using the Gurobi solver in Python on a computer with an M1 chip and an 8-core CPU. The optimum solution of the model is provided in the following section.

3. RESULTS AND DISCUSSION

According to Fig.1, as the total daily carbon emissions ($TDCO_2$) are decreased, the unit production cost increases. In the optimal scenario, where $TDCO_2$ is minimized, the unit production cost is 6.21 ($ kg^{-1} day^{-1}). On the other hand, when there is no restriction on carbon emissions, the unit production cost decreases to 4.65 ($ kg^{-1} day^{-1}).

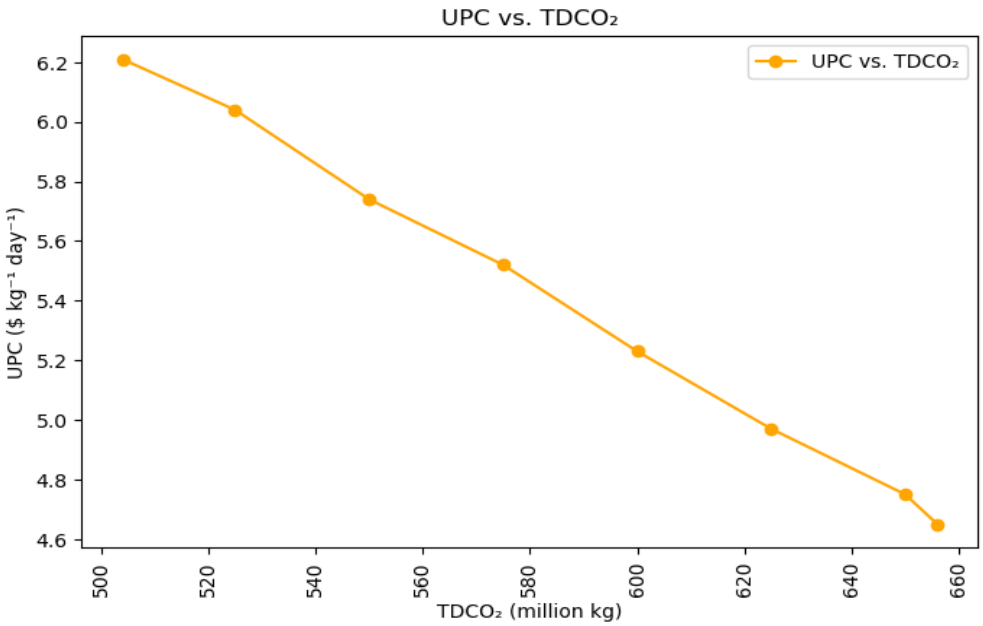

Fig. 1. Unit production cost vs. total daily carbon emission

Fig. 2 shows the number of plant types, sizes and unit production costs in the future HSC under various $TDCO_2$ levels.

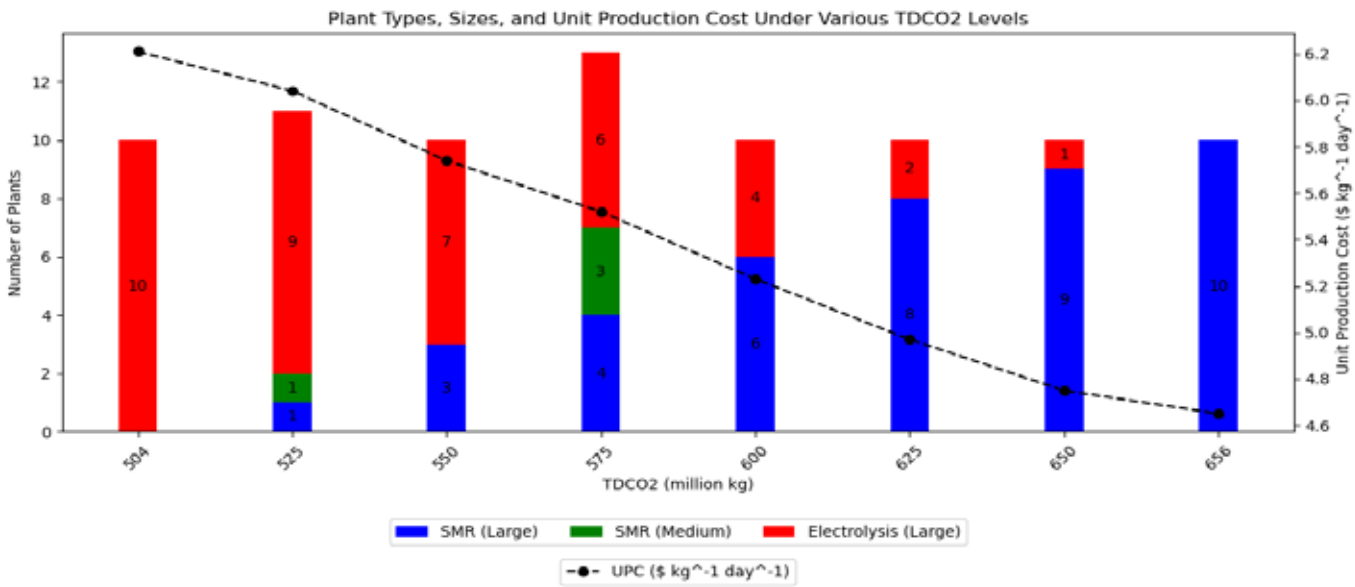

Fig. 2. Number of plant types, sizes and unit production costs under various $TDCO_2$ levels

Given that ELE technology has the lowest carbon emissions compared to the other technologies, it is reasonable to establish only Large ELE production plants in the Minimum Total Daily Carbon Emission case ($TDCO_2$ = 504 million kg). On the other hand, in the Minimum Total Daily Cost case ($TDCO_2$ = 656 million kg), it makes sense to build only the Large SMR production plant which has the lowest unit production cost among the other types. Furthermore, Large SMR production plants have the lowest Facility Capital Cost when compared to other Large-scale plant types.

4. CONCLUSIONS

Utilizing an optimization approach for the HSC_design can help determine the necessary investments to establish new production facilities and distribution networks. In other words, the results obtained by solving mathematical models can provide insights that could be crucial for both governments and policymakers while making strategic decisions [19]. Therefore, in this study, we use a MILP model to find an HSC configuration of Central Anatolia in 2050, with a particular focus on carbon emissions that contribute to global warming. From this perspective, this study provides valuable results

regarding the trade-off between carbon emissions and production costs. In future studies, Turkey's HSC can be handled with different objectives and approaches.

ABSTRACT

In this study, we focused on the development of ion conducting/semiconducting ceramic electrolytes that can be used in low temperature solid oxide fuel cells. $Ce_{0.9}Gd_{0.05}Nd_{0.05}O_2$ (CeO2:0,05Gd0,05Nd) was synthesised using the combustion technique with glycine. Composites with SrTiO3 were made by solid-state method. Conductivities were calculated at different temperatures. Conductivity value for 475 oC is 73,47 ohm.cm^{-1} and 575 ^{o}C is 12,24 ohm.cm^{-1}.

Keywords: heterostructure, composite electrolyte, solid oxide fuel cell

1. INTRODUCTION

Cerium oxide (CeO_2) is one of the most reactive rare earth metal oxides with a wide range of applications in various fields[1]. In recent years, cerium (IV) oxide (CeO_2, also known as ceria) nanoparticles have attracted much attention due to their many interesting properties, such as unique UV absorption ability, high stability at high temperature, high hardness and reactivity [2,3]. Therefore, CeO_2 and CeO_2-based materials have been widely used in a variety of applications, such as solid oxide fuel cells (SOFCs) [4], catalysis [5], luminescent materials [6], gas sensors [7], polishing materials [8] and ferromagnetic oxides [9]. Each Ce^{4+} cation (formally 4f0) is coordinated by eight equivalent O^{2-} anions at the corners of a cube, and each O^{2-} is in turn coordinated by a tetrahedral Ce^{4+} ion [10].
This research aims to develop ceramic electrolytes that have the potential to provide a sustainable and innovative solution for low-temperature operation of solid oxide fuel cells. Semiconductor/ion conductor heterostructures were used to develop this innovative ceramic electrolyte proposal. Gd, Nd-doped CeO_2 has been selected as the ion conductor in this heterostructure system to be developed. $SrTiO_3$ was selected as the semiconductor. $SrTiO_3$ is expected to prevent the formation of short circuits by not allowing electronic transitions in the cell and to contribute to the increase in ionic conductivity [11].

2. MATERIALS AND METHODS

Gd^{3+} and Nd^{3+} were doped into CeO2 using the burning technique with glycine. . According to Fig1, The starting compounds were dissolved in 100 ml water. The combustion process was carried out at 300 ^{o}C on a heated magnetic plate. After combustion, the final product was sintered at 650 ^{o}C for 4 hours. The composites were ground in agate mortar with a ratio of 60:40. The composite was calcined at 700 ^{o}C for 2 hours. XRD and empedance spectroscopy were used to determine the physical and chemical structures of the synthesised compounds

3. RESULTS AND DISCUSSION

X-ray diffraction patterns of $Ce_{0.9}Gd_{0.05}Nd_{0.05}O_2$ and 60:40 composite structures are given in Fig. 2. In the evaluations made with the Expert High Score program, it was determined that $Ce_{0.9}Gd_{0.05}Nd_{0.05}O_2$ and $SrTiO_3$ retained their crystal structure and there were no phase changes.

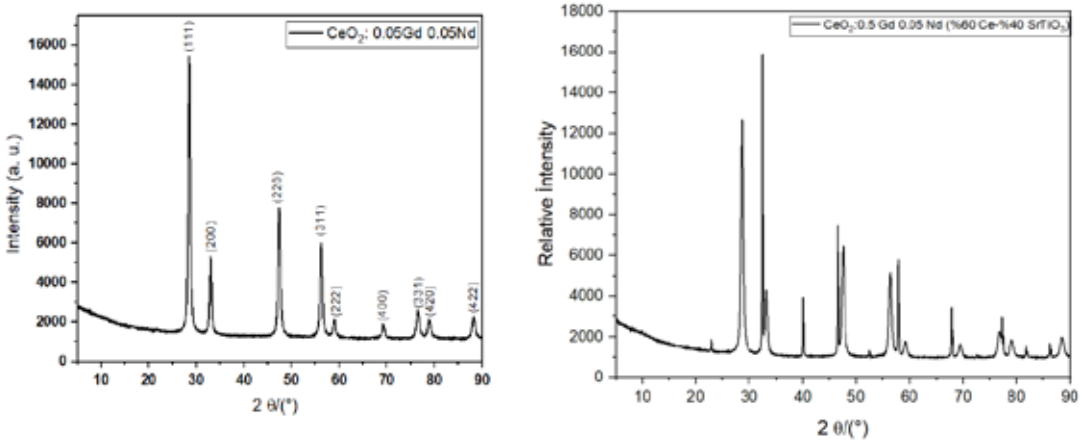

Fig. 2. X-ray diffraction patterns of $Ce_{0.9}Gd_{0.05}Nd_{0.05}O_2$ and 60:40 composite structures.

Fig.3. shows the conductivities of samples tested at different temperatures. 60:40 composite structures's total conductivity is determined as follows:

$$\sigma = t/RA$$

Where σ is the conductivity, t is the thickness of the electrolyte discs, A is the surface area of the electrolyte, and R is the resistance value obtained by fitting at different temperatures. Conductivity value for 475 oC is 73,47 ohm.cm^{-1} and 575 ^{o}C is 12,24 ohm.cm^{-1}.

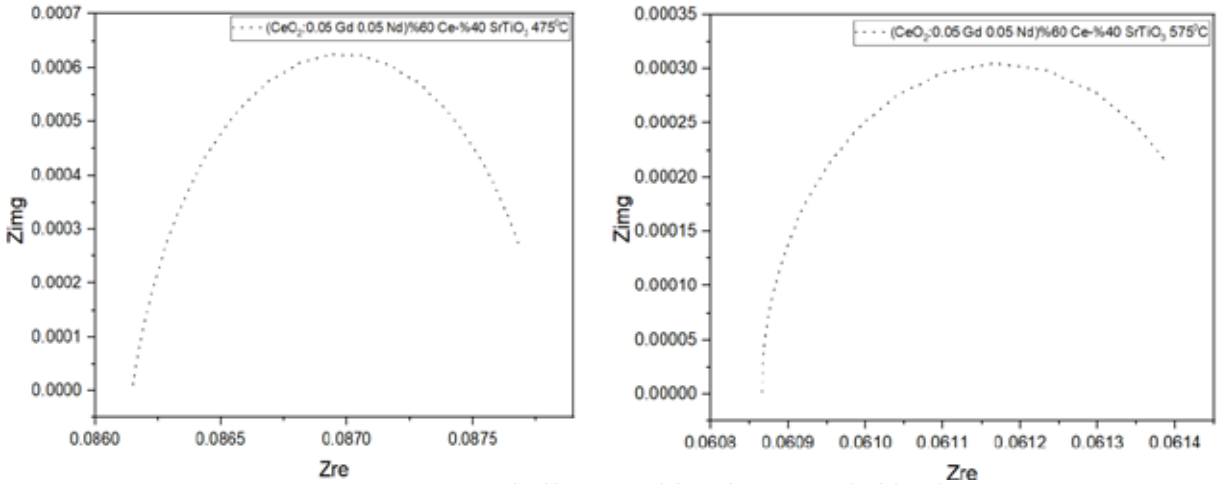

Fig. 3. Electrochemical impedance spectra (EIS) curves of $Ce_{0.9}Gd_{0.05}Nd_{0.05}O_2$ / $SrTiO_3$ composite samples 475-575 ^{o}C.

4. CONCLUSIONS

In this paper, $Ce_{0.9}Gd_{0.05}Nd_{0.05}O_2$ / $SrTiO_3$ was prepared by solid-state method for obtaining high ionic conductivity. The crystal structure and electrochemical performance of the materials $Ce_{0.9}Gd_{0.05}Nd_{0.05}O_2$ / $SrTiO_3$ electrolyte were investigated. The ionic conductivity reached ? cm-1.

ABSTRACT

In this study, A fluid mechanics model based on the finite element method has been developed to evaluate the effect of scaling up on the performance of a PEM fuel cell. Three different sizes of bipolar plates were designed with areas of 50 cm², 100 cm², and 225 cm². The aim was to ensure that hydrogen flows at the same velocity in channels with equal depths. Flow rate calculations were determined based on the current density obtained from the active area size, pressure drop, and velocity calculations were performed for different stoichiometries. The designed flow fields were analyzed using the finite element method, and similar flow velocities were obtained.

Keywords: Hydrogen, PEMFC, Scale-up, Flow Channel

1. INTRODUCTION

The demand for the energy we need is increasing day by day with the growing world population, developing economies, and emerging technologies in our lives. It is widely known that fossil fuel reserves are depleting and causing environmental pollution. This pollution not only endangers living organisms but also harms the global ecosystem. The use of clean energy has become a necessity for a sustainable future. Scientists are conducting research to develop and promote the use of new energy sources such as solar-based energy, wind-based energy, biomass-based energy, and hydrogen-based energy [1].

Fuel cells stand out among renewable energy sources because they can directly convert the chemical energy in various fuels into electrical energy through electrochemical reactions. Additionally, since fuel cells do not operate based on the heat engine principle, they are not limited by Carnot efficiency. The limitation is defined by the second law of thermodynamics [2].

Among fuel cells, PEM fuel cells have many advantages, such as ease of implementation, long lifespan, low operating temperature, high power density, rapid startup, low emissions, durability, stable power generation, and suitability for portable applications. Therefore, many industries are considering integrating PEMFC technology into their respective fields [3].

The development of PEM fuel cells can be categorized into two main areas. The first involves advancements in material science and the testing of materials in small-scale single cell. The second focuses on scaling up. Since electrochemical reactions occur in fuel cells, challenges such as irregular flow distribution, unpredictable pressure drops, water management issues, non-uniform heat distribution, and weak flow field designs are among the primary obstacles to scaling up. The goal of this study is to provide solutions to the challenges of scaling up using the finite element method [4].

2. MODELING

In a PEMFC, the theoretical hydrogen flow rate required for the reaction is calculated based on the desired current density. The necessary feed flow rate is determined considering the stoichiometric ratio. Although the flow rates of the fuel cells with three different active areas examined in the scaling-up study are proportional to their active areas, it is desired that the hydrogen flow per unit area remains equal. To achieve this, the hydrogen must have the same velocity within the channels of the three different fuel cells. To maintain equal velocities at different flow rates, the cross-sectional area needs to be increased. To preserve the cross-section of a single channel, the number of channels has been increased in proportion to the growth rate of the active area. Since the active area is square and the inlet and outlet are positioned diagonally. During this calculation, the ratio of the flow field to active area was also considered. This ratio has been kept close to each other across different active areas. The fuel cell designs with different active areas were modeled using finite element analysis, achieving nearly identical flow velocities.

In the studies, dry H_2 gas was selected as the working fluid, heat transfer equations were excluded from the modeling scope, the flow was assumed to be laminar, and an isothermal model was developed at 60°C. No material deformation was considered, and solid surfaces were assumed to be smooth.

3. RESULTS AND DISCUSSION

The flow distribution is shown in Fig. 1. In dual and quadruple serpentine channels manifolds are designed to ensure that the flow reaches the channels with equal flow rates. The radius added to the channel corners has been effective in achieving a homogeneous flow distribution. It has been observed that the flow velocity yields very similar results across different active areas.

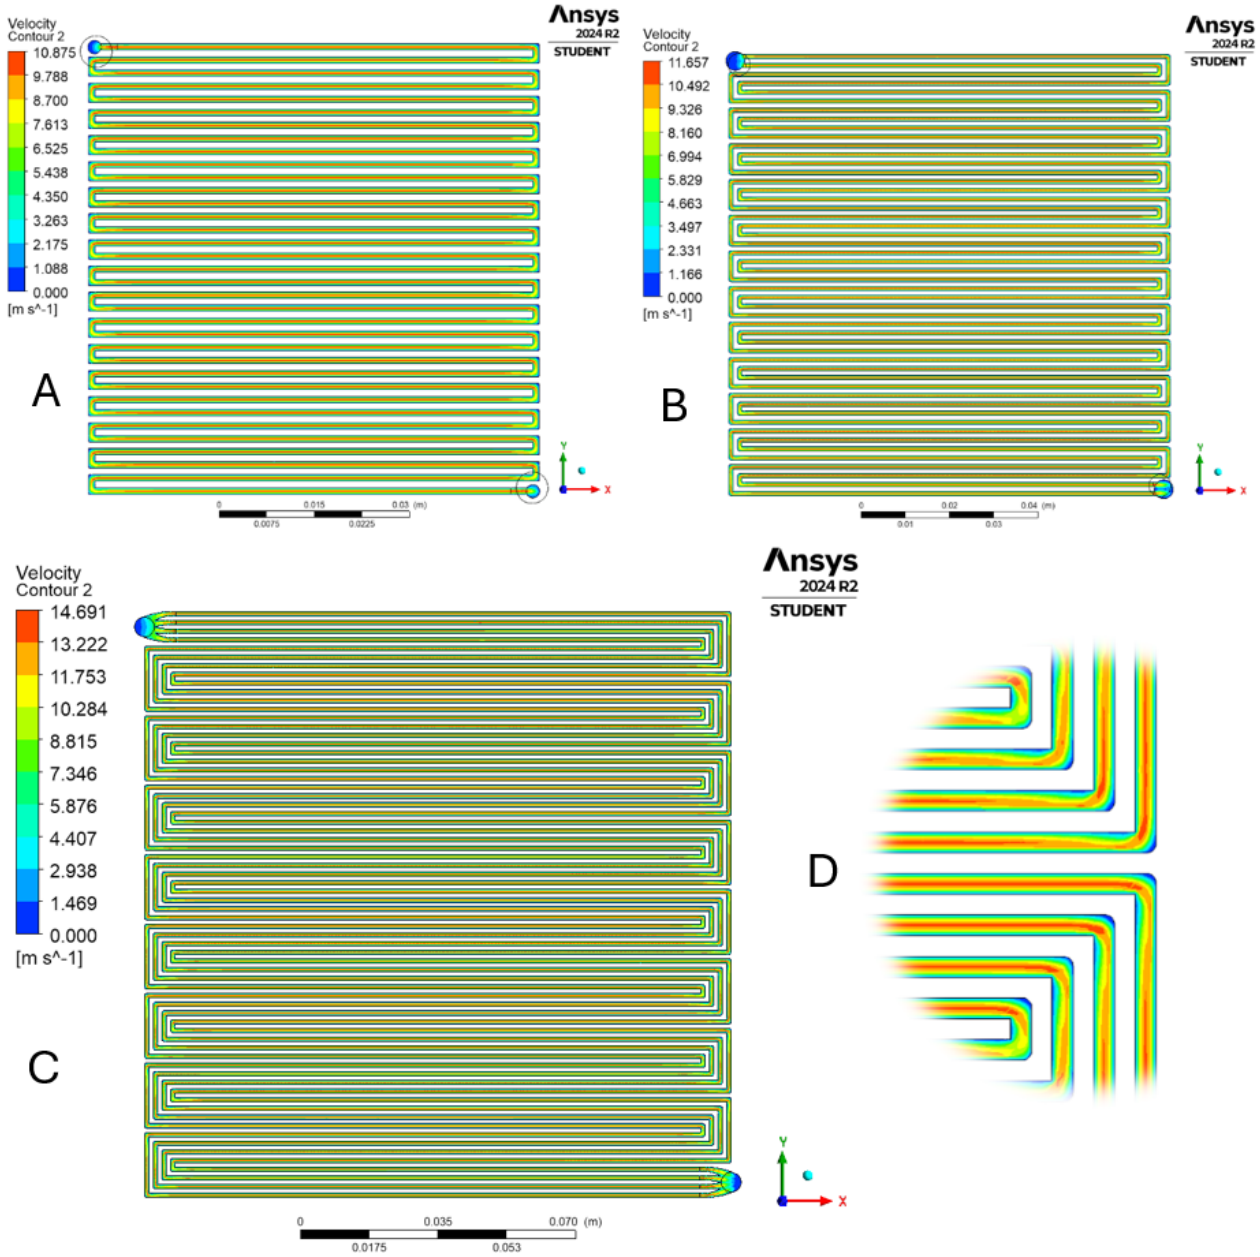

Fig. 1. Flow Distribution of the Cells (A: Single Channel Serpentine, B: Dual Channel Serpantine, C: Quadruple Channel Serpantine, D: Detail of the corners of the channels)

In Fig. 2, the relation of the required hydrogen flow rates for the desired current density and active area are shown for different stoichiometries. As stoichiometry and active area increase, the feed flow rate also increases linearly.

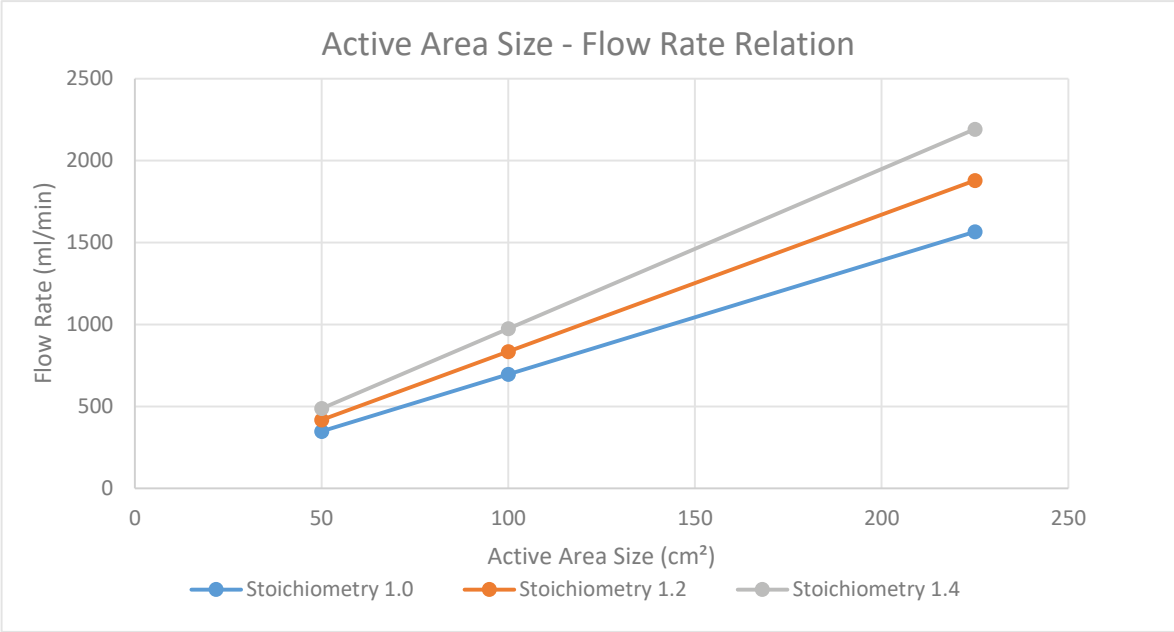

Fig. 2. Active Area Size – Flow Rate Relation

In Fig. 3, the pressure drop of the channel at different stoichiometry values for various active area sizes are shown.

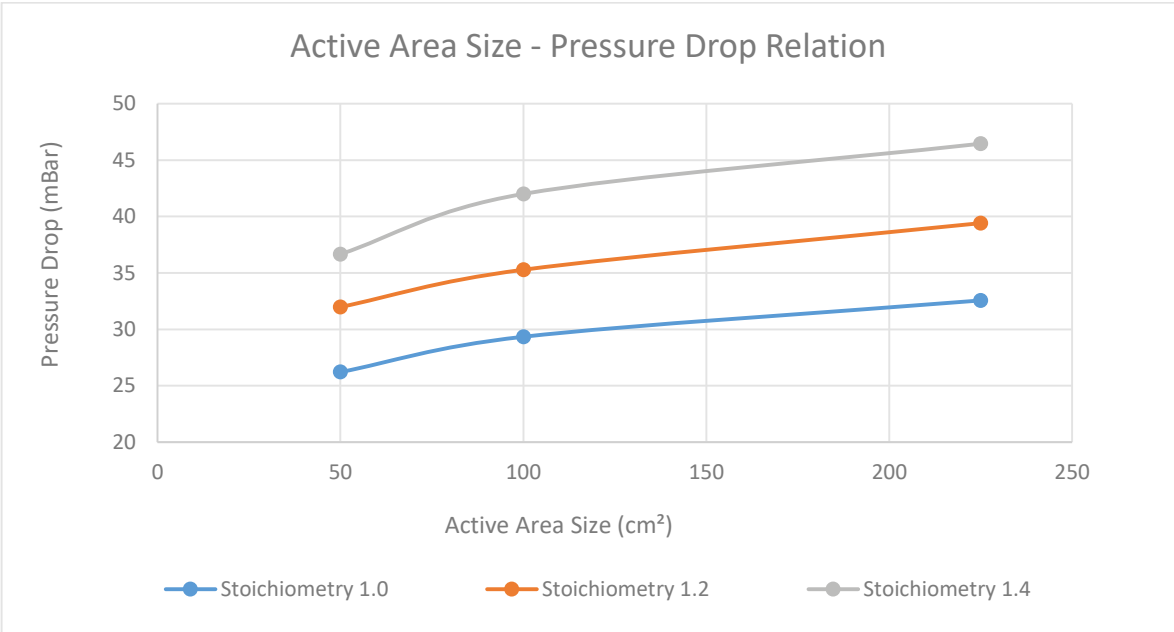

Fig. 3. Active Area Size – Pressure Drop Relation

In Fig. 4, the average velocity is shown for different active area sizes according to different stoichiometric values.

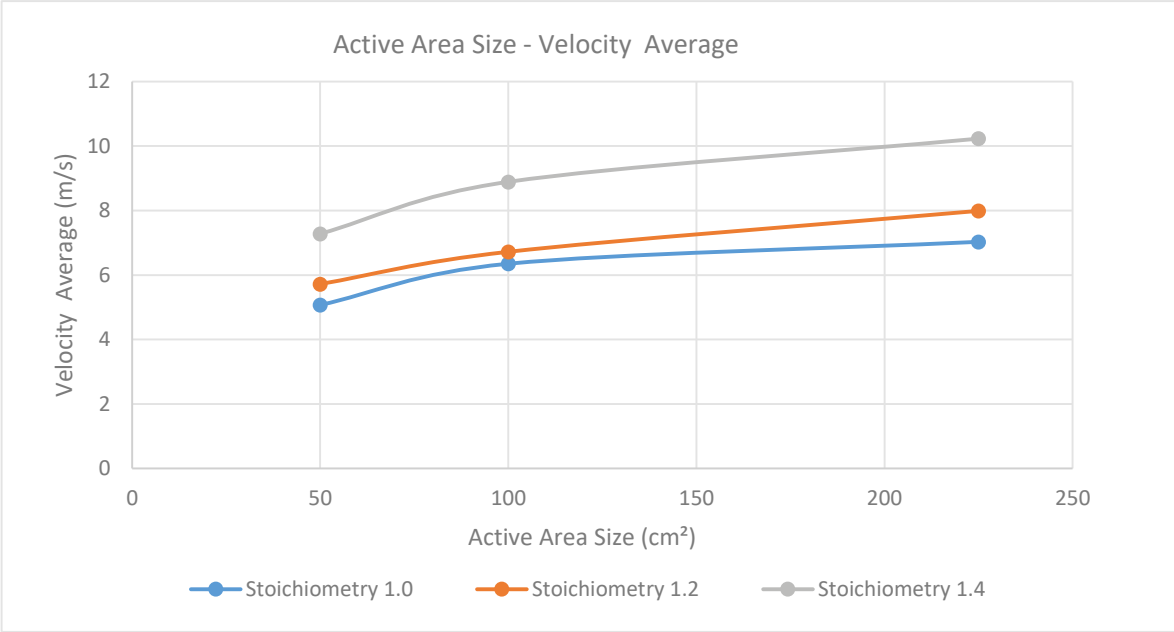

Fig. 4. Active Area Size – Velocity Average Curves

4. CONCLUSIONS

In this study, as part of the scale-up process of the PEM fuel cell, the first step, channel design, was evaluated using a fluid mechanics approach. Hydrogen supply was provided at three different stoichiometries for three active areas of different sizes. While calculating hydrogen flow rates, it was assumed that the current density of the cells was the same. Accordingly, the design was created to equalize the flow velocity in the channels within a single cell.

Modeling results showed that an increase in stoichiometry led to an increase in average velocity, pressure drop, and flow rate. While the increase in flow rate occurred linearly, the pressure drop and average velocity exhibited a nonlinear increase. In the next stage, the effect of the designed channels on performance will be experimentally examined. The relationship between performance variations and flow characteristics will be investigated.

ABSTRACT
As the world aims to reduce carbon emissions, hydrogen-powered internal combustion engines and fuel cells are emerging as an innovative technology. However, high pressures in hydrogen storage systems can cause hydrogen leakage due to small atomic size of hydrogen and plastic deformations in the Hydrogen Tank Valve (HTV) body.

In this study, prototype-phase research was conducted to determine the optimal assembly torque values and lubricant amount to assemble hydrogen tank valve. It was observed that even if same torque is used to assemble the sub-components to valve body, resulting axial force distribution was excessively high, causing uncontrollable deformations on the body and hydrogen leakage, preventing the achievement of mass production targets. Based on these findings, this research focuses on optimizing the bolting process of devices mounted on hydrogen tank valves. The study aims to enhance assembly efficiency by optimizing lubricant application, preventing overuse or underuse of lubricants, and controlling torque application and bolting techniques that could lead to hydrogen leakage.

Assembly trials are made using prototype valve body and sub-components. Axial loads are measured after applying various torque and optimum pre-assembly bolting cycle is tried to be achieved. Furthermore, to reduce testing costs, numerical models were developed using Computational Fluid Dynamics and Finite Element Method. These models were used to determine optimal lubricant application positions, angles, and speeds, as well as to validate the axial loads exerted on the components.

Keywords: Hydrogen storage, Hydrogen tank valves, Torque optimization, Axial load, Lubrication analysis

1. INTRODUCTION

Hydrogen-powered internal combustion engines have become a key technology in reducing carbon emissions. [1] Compared to fossil fuels, hydrogen offers higher thermal efficiency, significantly lower exhaust emissions, and releases water vapor as a byproduct of combustion. One crucial component for these engines is the Hydrogen Tank Valve (HTV), which connects the fuel tank to various independent components and devices. The HTV has several threaded connection points, one for the fuel tank and many others are for mounting additional components like pressure sensor, temperature sensor, service valves, safety valve, fueling port etc. Since those connections use a threaded assembly (female on the HTV side, male on the device side), a lubricant is applied to the male threads during installation. The type, quantity, application method, and temperature of the lubricant significantly affect the assembly quality.

The primary criteria for assembly quality include (i) ensuring no hydrogen leakage through the connection points and (ii) preventing excessive wear on the threads. Considering the internal tank pressure of approximately 700 bar and hydrogen atoms are too small, maintaining a leak-proof connection is a significant challenge. Moreover, minimizing thread wear is critical since it directly affects sealing integrity and the durability of components like service valves that may require repeated installation and removal.

Among those threaded connections, two critical components are the Manual Valve (MV) and Bleed Valve (BV). The BV ensures safety by releasing hydrogen once opened before the disassembly of tank valve from the tank. The MV allows for manual isolation of the hydrogen tank from the fuel injection or fuel cell system at service condition, ensuring a secure shutoff. Proper installation of these components is essential for operational reliability.

Initial assembly tests at BOSCH have revealed several challenges:

- The physical properties of the lubricant (viscosity, density, surface tension) influence both thread filling and wear resistance.
- The application temperature of the lubricant affects its flow characteristics and coverage between threads.
- The amount of lubricant used is crucial; excessive application leads to contamination, while insufficient amounts can result in increased friction and wear.
- Manual application of the lubricant often results in inconsistent distribution, leading to potential assembly failures.
- The maximum tightening torque influence wear and overall sealing effectiveness.

- Changing tank conditions like pressure and temperature effects the axial load on seal surfaces.
- Final axial load varies too much from assembly-to-assembly even though same torque is used.

Any combination of these factors can negatively impact the performance of the BV and MV, potentially leading to hydrogen leakage. To address these issues, the study aims to establish optimized assembly parameters to ensure precise and repeatable installations for service valves.

This research will develop an assembly method to control key parameters, including: (i) Lubricant type selection (ii) Lubricant application temperature (iii) Lubricant distribution method onto male threads (iv) Lubricant quantity control (v) Applied torque characteristics.

By implementing this method assembly system, the study seeks to achieve high-quality, leak-proof connections while minimizing wear and ensuring long-term durability of the HTV components. This initiative is a crucial step toward localizing advanced hydrogen fuel component manufacturing at BOSCH, supporting the transition to a sustainable hydrogen-powered future.

2. MATERIALS AND METHODS

To achieve the objectives of this research, both simulation and assembly tests were conducted to validate the optimized parameters for hydrogen tank valve assembly. The methodology includes the following key aspects:

2.1 Development of a Modular Assembly Station:

- A modular assembly system was designed to regulate the application of lubricant, control tightening speed, and monitor torque values and derived axial loads.
- The system ensures repeatable and precise installation of components to prevent hydrogen leakage and minimize thread wear.

2.2 Simulation Studies:

- Finite Element Method (FEM) was used to model the impact of different torque values and lubricant quantities on the mechanical integrity of the threaded connections.
- Computational Fluid Dynamics (CFD) simulations were conducted to analyze lubricant distribution between male and female threads under various application methods.

2.3 Assembly Testing:

- Prototype assembly tests were performed under controlled conditions to determine the optimal torque values for BV and MV components.
- Lubricant application experiments were conducted to evaluate viscosity, temperature, and distribution efficiency.
- Real-time monitoring of hydrogen leakage levels was carried out using pressure differential measurements.

2.4 Key Performance Metrics:

- Ensuring torque and axial load values remain within requested interval for BV and MV.
- Hydrogen leakage levels not exceeding the value coming from standards.
- Improvement in component service life up to 100 installation cycles.

By integrating both experimental and computational approaches, this study establishes a robust framework for optimizing the assembly of hydrogen tank valve components, enhancing efficiency, and ensuring long-term operational safety.

3. RESULTS AND DISCUSSION

[2] It is known that axial load occurs on the threaded connections after applying torque and is increased with the torque and decreases with the effective thread diameter and friction effected by thread angles, material, lubrication amount and distribution. Our experimental study shows that among those parameters, friction coefficient is the one that has major impact on the distribution of axial load after assembly. Considering geometrical factors and applied torque is constant,

machining imperfections and torque application has negligible tolerances, lubrication amount and distribution is the driving factor of friction coefficient and causing wide range of distribution at the resulting axial load.

It is also seen that at different temperatures and tank pressures, resulting axial force on metal-to-metal sealing contact of service valves to valve body are changing. Varying torque values are used to check final axial load. Combining these effects with atomic size of hydrogen, leakage can be observed above the accepted limits.

On Fig.1, different pressures with bar unit and temperatures with Celsius unit are introduced. Different colors state different initial assembly torques that result in different axial contact forces on seal surface. When HTV goes under different boundary conditions, at the end most of contact force on seal surfaces are lost due to contraction and deformation on the valve body.

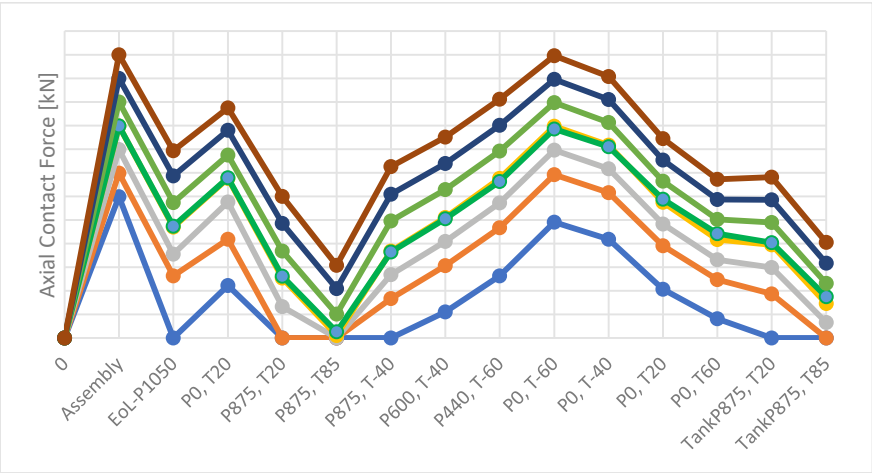

Fig. 1. Axial load of service valves for different conditions

This result is used as a good practice to choose what should be the best initial assembly torque for sealing elements to valve body. As final axial loads are decreased, ratio of initial loads and final loads are derived, and it is used to choose best assembly torques for each sealing component.

After deciding on what initial load should be, fixed amount of torque is applied to components to assemble them on the valve body. It is realized that same amount of torque does not always result in same amount of axial load and distribution of final load is too wide to obtain desired axial load for seal-proof surfaces at each assembly.

To overcome this challenge, service valves are repeatedly assembled and disassembled several times, until they plastically deform the sealing surface and create the best contact for leakage prevention. Before the assembly, lubricant is applied at a measured rate and made sure it was distributed to thread surface equally using special tooling. After specific cycle number is achieved, axial load passed necessary limit to ensure leak-proof seal.

On Fig. 2, axial forces are increasing after repeated cycles of pre-assembly. Red line represents desired axial load limit for the best sealing performance. Even though, some samples can already give necessary axial load from the first cycles, some are failing to do so. After many repetitions, it can be observed that axial loads are converging to specific values and distribution between results is getting smaller.

Furthermore, there is a visible difference between each sample caused by amount of lubrication and application method of lubrication to threads. Therefore, this assembly-trial method became a key indicator to distinguish between the best lubricant application method and amount among other methods where some of the axial load is lost due to non-homogenious distribution of grease and additional frictions introduced to the system.

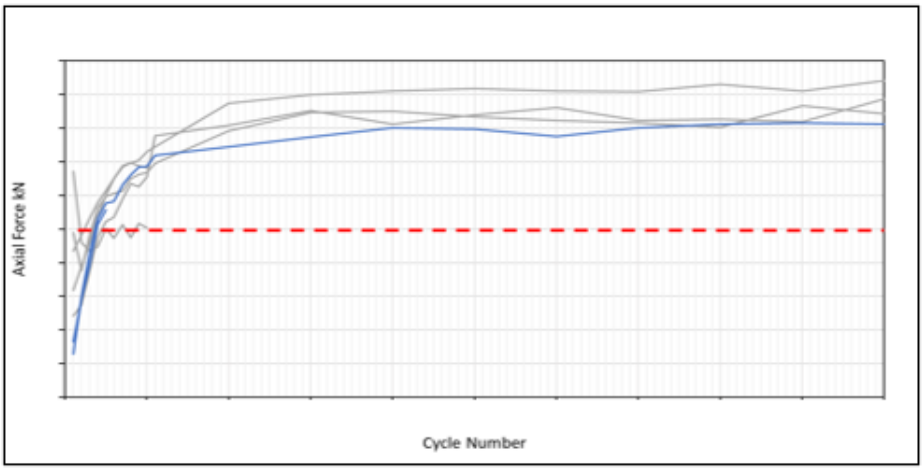

Fig. 2. Axial load of service valves after repeated assembly cycles

The results of this study confirm that optimizing lubricant application, torque control, and repeated assembly significantly improves the performance of hydrogen tank valve assemblies. Key findings include:

- Varying tank pressures and temperatures effects the axial load on seal surfaces; hence, initial assembly torque must be chosen accordingly.
- The optimized lubricant distribution method resulted in reaching desired axial loads with less cycles.
- Repeated assembly cycles before final assembly plastically deforms the seal surfaces and provide better sealing performance by keeping more axial load on the contact surface.

These findings support the importance of lubricant application on thread surfaces, as non-equal distribution of lubricant shows poorer performance to reach desired axial loads after repeated operations.

4. CONCLUSIONS

This study highlights the critical role of optimizing assembly torque and lubrication amount in ensuring the reliability and leak-proof performance of hydrogen tank valves. The findings demonstrate that friction coefficient, largely influenced by lubrication distribution, has a major impact on axial load variation.

By implementing a controlled lubrication method and repeated pre-assembly cycles, the study achieved a more uniform axial load distribution, enhancing sealing integrity and reducing the risk of hydrogen leakage. These insights contribute to the development of a standardized assembly process that enhances efficiency, extends component service life, and supports the large-scale production of hydrogen storage systems.

ABSTRACT
Water electrolysis (WE) powered by renewable energy is the leading technology for producing "green" hydrogen. Given that freshwater is a limited resource, the concept is to use desalinated seawater for the electrolysis process. The goal of the project is to develop water electrolysers with proton and anion exchange membranes (PEM-WE and AEM-WE). New solutions are being explored for the materials and individual cell components in PEM-WE to improve performance and durability while minimizing energy consumption. The focus is on reducing the noble metal content in the oxygen evolution reaction (OER) by developing core-shell structures with Ru oxide in the core and IrO_2 on the outer layers. For the hydrogen evolution reaction (HER), the main objective is to enhance the Pt/C cathode by increasing the electrochemically active metal surface area and achieving good Pt dispersion on carbon nanofibers to address mass transport issues. In contrast, AEM-WE-based electrolysis can operate with non-precious group metal (PGM-free) catalysts and non-critical raw materials (CRM) for both OER and HER, significantly lowering the capital cost of the device. Efforts are directed toward developing non-CRM nanostructured Ni-Fe and Ni-Mo-based electrocatalysts, such as spinel and layered oxides, hydroxides, or (oxy)hydroxides, for OER and HER to improve performance and minimize material loading. The synthesis methods for the cathode catalysts involve scalable, sustainable, and low-temperature techniques (such as colloidal, sol-gel, and complexation processes). The physical-chemical properties of the developed electrocatalysts are analyzed using various characterization methods, including XRD, XRF, and TEM. A Reverse Osmosis desalination unit will be fully integrated with multiple other treatments to achieve optimal water recovery, minimal waste discharge, and the lowest energy consumption and cost, by coupling with renewable energy sources.
Keywords: green hydrogen, nanocatalysts, sustainable energy supply

1. INTRODUCTION
Water electrolysis (WE) supplied by renewable energy is the foremost technology for producing "green" hydrogen. Since freshwater is a limited resource, the idea is to use desalinated sea water for the electrolysis. The project aims to develop Water Electrolysers (PEM and AEM) specifically suited for use with renewable energies and a wide range of water salinity (i.e., from UPW up to seawater). The CNR activity is to develop low-cost electrocatalysts for oxygen and hydrogen evolution reactions with low-noble metal loading for PEM electrolysis and non-noble metal loading for the AEM.

2. MATERIALS AND METHODS
2.1. Catalysts and electrodes preparation
For the AEM electrolyser, non-CRM Ni-Fe and Ni-Mo electrocatalysts were developed for OER and HER, respectively, while IrRuOx and Pt/C were used for the PEM electrolyser. Several physico-chemical and morphological studies were carried out by XRF, XRD, SEM-EDX, TEM and BET analysis to characterize the composition, surface and morphology of the catalysts. Special attention was paid to the electrochemical characterization in a single cell with in house test station by using Ti and Ni plates, as current collector, for PEM and AEM device respectively in a temperature range of 30-90°C (PEM) and 30-60°C (AEM) and under atmospheric pressure. The tests were conducted using water, with a resistivity of 18.2 MΩ·cm (≈ 0.05 μS/cm) at 25 °C, for PEM and 1M KOH for AEM, respectively.

3. RESULTS AND DISCUSSION
Polarization, impedance spectroscopy, and durability tests were carried on to evaluate electrochemical performance.
For AEM cell, the BoT polarization curves have shown that supported NiMo (orange curve) has reached 0.6 A/cm², while unsupported NiMo (green curve) has achieved 1 A/cm² at a potential of 2.2 V. At the EoT, after a durability test of 100 hours, supported NiMo has reached 1 A/cm², while unsupported NiMo has reached 3 A/cm² at 2.2 V. EIS measurements, at the EoT, confirmed a better performance for unsupported NiMo compared to supported one with a lower polarization resistance (109 mΩ·cm² vs. 325 mΩ·cm²).
For PEM cell, the developed anode catalyst IrRuOx has shown a current of 3 A /cm² at a potential of 1.96 V. These performances are in line with the state of the art of PEM technology.

4. CONCLUSIONS
The electrochemical performance for AEM has shown better performance for unsupported NiMo compared to supported one. Good performance was observed for PEM electrolyser cell based on IrRuOx developed by CNR.

ABSTRACT

Electrocatalysts with a synergistic combination of reliable and cost-effective are often used in hydrogen evolution reactions (HERs) in place of noble or toxic metals. In this study, a nanostructured $Na_3NiCo_2(PO_4)(SO_4)_2$ [NCPS(Ni)] composite was synthesized by doping NASICON structure with Nickel (Ni) and polyaniline (PANI) by chemical oxidative polymerization. The composite was found to exhibit an overpotential of 145 mV at -10 mA·cm^{-2} current density against a reversible hydrogen electrode (RHE) and a Tafel slope of 67 mV·dec^{-1}, which is a promising candidate as a polymer-based composite HER catalyst compared to SS (stainless steel). The results of this study propose an efficient and original electrocatalyst with potential applications in the development of electrocatalytic systems for HER.

Keywords: Electrocatalyst, Nasicon, PANI, Stainless steel, HER

1. INTRODUCTION

Hydrogen energy is used for many applications due to its advantages such as high energy density, energy conversion and storage. In particular, water splitting photocatalysis and electrocatalysis processes are the most popular candidates for green hydrogen production [1]. The process of hydrogen production from electrolysis processes consists of two half-reactions (hydrogen evolution reaction (HER)) in which an oxidation reaction takes place at the anode to produce oxygen (oxygen evolution reaction (OER)) and a reduction reaction takes place at the cathode to produce hydrogen gas [2]. Normally, since the two main processes on the electrocatalyst surface are in competition, an electrode designed as an electrocatalyst for HER should have a good balance between the two successive processes (adsorption and desorption) occurring on its surface.

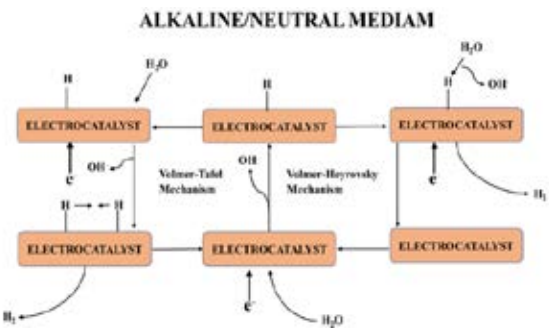

Fig. 1. HER mechanisms in alkaline media [3].

Conducting polymers are used in HER studies due to their advantages such as environmental friendliness, low cost and non-toxicity. When we look at the literature, especially conductive polymers such as polyaniline [4-6], polythiophene [7], polypyrrole [8,9] and their derivatives [10] are included.
In this work, the PANI/ NCPS(Ni) composite was synthesized via in situ chemical oxidative polymerization by incorporating NCPS(Ni) into polyaniline at the monomeric level.

2. MATERIALS AND METHODS

In the present work, PANI@NCPS(Ni) composites were synthesized by in situ chemical oxidative polymerization. Firstly, $(NH_4)_2[Co(SO_4)_2].6H_2O$ is prepared by reacting $CoSO_4.7H_2O$ with $(NH_4)_2SO_4$. After then it dissolved in 100 mL of DI water and stirred it for 1 h at temprature 80 °C. Then, 1 M NaH_2PO_3 was added to the above solution and stirred for 2 h for proper mixing. After that, 0.5 M $NiSO_4.7H_2O$ was added and Na_2CO_3 was mixed into the solution mixture, causing spontaneous CO_2 evolution. The pH of the reaction mixture was maintained basic by adding ammonia solution to precipitate, followed by calcination of as-prepared dried powder at 500 °C for 12 h in a muffle furnace (heating rate was maintained 5 °C per min) to get the final crystalline NCPS(Ni). The in situ chemical oxidation method was used to synthesise PANI/NCPS(Ni) composites. A predetermined amount of ANI monomer (0.1 M) was first mixed with 70 mL ice-cold 0.5 M hydrochloric acid (HCl) under continuous stirring. Previously synthesized nano-NCPS(Ni) was then added

to the above reaction mixture. The reaction mixture was stirred for 2 h to confirm adequate dispersion and interaction of the ANI monomer and NCPS(Ni). Next, 30 mL of 100 mM APS solution was slowly dropped into the reaction mixture for polymerization under stirring conditions. After the addition of APS, the reaction mixture was stirred for another 2 h. The mixture was then left overnight to complete polymerization. The next day, the formed composite was washed and filtered several times with DI water and ethanol to remove any residual contaminants and unreacted monomers. The materials were then oven dried at 50°C for 24 h before being used as active electrode materials. After the synthesis process was completed, coatings were deposited on the 304-type stainless steel surface selected as the substrate using the speed coating method. PANI@NCPS(Ni)/SS, PANI/SS and SS electrodes were analysed by EIS, LSV and Tafel techniques in 0.5 M KOH solution at room temperature using the three-electrode method.

3. RESULTS AND DISCUSSION

The electrocatalytic activity of the synthesized catalysts on SS was analyzed by linear sweep voltammetry at 5 $mV \cdot s^{-1}$ in 0.5 M KOH solution. The LSVs of all catalysts are shown in Fig.2a According to Fig.2b shows that the PANI@NCPS(Ni)/SS and PANI/SS catalysts exhibit activity trends with matching onset potential for HER and overpotential values of 145 and 232 mV at -10 $mA \cdot cm^{-2}$ respectively, compared to 304SS (391 mV). The higher electrocatalytic activity of PANI@NCPS(Ni)/SS compared to PANI/SS and bare SS can be attributed to its highly rough surface and the formation of a structure with a large number of protrusions [11]. This characteristic allows a greater number of active sites to be created on the surface of the catalyst, allowing increased adsorption of H_3O^+ and facilitating the desorption of H_2. The LSV curve was used to determine the Tafel slope of the catalytic materials. The determined Tafel slope of 145 $mV \cdot dec^{-1}$ (Fig.2c) suggest that the Volmer step is the rate determining step [12]. A summary of the comparative performance of HER on PANI-based catalysts from the literature in alkaline solutions is given in Table 1. The data show that the overpotential at j= - 10 $mAcm^{-2}$ is in the range of 40 to 400 mV, which means that the present PANI@NCPS(Ni)/SS represents has a potentially efficiency.

Table 1. Comparison of the performance of recently reported PANI-based HER electrocatalysts.

Metarial	Electrolyte	Tafel Slope (mV dec^{-1})	η (mV vs. RHE)	References
$FeAlO_3$/PANI	1.0 M KOH	62	165 mV	[13]
CeO_2-MoS_2 /PANI	1.0 M NaOH	62	44 mV	[14]
FeNi-LDH@Ni/SS	6 M KOH	109.1	399 mV	[15]
NiCo/ PANI	1.0 M KOH	79	220 mV	[12]
Nb_2C/$MoTe_2$(PANI)	2.0 M KOH	60.4	148.72 mV	[16]
V_2O_5/MnO_2/ PANI	1.0 M KOH	56.4	130 mV	[17]
PANI@NCPS(Ni)/SS	0.5 M KOH	67	145 mV	present work

The charging behaviour of the catalytic material was analysed using the EIS method. Nyquist plots are shown in Fig.2d using a three-electrode system in 0.5 M KOH as electrolyte, where the electrode is 304 stainless steel and Ag/AgCl and Pt are used as reference and counter electrodes respectively. The EIS measurement was performed for each electrode material at its respective onset potential between 10^5 and 10^{-2} Hz. It allows the charge transfer resistance (R_{ct}) on the surface of catalysts to be estimated. To obtain the R_{ct}, the spectra were fitted with the one-time constant that its electronic equivalent circuit is composed of a resistor (R_s) that represents the solution resistance in series connection with a resistor and a constant phase element (C_{CPE}) that are connected in parallel. C_{CPE} is used instead of ideal capacitor (C) because of deviation from ideal capacitive behaviour due to surface roughness and inhomogeneity. According to Fig.2d, it can be concluded that the PANI@NCPS(Ni)/SS (16.11 Ω) catalyst exhibits smaller charge transfer resistance (R_{ct}) compared to PANI/SS (19.35 Ω) and SS (253.28Ω).

Table 2. EIS data of PANI@NCPS(Ni)/SS composite in 0.1 M KOH

Material	R_s (Ω)	R_{ct} (Ω)	C_{CPE} (F)	n	X^2 (10^{-3})
PANI@NCPS(Ni)/SS	1.45	16.11	2.15×10^{-04}	0.91	1.19
PANI/SS	2.84	19.35	1.85×10^{-04}	0.84	6.97
SS	3.08	253.28	9.53×10^{-05}	0.89	7.69

4. CONCLUSIONS

A new material composition [PANI@NCPS(Ni)] for hydrogen evolution reaction (HER) catalyst was prepared by in situ polymerization method. The electrochemical tests showed that the hydrogen evolution reaction (HER) efficiency of stainless stell was significantly improved by the prepared catalysts. Higher value of current density and lower polarisation resistance was obtained with this electrode. The composite was exhibited an overpotential of 145 mV and a Tafel slope of 67 mV·dec^{-1} at a current density of -10 mA·cm^{-2} against a reversible hydrogen electrode (RHE) and was found to be a promising candidate as a polymer-based composite HER catalyst.

ABSTRACT
This study presents the green synthesis of MnVS and Co-doped MnVS nanoparticles using an extract derived from fresh almond bark. The synthesized nanoparticles were evaluated as photocatalysts for the photocatalytic reduction of methylene blue and as catalysts for hydrogen generation via $NaBH_4$ methanolysis. Structural and morphological properties were characterized through XRD, SEM-EDX, TEM, and XPS analyses. The influence of $NaBH_4$ concentration, methylene blue concentration, and catalyst dosage on the photocatalytic reduction process was systematically investigated. The catalytic performance of MnVS and Co-doped MnVS was assessed at different catalyst amounts (5 mg, 7 mg, and 10 mg). Kinetic analysis yielded rate constants (k) of 1.027, 1.2679, and 1.2273 min^{-1} for MnVS and 0.6868, 0.6865, and 0.3663 min^{-1} for Co-doped MnVS, indicating optimal catalyst amounts of 7 mg and 5 mg, respectively. Reaction kinetics were modeled using the nth-order and Langmuir-Hinshelwood models, with high R^2 values confirming their applicability. The activation energies (Ea) were determined as 28.09 kJ mol^{-1} for MnVS and 21.99 kJ mol^{-1} for Co-doped MnVS. This study highlights the potential of eco-friendly nanoparticle synthesis for efficient hydrogen production and organic pollutant removal, demonstrating its significance in sustainable catalytic applications.

Keywords: Green synthesis, Photocatalytic reduction, Methylene blue, Hydrogen production, $NaBH_4$ methanolysis

1. INTRODUCTION
In contemporary times, the excessive consumption of non-renewable resources such as natural gas, crude oil, and coal to meet global energy demands has significantly increased greenhouse gas concentrations in the atmosphere, leading to global warming [1]. This phenomenon has contributed to the escalation of natural disasters, either directly or indirectly, due to climate change. Consequently, the development of clean, renewable, and economically viable energy systems has become a major priority [2]. Hydrogen has emerged as an environmentally friendly and sustainable energy carrier. With an energy density up to three times that of petroleum, hydrogen holds significant potential as an alternative to fossil fuels. However, for hydrogen to be truly considered a "green" fuel, it must be produced from non-fossil fuel feedstocks [3]. Locally produced hydrogen facilitates the integration of renewable energy into the transportation sector, offering substantial economic and energy security advantages [4]. Among hydrogen storage technologies, chemical hydrides are particularly promising. Sodium borohydride ($NaBH_4$) is one of the most widely used hydrogen storage materials due to its non-flammability, air stability, and controllable hydrogen release [5]. The methanolysis reaction of $NaBH_4$ offers lower operating temperatures and faster hydrogen production rates compared to hydrolysis [6]. However, efficient catalysts are required to enhance the performance of this reaction [7]. Metal nanoparticles and metal composites are widely preferred as catalysts for $NaBH_4$ methanolysis [8]. On the other hand, one of the most critical global challenges of the 21st century is the provision of clean and safe water [9]. The expansion of modern industries, including the textile and energy sectors, has led to significant water pollution, posing severe environmental threats [10]. The textile industry, utilizing approximately 36,000 tons of dye annually, has become a primary contributor to global water contamination [11]. Methylene blue (MB) is a commonly used dye in the textile industry, exhibiting high resistance to biological degradation [12]. Various techniques, such as adsorption, ozonation, and photocatalytic degradation, have been employed for MB removal [10]. However, the $NaBH_4$ reduction method stands out as a more advantageous option due to its rapid and efficient results [13]. This reduction reaction can occur swiftly only in the presence of nanoparticle catalysts [14]. Nanoparticles (NPs) are generally insoluble materials with sizes below 100 nm and possess a large surface area, resulting in unique physical, chemical, optical, thermal, and mechanical properties compared to conventional bulk materials [15]. Although chemical synthesis methods are cost-effective for large-scale production, their reliance on toxic chemicals and the generation of harmful by-products pose significant environmental concerns [17]. Thus, plant-based green synthesis methods have gained attention as more eco-friendly alternatives [18]. Plant extracts can serve as both reducing and stabilizing agents in nanoparticle synthesis [19]. Recent studies have demonstrated that metal sulfide nanoparticles exhibit narrower band gaps than metal oxide, making them more efficient in the visible region of the electromagnetic spectrum. As a result, sulfide-based nanoparticles have emerged as promising alternatives to conventional metal oxide-based photocatalysts [20,21].
This study aims to utilize an extract prepared from fresh almond bark as a reducing agent in the green synthesis of MnVS and Co-doped MnVS nanoparticles. The synthesized nanoparticles were evaluated as photocatalysts for the

photocatalytic reduction of methylene blue and as catalysts for hydrogen production via $NaBH_4$ methanolysis. Structural and morphological properties of the synthesized catalysts were characterized using XRD, SEM-EDX, TEM, and XPS, analyses.

2. MATERIALS AND METHODS

$Co(NO_3)_2.6H_2O$, $MnCl_2.4H_2O$ and $Na_2S.H_2O$ were obtained from Sigma-Aldrich. $C_{10}H_{14}O_5V$ was obtained from Fluka company. Almond wet peel was obtained from Siirt market.

2.1. Preparation of plant extract extract

Extract from almond wet peels was prepared by hydrothermal method. To prepare the extract, 35 g of almond wet peels and 350 mL of pure water were placed in a 500 mL autoclave, then kept in an oven at 180 °C for 12 hours and cooled to room temperature. The extract was filtered and stored at 4 °C for use in the synthesis of MnVS nanoparticles.

2.2. Synthesis of MnVS and MnVS-Co nanoparticles

MnVS nanoparticles were synthesized by green synthesis method; 100 mL of almond wet peel extract and $MnCl_2.4H_2O$, $C_{10}H_{14}O_5V$, $Na_2S.H_2O$ in amounts determined as mole ratios (Mn:V:S=0.5:0.5:1) were mixed and the pH of the solution was adjusted to 10 with 1M NaOH. The resulting mixture was stirred at room temperature for 24 hours, then filtered through 0.22 mm membrane filter paper and the solid obtained was dried at 120 °C for 3 hours.
Co doped MnVS nanoparticles were synthesized by chemical reduction method; enough $Co(NO_3)_2.6H_2O$ and 1 g MnVS NPs were mixed in 50 mL water. After heating and turning into sludge, a certain amount of $NaBH_4$ was dissolved in 50 mL of water and added dropwise. It was then filtered with filter paper and the obtained material was dried at 120 °C for 2 hours. The synthesized nanoparticles were stored in a sealed container for use in methanolysis and photocatalytic reduction of methylene blue. The synthesized nanoparticles were characterized by XRD, SEM, EDX, TEM and XPS.

2.3. Hydrogen Production

Hydrogen production in $NaBH_4$ hydrolysis was carried out using a solution containing 10 mg of catalyst, 2.5% $NaBH_4$, 2.5% NaOH and 10 mL methanol.

2.4. Photocatalytic reduction of methylene blue

Photocatalytic reduction of methylene blue with NaBH4, 0.5 mL of NaBH4 at different molarities (15 mM, 20 mM, 25 mM and 50 mM) and 3 mL of methylene blue at different concentrations (15 ppm, 20 ppm, 25 ppm and 50 ppm) were dropped into a quartz container and exposed to UV spectroscopy. The concentration of methylene blue in the medium was determined by UV spectroscopy (wavelength=664 nm). The decolorization efficiency and pseudo-first order kinetics of methylene blue were determined.

3. RESULTS AND DISCUSSION

3.1. Characterization of Nanoparticles

The nanoparticles synthesized by green synthesis method were characterized by XRD, SEM, EDX, TEM and XPS. it was determined from the characterization results that the nanoparticles were synthesized in pure and nanoscale.

3.2. Catalytic Activity

The activity of sodium borohydride was first assessed at varying concentrations in the methanolysis application of MnVS and Co-doped MnVS catalysts. It was observed that an increase in $NaBH_4$ concentration generally resulted in an elevated reaction rate. The efficiency of catalyst quantity was also evaluated alongside the concentration efficiency of sodium borohydride. The volume of hydrogen produced was shown to rise with the quantity of catalyst used. The rise in the methanolysis rate with a higher catalyst quantity is attributed to the augmented number of catalytic sites available. The impact of temperature on methanolysis was also examined. To examine the influence of temperature on the methanolysis process, tests were conducted at several temperatures (30-60 °C) using 2.5% $NaBH_4$ and 10 mg of catalyst, and the resulting graph is shown in Figure 1.

Fig. 1 illustrates that the duration of methanolysis diminishes as temperature rises. The rate of hydrogen synthesis escalates with rising temperature. This occurs because an increase in temperature leads to a rise in the frequency of intermolecular collisions and an elevation in the kinetic energy of the molecules. Kinetic studies elucidate the characterization of reaction processes. The rates of H_2 generation from $NaBH_4$ hydrolysis were assessed using nth order and Langmuir-Hinshelwood kinetic models using experimental data collected at various temperatures. The activation energy (Ea) was ascertained by the Arrhenius Equation utilizing k values derived from the nth order and Langmuir-Hinshelwood kinetic models at various temperatures. Arrhenius plots of ln (k) versus 1/T for nth order and Langmuir-Hinshelwood kinetic models are shown in Figure 2. It can be seen that both models have high R^2 values. The activation energy (Ea) values for the nth order and Langmuir-Hinshelwood kinetic models were found to be 28.10 $kJmol^{-1}$ for MnVS

and 21.99 kJmol^{-1} for Co doped MnVS. The Langmuir-Hinshelwood model is widely used to better understand the changes in n and Ea values of chemical reactions.

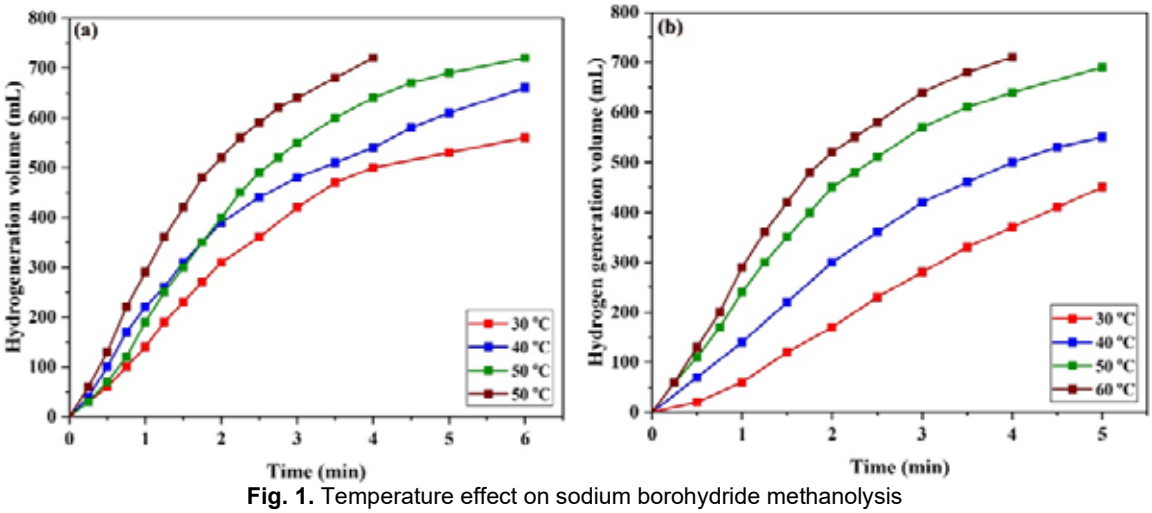

Fig. 1. Temperature effect on sodium borohydride methanolysis

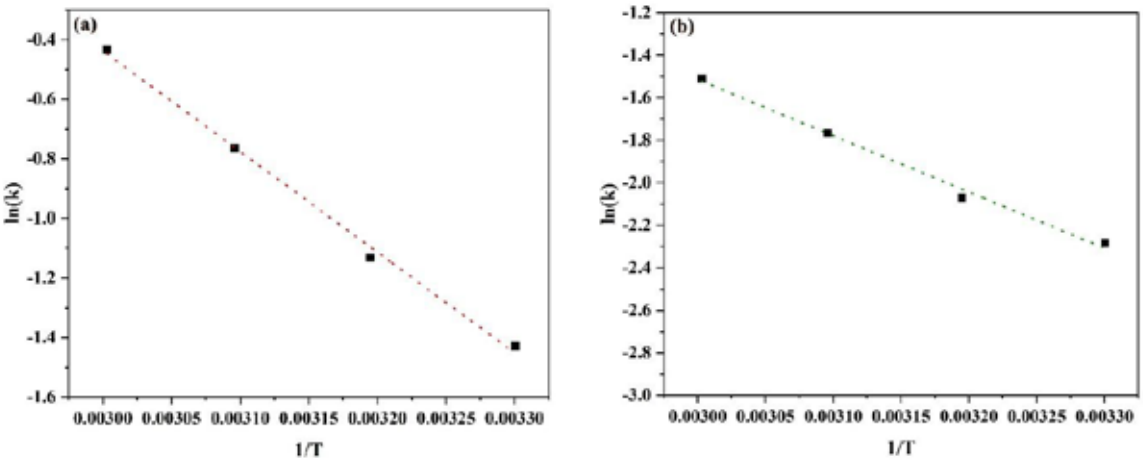

Fig. 2. Plot of ln(k) against 1/T

3.3.Photocatalytic Reduction

The factors influencing the photocatalytic reduction of methylene blue using NaBH4, including NaBH4 concentration, methylene blue concentration, and catalyst quantity, were examined. The impact of varying catalyst quantities on the photocatalytic reduction of MnVS and Co-doped MnVS catalysts was examined, and the kinetics were assessed based on these findings. This assessment revealed k values of 1.027, 1.2679, and 1.2273 min-1 for the MnVS catalyst at varying catalytic concentrations of 5 mg, 7 mg, and 10 mg, respectively. For the Co-doped MnVS catalyst at identical catalytic quantities (5 mg, 7 mg, and 10 mg), the k values were 0.6868, 0.6865, and 0.3663 min^{-1}, respectively. The optimal catalyst quantity for MnVS was 7 mg, but the ideal quantity for Co-doped MnVS was 5 mg.

4. CONCLUSIONS

In this study, the effects of MnVS and Co-doped MnVS nanoparticles produced by green synthesis method on hydrogen production and photocatalytic reduction of methylene blue were investigated. Kinetic analyses revealed that MnVS showed higher activity in the photocatalytic reduction process and the optimum amount of catalyst was 7 mg. The activation energy values determined according to the Langmuir-Hinshelwood kinetic model showed that Co-doped MnVS has a lower energy barrier. The results obtained reveal that environmentally friendly nanoparticles offer an effective alternative for energy production and water treatment.

ABSTRACT
This study focuses on hydrogen production via sodium borohydride methanolysis using Fe-Zr as a catalyst supported on Al_2O_3 and examines the hydrogen generation rate performance (HGR) concerning different Al_2O_3 quantities and different temperatures. Results have obtained within the temperature range from 20 to 50 ºC and Fe-Zr / Al_2O_3 (wt%) range from 5% to 15%. Characterisation of the catalyst was performed by XRD and SEM. The hydrogen generation rate for 5% Fe-Zr/ Al_2O_3 was obtained at 30 ºC was 7003.4 $L.min^{-1}$. g cat^{-1}. The power law model is used in order to calculate a reaction order of 0,824 and the Arrhenius equation for an activation energy of $kJ.mol^{-1}$. This study shows that 5% Fe-Zr over Al_2O_3 (wt%) is the most effective. Higher Fe-Zr ratio has been observed to result in lower performance, which can be attributed to the formation of multilayer adsorbtions. These findings underscore the potential of Fe-Zr/ Al_2O_3 catalyst for efficient hydrogen production with optimal performance achieved at lower Fe-Zr ratios, offering valuable insights for the design of cost-effective and alternative, sustainable hydrogen generation systems.

Keywords: Hydrogen generation, Sodium borohydride, Methanolysis, Support material, catalysis

1. INTRODUCTION
Hydrogen has a promising potential as an alternative energy source in the global transition and industry. Its high energy density, zero-emission combustion, and promising application potential make it a key player for the challenges of climate change and energy security.[1] In addition hydrogen can be used in fuel cells which has a potential of reducing greenhouse gas emissions to the nature. However, in the industry, efficient and sustainable production of hydrogen and storage of hydrogen is still a critical challenge. Sodium borohydride is one of the most studied hydrogen studied material because of its ability of delivering high purity H_2 at room temperature wih controllable kinetics. But efficient and cost-efficient catalysts and its regeneration has been challenging [2].
Among many methods of hydrogen generation, methanolysis of sodium borohydride has gained significant attention due to the spontaneous nature of the reaction, mild reaction conditions and environmentally benign by-products [3]. In this study according to the reaction showed below, methanolysis of $NaBH_4$ with Fe-Zr catalyst on a $Al2O_3$ support material is examined and effect of Fe-Zr ratio over Al_2O_3 and temperature is investigated.

2. MATERIALS AND METHODS
Hydrogen from sodium borohydride ($NaBH_4$ ≥98 %, Merck) is generated at athmospheric pressure through methanolysis reaction with Fe-Zr/Al_2O_3. Fe-Zr/Al_2O_3 is obtained from reduction of ferric chloride hexaydrate (≥97%, SRL) and Zirconium (IV) oxynitrate hydrate (≥99%, Sigma-Aldrich) by using sodium borohydrate ($NaBH_4$ ≥98, SRL) as reducing agent. Reduction reaction were carried out in a 200 mL glass beaker at room temperature. Ferric chloride hexaydrate and Zirconium (IV) oxynitrate hydrate was first added to the beaker with 50 mL of water then stirred with the magnetic stirrer for 3-5 minutes to obtain transparent solution. Afterwards Al_2O_3 is added and stirred for 2 hours in order to obtain uniformly distributed suspension. Afterwards sodium borohydrate diluted with 30 mL of water has been added to the beaker drop by drop for the reduction then stirred for 3 more hours. To ensure complete reduction 50% excess $NaBH_4$ is used. Upon the completion of the reaction, a dark orange colour should be observed. After confirming the completion of the reaction, the mixture is filtered using a membrane filter via a funnel and then dried in oven at 80 ºC for 4 hours. Finally, the catalyst was transferred to an Ependorf tube.

The experimental in order to measure HGR is illustrated in Fig. 1 [4]. The cylinder is filled with water (500 mL) was placed upside down in a contained with filled with water. Then certain amount of catalyst and methanol was added to an Erlenmayer flask and put into the water bath. Then by using the control unit rpm and temperature has been set. Flask was shaken by a device with rpm set from the control unit. Then flask is connected with the measuring cylinder by a plastic pipe in which the end of the pipe is placed into the cylinder. Later certain amount of $NaBH_4$ had added to the Erlenmayer flask and reaction began. The volume of hydrogen gas produced by the methanolysis of $NaBH_4$ is measured by water-gas displacement technique [5]. As the time progressed, the amount of hydrogen gas increased, resulting in a decrease of the water level in the cylinder. Therefore, the difference between the final and initial volume of the water in the cylinder indicates the volume of hydrogen gas produced.

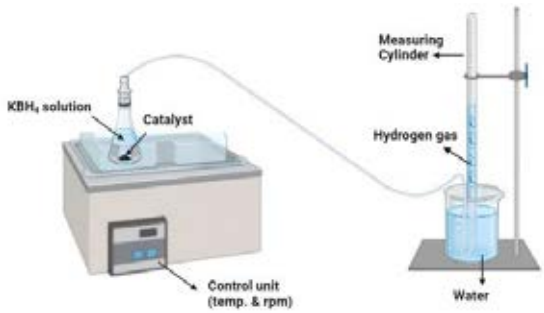

Fig. 1. Reaction setup of methanolysis process. [4]

3. RESULTS AND DISCUSSION

3.1. Characterization of the Catalyst

The SEM and EDX images and SEM EDX spectrum of 5% Fe-Ze/Al_2O_3 catalyst are given in Fig. 2. Also, smart quaf results are shown in Table 1. The images taken from the 5% Fe-Zr/Al_2O_3 catalyst sample shows an agglomerated, smooth surface structure and no phase separation between the catalyst and the support material. The images taken and spectrums given in Fig. 2. Prove the presence of Fe, Zr, Al and O and it can be seen that Fe and Zr are distributed over the support material, forming a smooth structure.

The XRD pattern shown in Fig. 3. shows that metallic Fe [6] and Zr [7] were observed in catalyst material. Also peaks at 37.4º, 45.7º, 67.05º corresponds to Al_2O_3 [8]. It can also be seen on the Fig.3. that at the 45.7º peak Fe and Al_2O_3peaks are overlapped. In conclusion, those results are proving that the metals are loaded on support material successfully.

3.2. Effect of Fe-Zr / Al_2O_3 Ratio and Temperature

Fig. 4a. shows the impact of Fe-Zr / Al_2O_3 (wt%) ratio on HGR. For the experiment $NaBH_4$ concentration, methanol volume and temperature were kept constant at 0.264 M, 10 mL and 30 ºC respectively. Catalysts with Fe-Zr / Al_2O_3 (wt%) ratio of 5-10-15% have been obtained as 7003.4, 5840.0, 5522.8 $L.min^{-1}$. g cat^{-1} respectively. Results have shown that increasing Fe-Zr / Al_2O_3 ratio decreases the hydrogen generation rate.

Fig. 4b. shows the effect of temperature on HGR. Results show that HGR increases with temperature. The HGR values obtained for 20,30,40,50 ºC are 3506.1, 7003.4, 9253.5, 14219.0 $L.min^{-1}$. g cat^{-1} respectively. Higher temperatures accelerate the methanolysis reaction by increasing the frequency of essential frequencies between reactant molecules. Therefore, as shown in Fig. 4b., HGR is increased with the temperature.

3.3. nth Order Reaction Kinetics

In order to analyze the kinetic behaviour of the catalysts and reactants, the kinetics of the methanolysis reaction of the $NaBH_4$ is mathematically analyzed with the nth order reaction kinetic model. The equations used are as below;

$$-r_{NaBH_4} = \frac{dC_{NaBH_4}}{dt} = kC_{NaBH_4}^{n} \quad (1)$$

In the equation above $-r_{NaBH4}$ represents the reaction rate of $NaBH_4$ methanolysis. C_{NaBH4} represents the concentration of $NaBH_4$ and t represents time. dC_{NaBH4} represents the rate of change of sodium borohydride concentration over time. k is for reaction rate constant and it depends on some certain parameters such as temperature and catalyst presence. n is for the reaction order. Integrating equation (1) From t=0 to t=t gives a linear equation including relationship between the reaction rate and sodium borohydrate concentration over time which is shown below;

$$\frac{1}{C_A^{n-1}} - \frac{1}{C_{A0}^{n-1}} = (1-n)kt \quad (2)$$

For for 5% Fe-Zr / Al_2O_3, by using the equation (2) a graph is created with the data calculated (drom the left side of the equation) against time. Then, by setting n values R^2 values are evaluated. The n value that gives the nearest R^2 value to 1 indicates the correct order of the reaction. According to the calculations n value of 0,824 is obtained. Later, activation energy is calculated by using the Arrhenius equation as 42.34 kJ mol^{-1}.

$$k = A \exp\left(-\frac{E_A}{RT}\right) \quad (3)$$

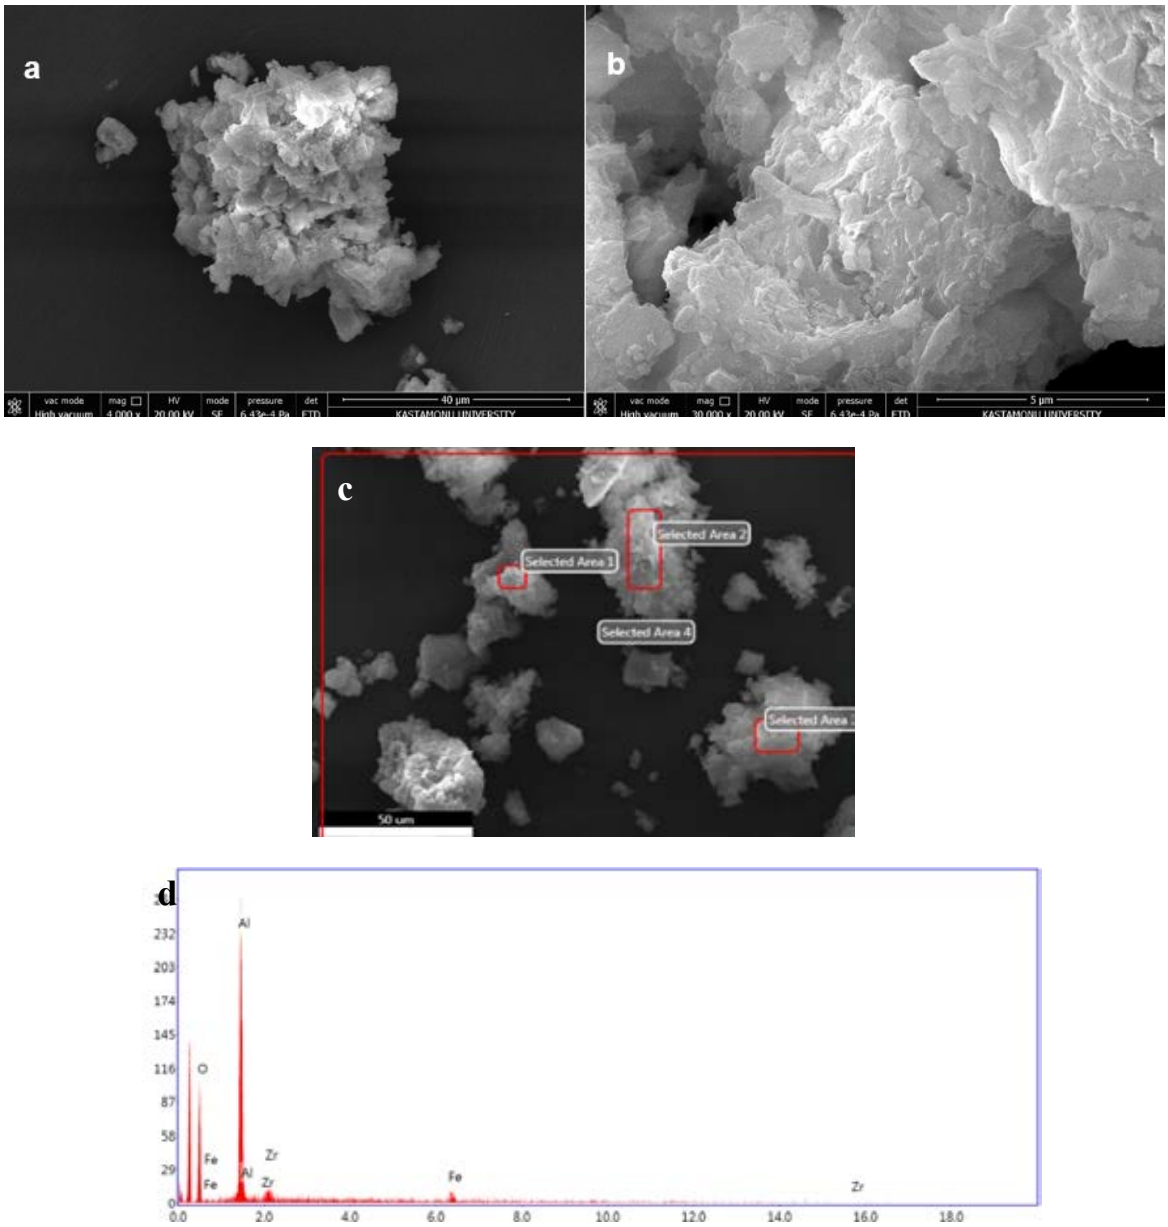

Fig. 2. SEM EDX image (a,b,c) and SEM EDX spectrum of Fe-Zr/Al_2O_3 (d, from selected area 4)

Table 1. Smart Quant Results (from selected area 4)

Element	Weight %	Atomic %
O	52.79	66.56
Al	43.11	32.23
Fe	2.19	0.79
Zr	1.91	0.42

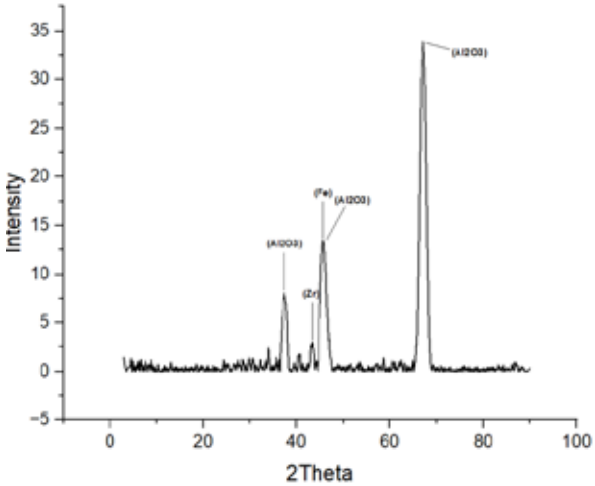

Fig 3. XRD pattern of Fe-Zr/Al2O3 catalyst

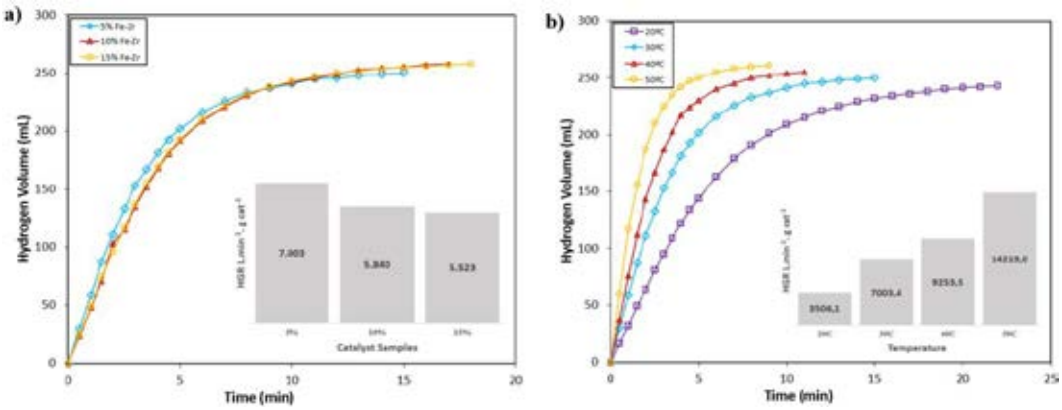

Fig. 4. Effect of Fe-Zr ratio (a) and temperature (b) on HGR

4. CONCLUSIONS

This paper studies the temperature and Fe-Zr ratio effects on hydrogen production via methanolysis of $NaBH_4$ with Fe-Zr catalyst on a Al_2O_3 support material.

This research obtained a HGR of 7003.4 $L.min^{-1}$. g cat^{-1} at 30 ºC with the reaction order of 0,824 and activation energy of 42,34 kJ mol^{-1}. Also, it is shown that increasing Fe-Zr ratio over Al_2O_3 negatively affects the performance. On the other hand, increased temperature notably boosts HGR.

This study indicates that with the lower ratios of Fe-Zr over Al_2O_3 optimal hydrogen generation efficiency can be maximized. That outcome may be promising approach to hydrogen production applications when using Fe-Zr and Al_2O_3 as an alternative catalyst and support material.

ABSTRACT

This paper presents a simulation-based study on the performance and cost optimization of alkaline water electrolysers. COMSOL Multiphysics was used for electrochemical modeling, while the Engineering Equation Solver (EES) was employed for cost analysis. The key parameters investigated include temperature, electrolyte concentration, electrode-separator distance, and separator porosity. The study demonstrates that optimizing these parameters enhances efficiency and significantly reduces the levelized cost of hydrogen (LCOH), particularly in large-scale applications.
Keywords: Alkaline water electrolysis, cost optimization, performance optimization, LCOH, LCOE.

1.INTRODUCTION

The increasing global energy demand and the limitations of fossil fuels necessitate alternative energy sources. Hydrogen, with its high energy content (39.42 kWh/kg), is a promising clean energy carrier. Alkaline water electrolysis is one of the most commercially mature hydrogen production methods, offering cost-effectiveness and durability compared to other technologies like proton exchange membrane (PEM) or solid oxide electrolysis (SOE) [1–4].
Electrolysis involves splitting water into hydrogen and oxygen using an electrical current. The fundamental electrochemical reaction is expressed as:

$$H_2O_{(l)} + Electricity + Heat \rightarrow H_{2(g)} + {}^{1}/_{2}\, O_{2(g)} \quad (1)$$

A typical alkaline electrolysis cell consists of nickel-based electrodes in a KOH solution, operating at 60-90°C and below 30 bar pressure [5]. The minimum potential required for electrolysis is determined by the Nernst equation, with the standard reversible voltage being 1.229 V at 25°C [6].

2. ELECTROCHEMICAL MODELING AND SIMULATION APPROACHES

Electrochemical modeling is essential for understanding the reaction mechanisms, kinetics, and mass transport phenomena in alkaline water electrolysers. The cell voltage is expressed as the sum of the reversible voltage and the overpotentials due to ohmic resistance, activation, and mass transfer limitations:

$$U = U_{rev} + U_{ohm} + U_{act} + U_{conc} \quad (2)$$

where U_{rev} is the reversible voltage, and the remaining terms represent ohmic, activation, and concentration overpotentials. A widely used form of the current–voltage relationship, originally proposed by Ulleberg, is given by:

$$U = U_{rev} + r \cdot i + s \cdot \log(t \cdot i + 1) \quad (3)$$

2.1. COMSOL Modelling and Simulation Approaches

COMSOL Multiphysics 6.1 is used to simulate a 2D electrolyser cell where the geometry is simplified to clearly define the boundaries for the electrodes, separator, and gas compartments. The modeling framework incorporates the Nernst equation for equilibrium potential, Butler–Volmer kinetics for electrode reactions, and Ohm's law to describe ion transport. In the CFD modeling process, 20 different analysis utilized for determining the effects of different parameters. The parameters used in the simulation are provided in here. For the both cathode and anode side electrode-separator distance range used 2 and 4 mm. Seperator width is 1 mm and cell height is 10 mm. Temperature range used in the analysis are 25 and 75 C and separator porosity is in here 0.3-0.4. Two different electrolyte solution and concentration is used: KOH and NaOH, 6 and 10 M, respectively.

2.2. Cost Optimization Modelling

This study utilizes the EES program to calculate and optimize costs associated with alkaline water electrolyzers. The cost of alkaline water electrolyzers was determined based on real-world market data at the end of 2024, as provided in Table 2.3 for the 25 kW, the stack, mod and systems costs is 25,000, 90,000 and 160,000 $ respectively. For 250 kW system, these prices is 150,000, 350,000 and 450,000 $, respectively. Using these data, the cost per square meter of active area was calculated. This calculation yielded a single-cell cost of $19,200 per m², incorporating factors such as material costs, labor, and other project-related expenses.

In addition to the 20 analyses mentioned above, an independent analysis was conducted for the cost optimization. This analysis considered operational parameters such as a temperature of 75°C, a 6M KOH solution concentration, a separator porosity of 0.8, and a separator-electrode distance of 2 mm. The calculations were performed for a voltage range of 1.8 V to 2.5 V, and the output data obtained from analysis used in the EES program for cost optimization.

The I-U curve data were used to derive a I-U function for total system power calculations, which was subsequently implemented in the EES program using Eq.(4). The current values obtained from the function correspond to a per-square-meter basis. To determine the total area for achieving the desired system power, Eq. (5) was employed.

$$\mathrm{V}_{cell} = -0{,}000000000293 * \mathrm{I}_{cell}{}^{2} + 0{,}0000627 * \mathrm{I}_{cell} + 1{,}816 \quad (4)$$

$$\mathrm{A}_{total} = (\dot{W}_{total}/(\mathrm{V}_{cell} * \mathrm{I}_{cell})) * 1000 \quad (5)$$

Market prices for 25 kW and 250 kW systems were obtained from current sources, including manufacturer quotes, industry-specific market reports. For larger systems, these costs were interpolated using available unit prices. Based on the interpolated data, two critical factors were derived: The system factor (F_s) represents the costs associated with auxiliary systems (e.g., power sources, piping, control systems) surrounding the electrolyzer module. This factor incorporates the costs of infrastructure and integration requirements. The module factor (F_m) relates to the scale of the electrolyzer module or its capacity. Smaller systems typically have higher unit costs due to limited economies of scale, reflecting the higher installation and production expenses for smaller modules. LCOH calculations were performed using Eq. (6), dividing the total cost by the total hydrogen production.

$$LCOH = (CapEx + OpEx)/\ H_{2,total} \quad (6)$$

3. RESULTS AND DISCUSSIONS

3.1. COMSOL Analysis Results

For Effect of Temperature on Average Cell Current Density, temperature has been identified as one of the most significant factors influencing the average cell current density in the electrolysis process. This is primarily because temperature affects both the electrochemical reaction kinetics and the ionic conductivity of the electrolyte. Temperature is a critical factor influencing current density, with significant improvements observed across different electrolytes and separator porosity values, highlighting its key role in optimizing electrolysis performance.
For the Effects of Electrode-Seperator Dist. on Avg. Cell Current Density, Increasing the electrode-separator distance significantly reduces current density, with the magnitude of the decrease slightly influenced by temperature and separator porosity, while the choice of electrolyte has negligible impact.
For the Effect of Concentration on Average Cell Current Density, Increasing the electrolyte concentration from 6 M to 10 M generally reduces current density, with the magnitude of the reduction being more pronounced at lower temperatures and smaller electrode-separator distances.
For Effect of Separator Porosity on Average Cell Current Density, Increasing separator porosity significantly enhances current density, with the effect being more pronounced at lower temperatures. The trend is consistent across both KOH and NaOH, with NaOH showing a slightly higher sensitivity to porosity changes.
For the Effect of Electrolyte Solution on Average Cell Current Density, Used in here two different solution and the efficiency difference between KOH and NaOH decreases with increasing temperature, KOH is more efficient than NaOH for optimal temperatures especially at lower temperatures.

The figure above summarizing the aforementioned results. This figure focus on the parameters that most significantly affect current density, and the combined effects of these parameters are presented in graphical form. Fig.1 illustrates the impact of temperature and separator porosity on current density for KOH solution. The effects of four different temperature values on current density at porosity levels of 0.3 and 0.4 are shown in Fig.1.

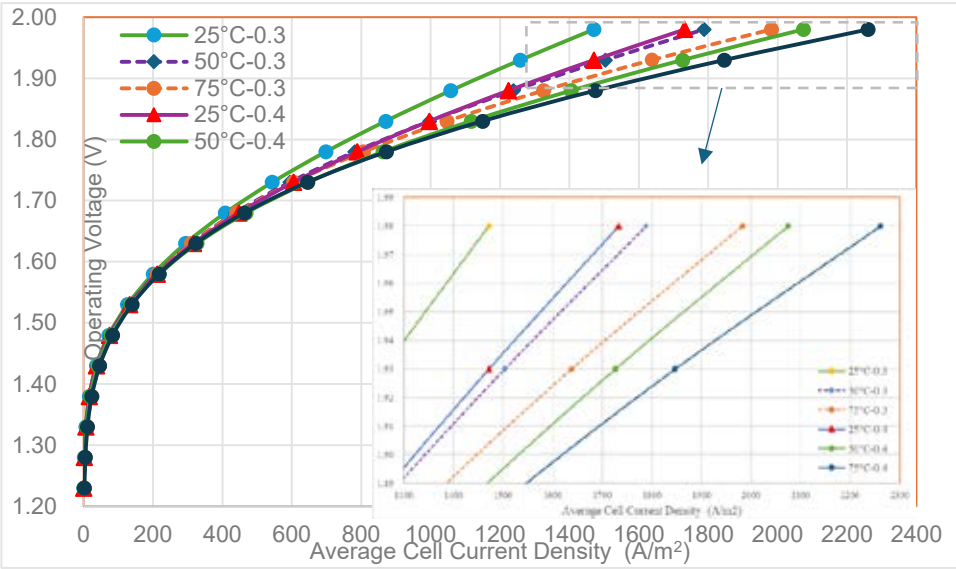

Fig.1. I-U Curve for Effect of Temperature and Separator Porosity

3.2. EES Analysis Results

In this study, cost optimization was performed using 1D modelling in COMSOL Multiphysics, providing a simplified yet effective approach to analyze the electrochemical performance and economic implications of alkaline water electrolyzers. The 1D model enabled the evaluation of key operational parameters, such as current density, voltage, and efficiency, which were subsequently integrated into the cost analysis framework to calculate the Levelized Cost of Hydrogen (LCOH).

The results from COMSOL modelling were transferred into the engineering equation solver (EES) environment to extend the analysis and systematically explore the impact of technical parameters on economic outcomes. This hybrid approach ensured that the cost optimization process combined accurate simulation data with flexible economic modeling, enabling the identification of operating conditions that minimize LCOH. By utilizing this methodology, the study demonstrates the practicality of 1D modelling-based analysis as a foundation for cost-effective hydrogen production and future design improvements.

Using the current-voltage formula derived from COMSOL data, calculations were performed in the EES program for systems with capacities of 25 kW, 100 kW, 1,000 kW, 5,000 kW and 10,000 kW. For these calculations, LCOE values of $ 0.05/kWh and $ 0.1/kWh were considered, and analyses were conducted for current densities of 10,000 A/m^2 and 20,000 A/m^2. The analysis focused on determining CapEx and OpEx values for cost optimization, while simultaneously calculating the total hydrogen produced by the system and deriving the LCOH values. A total of 20 analyses were conducted, incorporating these parameters.

As a result of the calculations, a LCOH value of $3.97 was obtained for a 10,000 kW system with an LCOE value of $0.05/kWh.

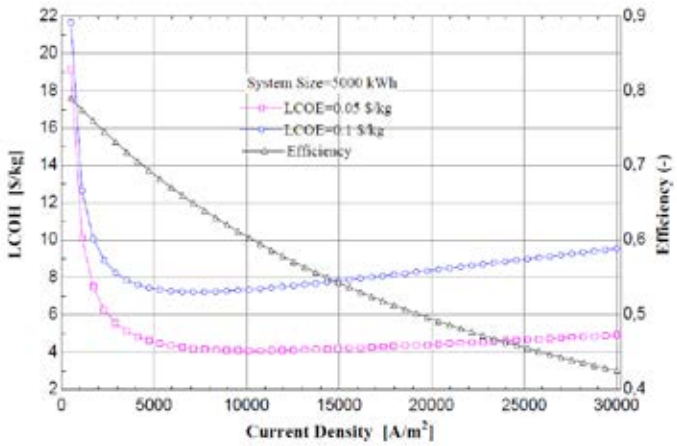

Fig. 2. LCOH and Efficiency vs. Current Density Curve for Fixed System Size

The presented graph highlights the relationship between cell current density I_{cell}, Levelized Cost of Hydrogen (LCOH), and hydrogen production efficiency. As the current density increases, LCOH initially decreases due to improved utilization of system capacity and reduced relative fixed costs. However, beyond a certain point, the efficiency starts to decline significantly because of increased energy losses, such as ohmic resistance and overpotentials, leading to diminishing returns in cost reduction. The optimal operating range for the system appears to be between 8000-12000 A/m², where a balance between low LCOH and reasonable efficiency is achieved. In this range, LCOH values for low LCOE value are around 4$/kg. The analysis further demonstrates that electricity cost (LCOE) plays a critical role in determining the overall hydrogen production cost. For instance, systems operating with a lower LCOE of 0.05 $/kWh achieve significantly reduced LCOH compared to those with a higher LCOE of 0.1 $/kWh. This underscores the importance of optimizing both current density and electricity costs to ensure economically viable and energy-efficient hydrogen production.

4. CONCLUSIONS

This study integrates electrochemical modeling in COMSOL Multiphysics with cost optimization in the Engineering Equation Solver (EES) to comprehensively evaluate the performance and cost-effectiveness of alkaline water electrolyzers. Through systematic analysis, 20 different simulations were conducted in COMSOL by varying key parameters such as temperature, electrode-separator distance, separator porosity, and electrolyte concentration and solution. The results of these simulations were used to generate current-voltage (I-V) curves, providing a detailed understanding of how each parameter influences system performance.

Among the analyzed parameters, temperature and porosity were identified as having the most significant impact on system performance. For instance, increased temperature enhanced reaction rates and reduced energy consumption, while higher porosity improved ion flow and minimized ohmic resistance. These findings emphasize the critical role of these parameters in optimizing electrolyzer efficiency.

The simulation results from COMSOL were subsequently used as inputs for cost optimization calculations in EES. Real-world market data were utilized to calculate model and system factors, which served as a foundation for system scaling studies. Additionally, analyses were conducted for two different current densities and two distinct Levelized Cost of Electricity (LCOE) values across varying system capacities. These analyses provided the necessary data to calculate the Levelized Cost of Hydrogen (LCOH). The findings demonstrated that optimizing these parameters is essential for improving both performance and economic feasibility.

Key findings of this study include the Impact of Temperature and Porosity, LCOE Sensitivity and System Scaling and Optimization. For the impact of temperature and porosity, among all parameters, temperature and porosity exhibited the most significant influence on system performance, with direct effects on energy efficiency and current density. For the LCOE sensitivity, the analyses revealed that LCOE is the dominant factor affecting LCOH, with lower electricity costs (e.g., $0.05/kWh) significantly reducing hydrogen production costs, particularly in large-scale systems. For the last finding system scaling and optimization, scaling studies based on real market data highlighted the trade-offs between capital and operational expenditures, emphasizing the need for system-specific designs to minimize overall costs.

This study provides a robust framework for evaluating alkaline water electrolyzers, offering valuable insights for system selection and optimization during the project development phase. By combining advanced electrochemical modeling with economic analyses, it establishes a pathway for designing systems that achieve the lowest possible LCOH under realistic market conditions.

ABSTRACT
In the present research, the performances of a uniquely designed Hydrogen$_2$/Bromine redox flow battery with fixed cathode feed composition and fixed anode feed at different temperatures and cathode feed flow rates were investigated. The highest power density obtained was 0.33 W/cm^2. The hydrogen consumption acted in accordance with the polarization curve.

Keywords: Hydrogen, Bromine, Redox flow battery

1. INTRODUCTION

Electric Energy Storage (EES) is a set of technologies that allows the produced electrical energy to be used at times other than when it is generated [1, 2, 3]. At the core of this technology, energy is stored when supply exceeds demand and the unit cost of energy is low, and then used when demand rises or when production cannot directly supply the system [1, 2, 3, 4, 5]. Energy storage systems have a wide range of applications, as they can be used in mobile, transportation, and stationary applications [3, 6, 7, 8].

Redox flow batteries are considered within electrochemical energy storage technologies and are a highly promising technology for the future [9, 10]. Redox flow batteries (RFB) attract attention due to their ability to meet varying power and energy demands, operate independently of the grid, support a high number of charge-discharge cycles, allow for deep discharge, and be quickly deployed [11]. All of these features have highlighted the use of redox flow batteries when coupled with intermittent renewable energy sources, emphasizing their potential for continuous energy storage and supply.

There are many types of redox flow batteries. In addition to the all-vanadium redox flow batteries, which have received the most research and commercialization efforts, redox flow batteries are also being developed using iron-chromium, sodium-polysulfide, and Zn/Br_2 pairs. In addition to these, H_2/Br_2 RFBs are also a rosy type [10, 11, 12]. H_2/Br_2 RFBs are a rosy technology due to their high reaction kinetics and the use of cheap reactants [13, 14].

Cho et al. (2013) found that the composition of the solution, including HBr/Br_2, affects the area-specific resistance, hence impacting on the performance of the redox flow battery. Reach the effect of ASR led to a reduction in thickness of the membrane, achieving a 1.46 W/cm² power density and power density of 0.64 W/cm² at 80% charge-discharge efficiency [15].

Kreutzer an others tested a MEA which include electrodes with 0.55 mg Pt/cm² catalyst loading and N212 membrane under H_2-H_2, H_2-Br_2, and H_2-O_2 pairs at room temperature and evaluated their performance. The current density for the Br^-/Br_2 reactions on catalyst was 0.3 mA/cm², while for H_2-O_2 reactions, this value was 1.2 mA/cm² [16].

Peled et al. (2000) chose a high platinum loading of 1.5 mg/cm² when constructing the electrodes. After experimenting with various parameters, they reported achieving the highest power density of 1.5 W/cm² [17].

This study also investigates the performance of a uniquely designed a cell H_2/Br_2 RFB in discharge mode, under different temperatures and cathode feed flow rates.

2. EXPERIMENTAL

In this study, a redox flow battery with 10 cm^2 active area was designed and manufactured. A fixed hydrogen feed rate was used in the anode section. The anode electrode consists of a 0.75 mg/cm^2 Pt/C coated SGL 29 BC gas diffusion layer. N115 was used as the membrane. LT1200 carbon fabric was used as a three-layer in the cathode section. Cell feeds were provided via Teflon connections, a peristaltic pump in the cathode section, and a pressure tube in the anode side. Tests were conducted at 2 different temperatures as 30 and 35 °C. Cell heating was provided via a PID controller via the cathode end plate. The cathode composition was used as 1 M HBr/0.9 M Br_2. Hydrogen was provided with a dry flow rate of 60 ml/min. The gasket material was Teflon filled glass fibre material and the tightening torque was 1.5 Nm.

At 22 °C, this type of redox flow batteries OCV is 1.098 V. (Eq. (1) [18]

$$2HBr_{(aq)} \xleftrightarrow{Charge/discharge} H_2 + Br_{2(aq)},\ E_{0,cell} = 1.098\ V \quad (1)$$

3. RESULTS AND DISCUSSION

The experiments are numbered for easier understanding. Numbering details are given in Table 1.

Table 1. Parameters of the experiments

Parameter	1	2	3	4	5	6
Temperature (°C)	30			35		
Cathode flow rate (ml/min)	10	15	20	10	15	20

In Fig. 1, the polarization curves, which are the most definitive feature of the redox flow battery, are given. As can be understood from the curves, the value of 0.6 V can be determined as the limit value at which this type of battery can operate. After this value, the polarization curve reversed. The increase in temperature generally increased the performance as a result of increasing the catalytic effect. In addition, the increase in cathode flow rate also provided an increase in performance at constant temperature.

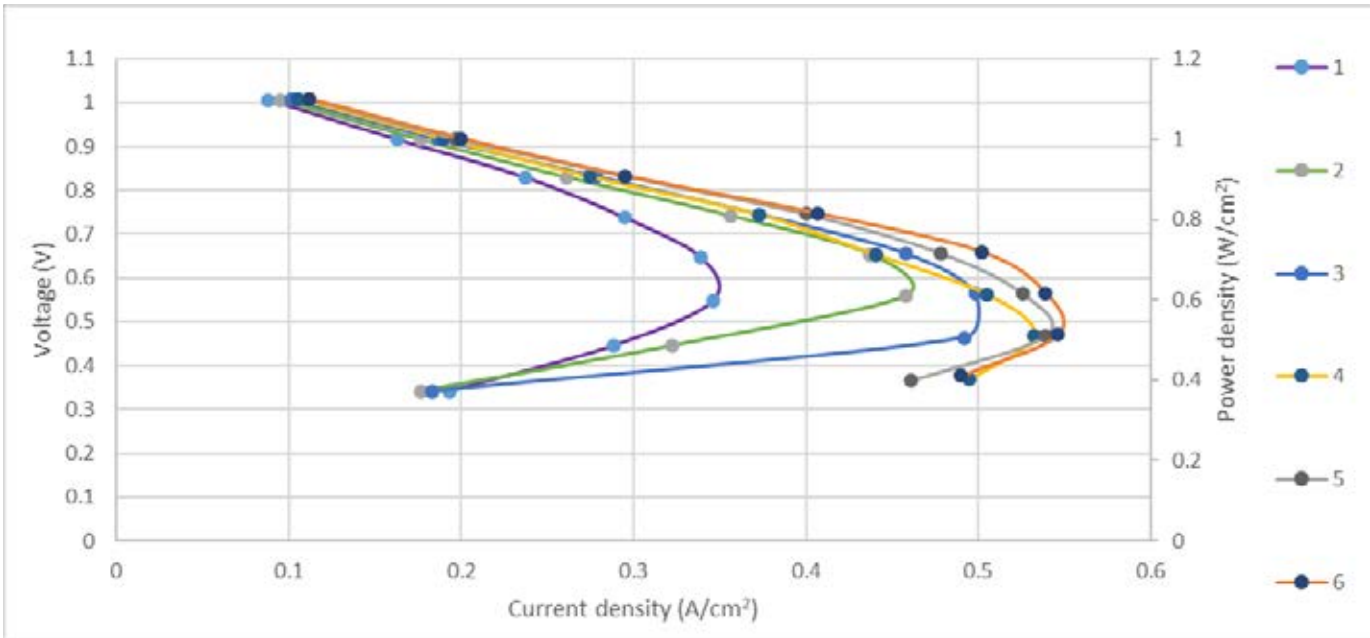

Fig. 1. Polarization curves

When looking at the power curves (Fig. 2), the highest power value obtained within the parameters used in this study was 0.33 W/cm^2.

Hydrogen consumption curves are given in Fig. 3. Hydrogen consumption follows the trend of the performance curves. There was no hydrogen flow rate limiting the cell performance. Based on this, it was determined that the reaction rate of the cathode part was the determining part of the performance.

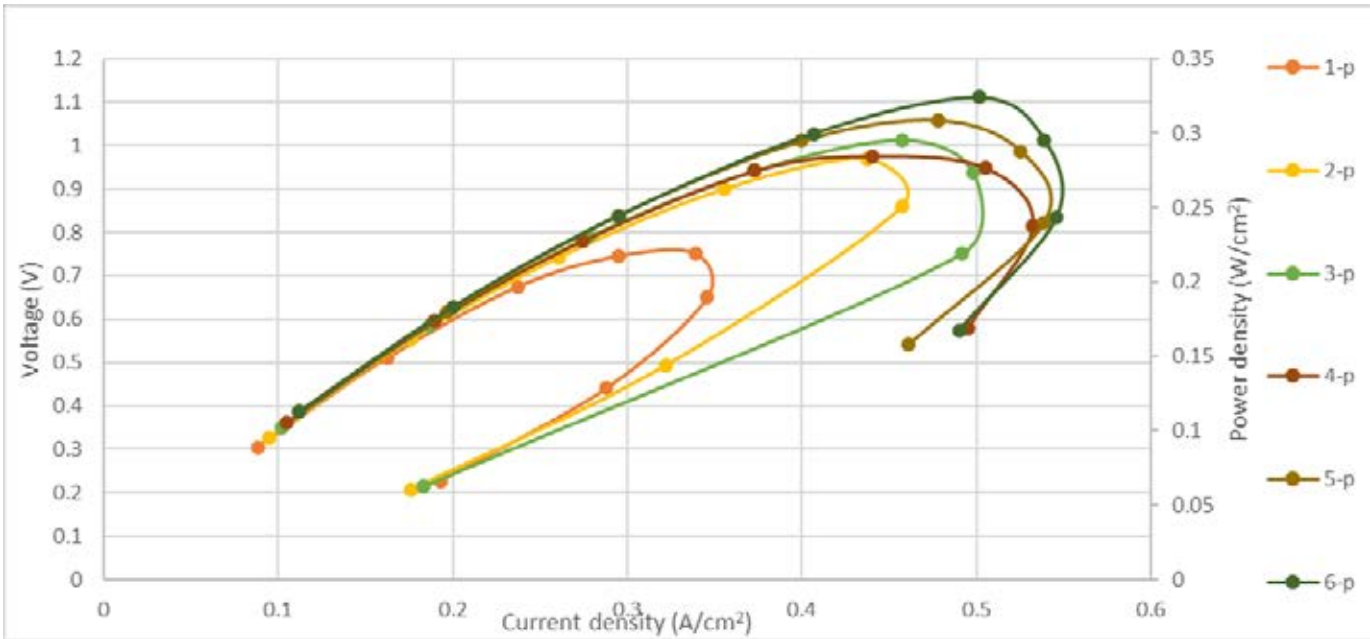

Fig. 2. Power curves

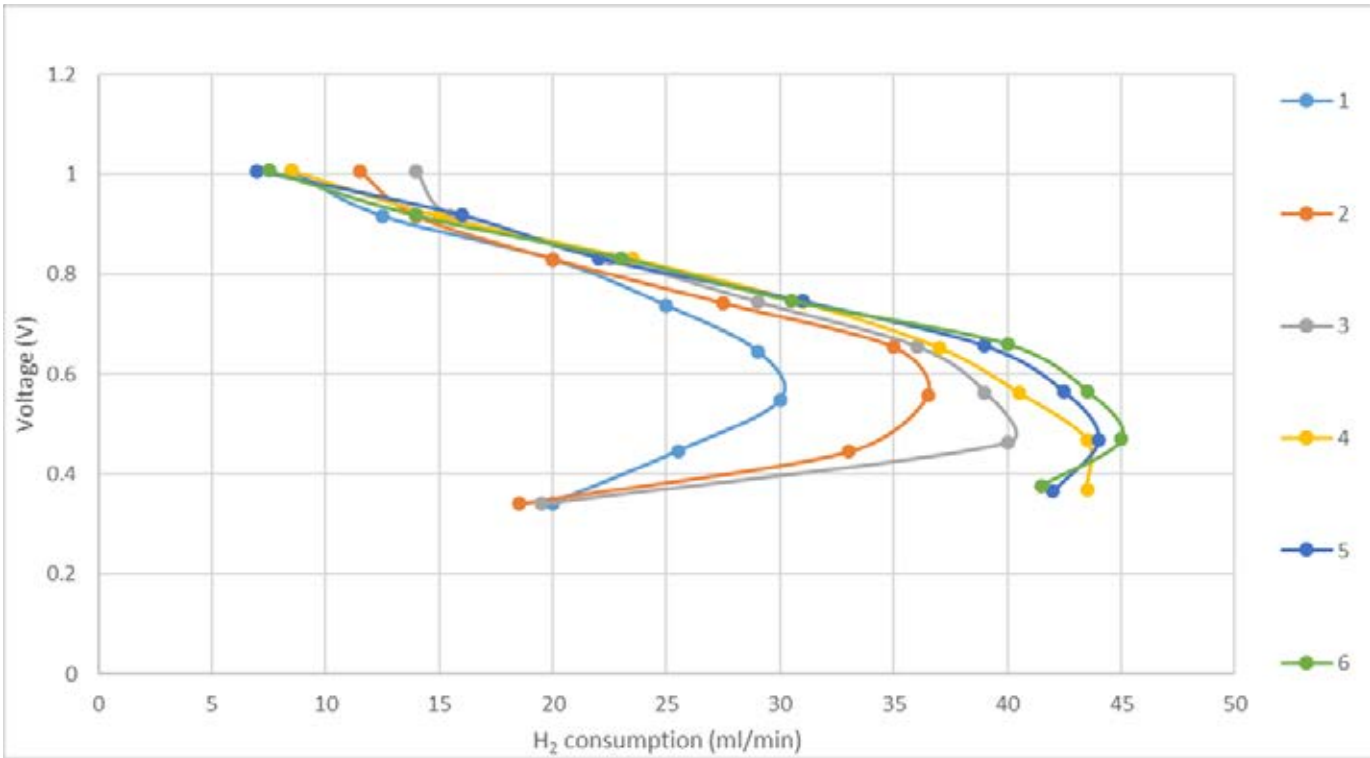

Fig. 3. Hydrogen consumption

4. CONCLUSIONS

In this study, the performance of the originally designed H_2/Br_2 redox flow battery was studied at cathode flow rates and different temperatures. It was observed that the increase in temperature and flow rate positively affected on the performance of the cell. The operating voltage of this type of redox flow battery was limited to 0.6 V levels. After this value, since the polarization is reversed, the minimum voltage that can be operated can be determined as 0.6 V. The point to be noted is that low temperature, high flow rate usage and high temperature, low flow rate usage gave similar performances. It is understood from this that when a system design is made, the operating parameter can be selected according to the importance of temperature and flow rate.

ABSTRACT
This work examined the efficacy of IrO_2-FeVS and IrO_2-FeVS-Co catalysts, produced at varying calcination temperatures (500-800 ºC), as anode catalysts in a PEM electrolyzer cell (PEMEC). The electrochemical activity of the catalyst calcined at 500ºC was assessed at various cell operating temperatures (20-70ºC). The findings indicate that the operating temperature directly influences the performance of PEMEC. At 20ºC, the voltage readings were elevated; nonetheless, the electrolysis process was inefficient owing to limited ionic conductivity and sluggish reaction kinetics. With the rise in operational temperature, proton conductivity enhanced, the reaction expedited, and the system functioned at reduced voltage levels. The optimal electrochemical performance was attained at 70°C. The catalysts calcined at 500-600ºC demonstrated optimal activity by yielding the lowest voltage values when assessed based on calcination temperature. At 700ºC, activity diminishes, although at 800ºC, the maximum voltage values were recorded owing to particle development and a decrease in active surface area. The ideal parameters for performance in PEMEC were identified as a calcination temperature of 500-600ºC and an operating temperature of 70ºC. The elevated working temperature has enhanced the catalyst's efficiency, yielding high current density at reduced voltage.

Keywords: PEM electrolysis cell (PEMEC), Anode catalyst, Calcination temperature, Electrochemical performance

1. INTRODUCTION

The global need for energy is rising due to technological advancements, population expansion, and enhanced societal wellbeing. This predicament has prompted individuals to strategically use non-renewable energy resources to fulfill demand while simultaneously enhancing and diversifying the application of renewable energy resources [1]. Among various methods for hydrogen production, electrolysis is the most environmentally sustainable technique, which utilizes electricity to separate water into high-purity hydrogen and oxygen [2]. Proton exchange membrane electrolyzer cells (PEMECs) have garnered significant attention for electrolysis owing to their small design, high-purity hydrogen generation, broad operational current density, and rapid system response [3]. The architecture of a proton exchange membrane electrolysis cell resembles that of a proton exchange membrane fuel cell, differing only in certain components, with both exhibiting symmetric structures. The typical PEMEC architecture has two bipolar plates, two gas diffusion layers, and a membrane electrode assembly (MEA), typically arranged in a symmetrical configuration with flow channels integrated into the bipolar plates. Electrochemical reforming, which consists of electrocatalytic oxidation of hydrogen-containing compounds on the anodic side of the PEMEC, can produce very pure gaseous hydrogen on the cathodic side by reducing protons passing through the membrane. Importantly, this process can take place under moderate conditions such as ambient temperature and pressure. Noble metals such as platinum and iridium-based materials have been widely selected as electrochemical catalysts for PEMECs due to their high electrochemical performance [4]. A multitude of researchers has focused on developing alternative, cost-effective electrocatalysts to substitute these metals. Consequently, a range of non-precious materials, including transition metal-based nitrides [5], carbides [6], phosphides [7], selenides [8], and sulfides [9], have been employed in PEMEC applications. Transition metal dicalcogenide materials, particularly disulfides and diselenides, are promising candidates for PEMECs owing to their affordability, remarkable stability, elevated catalytic activity, and abundant availability. Sulfur and selenium-based catalysts can offer extensive active surface area or centers to facilitate swift proton/electron adsorption and enhance overall kinetics [10]. Certain investigations demonstrated the synthesis of electrocatalysts derived from sulfur-based dichalcogenides using inexpensive and readily available transition metal elements, including molybdenum sulfide, tungsten sulfide, cobalt sulfide, and iron sulfides. The manufacture of nanoparticles used as electrocatalysts in the PEMEC system by green methods enhances their significance due to their simplicity, cost-effectiveness, and environmental sustainability. The green synthesis approach emphasizes the use of bacteria, fungus, algae, yeast, and plant extracts as reducing agents for nanoparticle production. The production of nanoparticles using natural plant extracts is an eco-friendly and cost-effective method that eliminates the need for intermediary base groups. The process may be accomplished within a few hours at ambient temperature by amalgamating plant extract and metal salt. Numerous variables affect the formation of nanoparticles from plant extract [11]. Plant extracts include many chemical elements, including flavonoids, alkaloids, steroids, tannins, saponins, cardiac glycosides, and phenolic chemicals, which are generated and stored in specific or all portions of plants [12-15]. In this study, extract was prepared from sunflower seed hulls using green synthesis method

and FeVS and Co-doped FeVS nanoparticles were produced by using this extract as reducing agent. By combining the obtained nanoparticles with IrO_2 as a support material, IrO_2-FeVS and IrO_2-FeVS-Co catalysts were synthesized to be used as anode catalyst of PEM electrolysis cell. The structural and morphological properties of the synthesized catalysts were characterized by XRD, SEM-EDX, TEM, XPS and Raman analysis. Cyclic voltammetry (CV) and impedance spectroscopy measurements were also performed to determine their electrochemical properties.

2. MATERIALS AND METHODS

2.1. Preparation of plant extract extract

Hydrothermal method was used to produce extracts from sunflower seed shells. To prepare the extract, 35 g of sunflower seed hulls were taken. 350 ml of distilled water was added to a 500 ml autoclave. It was then kept in an oven at 180 °C for 12 hours and then cooled to room temperature.

2.2. *Synthesis of FeVS and FeVS-Co nanoparticles*

For the synthesis of FeVS, 100 ml of almond green shell extract and the amounts of Fe $(NO_3)_3$ $9H_2O$, $C_{10}H_{14}O_5V$, Na_2S H_2O were mixed in molar ratios (Fe:V:S=0.5:0.5:1), and the pH of the solution was adjusted to 10 with 6M NaOH. The obtained mixture was stirred at room temperature for 24 hours, then filtered with 0.22 mm membrane filter paper, and the resulting solid was dried at 120 °C for 3 hours. Synthesize 10% Co-doped FeVS NPs, the calculated amount of $Co(NO_3)_2$ $6H_2O$ and 1 g of CoVS NPs were mixed in 50 ml of water. After being heated and turning into a paste, a certain amount of $NaBH_4$ was dissolved in 50 ml of water and then added dropwise onto it. Then, it was filtered with filter paper, and the obtained substance was dried at 120 °C for 2 hours. The synthesized nanoparticles were calcined at 500, 600, 700 and 800 ºC in nitrogen gas environment.

2.3. Synthesis of IrO_2-doped catalysts

IrO_2-FeVS and IrO_2-FeVS-Co nanoparticles were synthesized to be used as anode catalyst in the MEA of PEM electrolysis cell. 2 ml $IrCl_2$ and a certain amount of NaNO3 were mixed and then 0.2 mg FeVS nanoparticles were added and stirring was continued for 6 hours. It was then dried at 50 C in a stirring medium. The produced catalyst was calcined at 400 ºC in air. After calcination, it was washed and dried again. IrO_2-FeVS-Co nanoparticles were synthesized by the same method. The PEM electrolysis cell cathode catalyst, Pt/C catalyst containing 40 wt.% Pt, was stirred on a magnetic stirrer for 2 hours. Then, the solution was stirred at 80 ºC solution temperature for 1 hour and the solution was cooled, filtered and dried in an oven at 80 ºC for 6 hours. In order to create the MEA of the PEM electrolysis cell with 1x1 cm^2 active area, the synthesized catalysts were made into sludge, applied on carbon fabric with the help of a brush and nafion 117 membrane was used between the electrodes.

3. RESULTS AND DISCUSSION

3.1. Characterization of Nanoparticles

The nanoparticles synthesized by green synthesis method were characterized by XRD, SEM, EDX, TEM and XPS. it was determined from the characterization results that the nanoparticles were synthesized in pure and nanoscale.

3.2. PEM Electrolysis Cell Applications

In this study, FeVS and FeVS-Co nanoparticles synthesized at different calcination temperatures using the green synthesis method were tested as anode catalysts in proton exchange membrane (PEM) electrolysis cell using IrO_2 as support material and IrO_2-FeVS and IrO_2-FVS-Co catalysts. The electrochemical performances of the catalysts were evaluated at different calcination temperatures and the effect of these temperatures on the catalytic activity was investigated. In Figure 1, the electrochemical properties of the catalysts calcined at different temperatures are presented comparatively. The results obtained provide important data to determine the role of calcination temperature on the oxygen evolution reaction (OER) activity of the catalysts.

Fig. 1 illustrates the voltage-current density (V-J) curves of IrO_2-FeVS catalysts synthesized at various calcination temperatures. The catalysts' performance was assessed regarding the influence of calcination temperature on electrochemical activity. Catalysts calcined at 500 ºC and 600 °C exhibited comparable trends, however calcination at 600 ºC demonstrated superior performance with reduced voltage levels. The catalyst calcined at 700ºC exhibited effective performance at low current densities; however, the voltage escalated swiftly at elevated current densities. Calcination at 800ºC yielded the lowest performance with the greatest voltage levels. The optimal calcination temperature was shown to be between 500 and 600 °C. At 800 °C, the catalytic activity decreased markedly owing to crystal growth, reduction in surface area, and phase transitions. This suggests that high-temperature calcination negatively impacts the catalyst structure and diminishes electrochemical performance. Fig. 2 displays the performance curves of the IrO_2-FeVS catalyst calcined at 500 ºC across various cell temperatures (20, 40, 50, 60, and 70ºC). The changes in the electrochemical activity of the catalyst with rising cell temperature were examined.

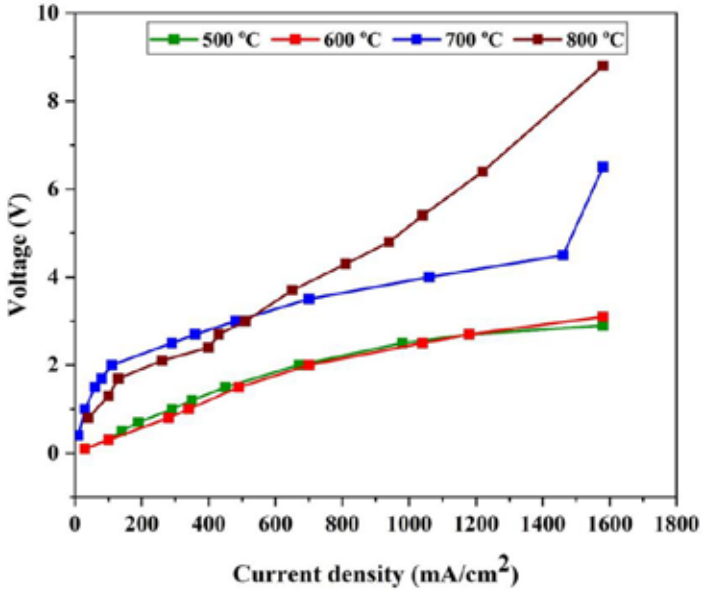

Fig. 1. Effect of different calcining temperatures on the activity of IrO_2-FeVS catalyst.

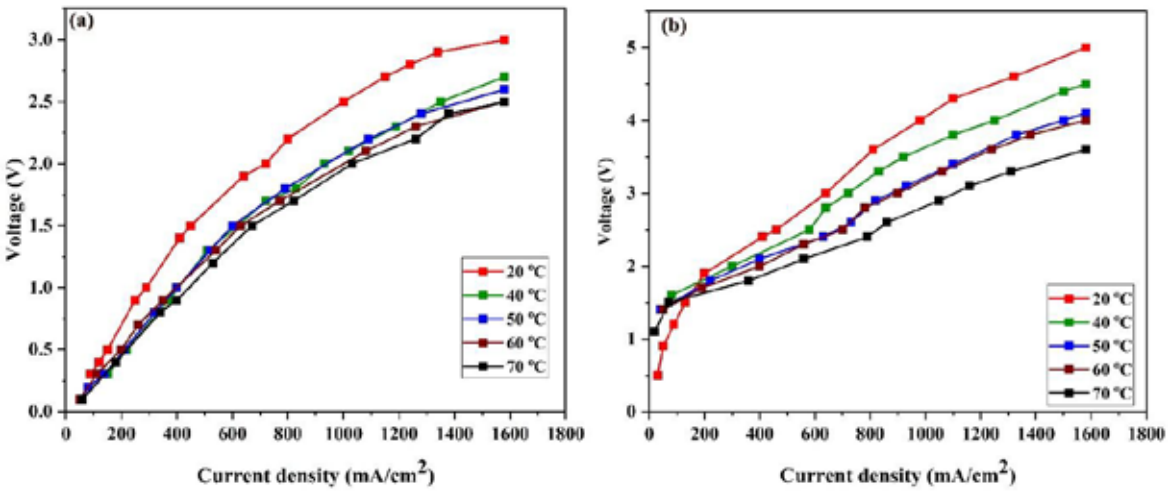

Fig. 2. Activity of IrO_2-FeVS and IrO_2-FeVS-Co catalysts at different cell temperatures

In proton exchange membrane electrolysis cells (PEMEC), the response of the anode catalyst to temperature variation is of great importance for the overall efficiency of the system. In this study, the electrochemical performance of IrO_2-FeVS and IrO_2-FeVS -Co catalysts calcined at 500 ºC at different cell temperatures (20-70 °C) were compared. The results obtained show that the voltage values of both catalysts decrease with increasing cell temperature and the efficiency of the system increases. Lower voltage levels imply that there is less energy loss in the electrolysis process and the catalyst works efficiently. In general, the IrO_2-FeVS catalyst provided lower voltages and performed better than the IrO_2-FeVS -Co catalyst at all temperatures. Especially at 20 °C and 40 °C the IrO_2-FeVS -Co catalyst showed higher voltages, indicating more energy loss. However, at 60 °C and 70 °C the performance of the IrO_2-FeVS -Co catalyst approached that of IrO_2-FeVS, but still remained slightly higher in terms of voltage. This can be explained by the fact that the Co element reduces the active surface area by oxidation in the catalyst structure and causes some limitations in terms of ion conductivity. The increase in cell temperature has accelerated the reaction kinetics, increased ion conductivity, and reduced the resistances at the electrode/electrolyte interface. Therefore, both catalysts exhibited the best performance at 70 °C. However, the IrO_2-FeVS catalyst provided significantly lower voltage at low temperatures (20-40 °C) compared to the IrO_2-FeVS -Co catalyst, making it a more efficient option under low-temperature conditions. On the other hand, the IrO_2-FeVS -Co catalyst has increased energy consumption, particularly due to the high voltage requirement at low temperatures. The addition of Co has increased the catalyst stability and improved performance at high temperatures, but it has negatively affected the reaction kinetics at low temperatures. As a result of the comparisons, the IrO_2-FeVS catalyst generally exhibited better electrochemical performance by operating at lower voltage levels. Although the IrO_2-FeVS -Co catalyst exhibited performance approaching that of IrO_2-FeVS at high temperatures (60-70

°C), it was disadvantageous in terms of efficiency at low temperatures due to energy losses. The best performance for both catalysts was achieved at 70 °C. The IrO_2-FeVS catalyst operated more efficiently at lower temperatures, consuming less energy. Although the IrO_2-FeVS -Co catalyst shows stability at high temperatures, it causes a loss of performance at low temperatures. If it is planned to operate at low temperatures in PEMEC systems, the use of the IrO_2-FeVS catalyst is more advantageous. In conclusion, while the IrO_2-FeVS catalyst offers better electrochemical efficiency at lower temperatures, the IrO_2-FeVS -Co catalyst has shown more stable performance at higher temperatures.

4. CONCLUSIONS

In this study, the electrochemical performance of IrO_2-FeVS and IrO_2-FeVS-Co catalysts, calcined at 500 °C, was compared at different cell temperatures (20-70 °C). The obtained data show that with the increase in cell temperature, the voltage values of both catalysts decreased and the electrolysis process became more efficient. Overall, the IrO_2-FeVS catalyst provided lower voltage levels and exhibited better electrochemical performance compared to the IrO_2-FeVS -Co catalyst at all temperatures. At low temperatures (20-40 °C), the IrO_2-FeVS -Co catalyst exhibited higher voltage values, indicating greater energy loss. However, at high temperatures (60-70 °C), the performance of both catalysts approached each other, but IrO_2-FeVS still provided a lower voltage, making it advantageous. The addition of cobalt to the IrO_2-FeVS -Co catalyst increased stability at high temperatures, but caused a loss of performance at low temperatures. As a result, in terms of energy efficiency at low temperatures, the IrO_2-FeVS catalyst stands out as a better option, while at high temperatures, both catalysts exhibit similar performance.

ABSTRACT
Today's increasing energy demand and the environmental effects of fossil fuels have increased the importance of sustainable energy sources. In this context, green hydrogen production draws attention as an environmentally friendly and renewable energy source. The characteristics and efficiency of the materials used in hydrogen production directly affect the success of the production process. In this study, the performance of CeO_2 Sm 4%, 6% and 8% doping in hydrogen evolution reaction (HER) was investigated.
Keywords: H_2 Evolution, CeO_2, Sm

1. INTRODUCTION

Hydrogen, as an environmentally friendly energy carrier, has an increasing importance in modern energy systems. It seems that hydrogen plays a critical role in the energy sector's transition away from fossil fuels and towards a more sustainable structure. Hydrogen, which is used in both power generation and industrial processes, is widely evaluated especially in sectors such as steel production, chemical industry and aviation. However, rapid developments in electric vehicles and battery technologies are increasing the role of hydrogen obtained from renewable energy sources in energy storage and transportation systems. Hydrogen, which has a wide usage area, can be produced by different reactions. This reaction is generally called the electrocatalytic reaction. The reaction occurs with two half-reactions. These are hydrogen reduction (hydrogen evolution reaction, HER) at the cathode and H_2O oxidation (oxygen evolution reaction, OER) at the anode. [1] The efficiency of these reactions is highly dependent on the properties of the electrocatalysts used.

The effectiveness of electrocatalysts is critical to make hydrogen production economical and efficient by reducing the energy requirements of the reactions. An ideal electrocatalyst is expected to have a large surface area, maintain chemical stability and exhibit high catalytic activity with low overpotential. In this context, developments in the field of materials science in recent years have revealed new strategies to increase the performance of electrocatalysts used for hydrogen production. TiO_2, Fe_2O_3, La_2O_3, CeO_2 are metal oxide compounds that can be used as electrocatalysts. [2, 3.] A good HER electrode is expected to have a porous, chemically stable and conductive structure. [4]. CeO_2, metal oxide, high surface active area, high catalytic activity, long-term durability in reactions and low overpotential enable the use of CeO_2-based electrodes in hydrogen production. [5-7]. Sun et al. investigated various electrocatalyst properties of CeO_2 compound prepared with graphene. They observed that it can be used for both OER and HER.[8]. By comparing the H_2 production made by changing the surface structure of CeO_2, it has been reported that the efficiency increases as the surface area of the nanoparticles increases. [9]

In previous CeO_2 studies, the results of limited studies on rare earth element-doped compounds have been reported. In this study, the hydrogen evolution reaction of CeO_2 compound doped with Sm at different rates was investigated comparatively. Glycine combustion [10] technique, which is used to produce nanoparticles with large surface areas, was used in the syntheses.

2. MATERIALS AND METHODS

Pure water, Cerium (III (nitrate hexahydrate, 99.9%, Alfa Aesar), Samarium [Samarium (III) nitrate hexahydrate, 99.9%, Acros Organics] and Glycine (Merck) are the materials used.

The glycine combustion method was used in the synthesis of doped CeO_2 compounds. For this method, Sm ($^{+3}$) cations were doped into the CeO_2 structure at 4,6,8 mole ratios. After the chemicals were weighed, they were dissolved in 40 ml of pure water. Glycine was added to the solution and the solution temperature was increased to 300^0 C on a heated magnetic stirrer and the combustion process was expected to take place. After the combustion process took place, the compound was burned on a heated table at 300^0 C for another hour. After the combustion process, the powder samples were taken into alumina crucibles and annealed at 700^0 C for 4 hours.

To determine the crystal structure properties, X-ray powder diffractometer scanning was performed between 0 and 90^0. HER evolution measurements were used CV analyzer.

3. RESULTS AND DISCUSSION

The powder XRD results of Sm doped nanoparticles taken between 0-90^0 are shown in Figure 1. The obtained graphics are consistent with the cubic structure with space group Fm-3m in the literature [11]. The peak of Sm was not observed. This indicates that Sm^{+3} ions have been successfully incorporated into the crystal lattice of CeO_2 by replacing Ce^{+4} ions. Using Scherrer's equation, the average crystallite size was determined using all peaks. When the size of the crystallites is examined in detail in terms of additives, it is seen at what level the Sm doped compounds are.

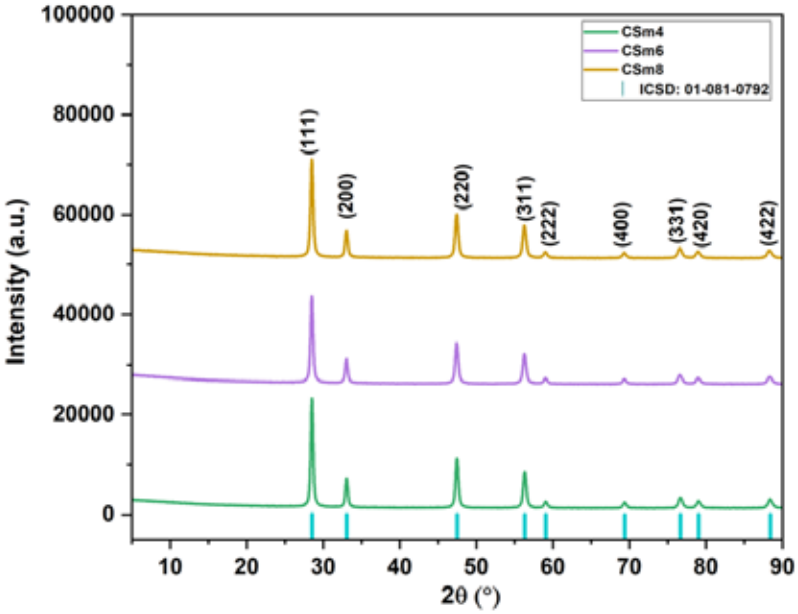

Fig. 1. X-ray pattern of Sm-doped CeO_2 samples

To investigate the crystal lattice structure and microstructure of Sm^{+3} doped CeO_2 powders, Rietveld analysis was performed using Highscore Plus software (Figure 1). The pseudo-Voigt function was used in fitting the diffraction peaks. The effects of Sm^{+3} addition to the crystal lattice sites of CeO_2 were reflected in the values of the unit cell parameters. The increase in the amount of Sm doping changes the unit cell parameter linearly. The main reason for this is the difference in the ionic radii of Ce^{+4} (0.97 Å) and Sm^{+3} (1.08 Å) ions.[12]

4. CONCLUSIONS

Glycine combustion technique was used to synthesize nanopowders of CeO_2 doped with 4,6,8 mol% Sm^{+3}, respectively. It was determined that all compounds had a cubic crystal lattice. Nanostructured compounds were obtained. The values of the obtained compounds for HER were compared. The best result in hydrogen production was observed as 19.54 minutes per 1 ml in CSm8.

ABSTRACT

Proton exchange membrane (PEM) electrolysis is a key technology for sustainable hydrogen production, but its reliance on expensive platinum-group metal (PGM) catalysts poses a significant cost challenge. This study evaluates the techno-economic feasibility of replacing conventional Pt/C cathodes with molybdenum disulfide (MoS_2)-based alternatives. Two different MoS_2-based catalysts, MoS_2/Vulcan and MoS_2/RGO, were investigated. The analysis considered various electricity price scenarios and compared each system's Levelized Cost of Hydrogen (LCOH). The results indicate that the MoS_2/Vulcan system produced hydrogen at a lower LCOH than the MoS_2/RGO system. Specifically, the LCOH for MoS_2/Vulcan ranged from $6.27 to $8.05 per kg, while for MoS_2/RGO, it ranged from $6.72 to $8.62 per kg. These findings suggest that MoS_2/Vulcan is a more economically viable alternative to traditional Pt/C catalysts, approaching the lower end of the LCOH range reported for conventional systems.

Keywords: Green Hydrogen Production, PEM Electrolyzers, Techno-Economic Analysis

1. INTRODUCTION

Hydrogen, as a clean energy carrier, plays a pivotal role in the transition towards a low-carbon economy, offering a promising solution for reducing greenhouse gas emissions and mitigating climate change [1]. Proton exchange membrane electrolysis is a promising technology for sustainable hydrogen production, offering high efficiency and potential integration with renewable energy sources[2]. The widespread adoption of PEM electrolyzers is crucial for achieving a sustainable hydrogen economy, but it is hindered by the high cost of platinum-group metal (PGM) catalysts, which are commonly used in both anode and cathode electrodes [3]. Among them, platinum supported on Vulcan carbon remains the industry standard due to its high surface area and electrical conductivity.

The reliance on expensive PGMs increases the overall cost of hydrogen production and raises concerns about the sustainability and availability of these materials. Therefore, there is a growing interest in developing alternative catalysts that can provide similar or improved performance at a lower cost. MoS_2 has emerged as a promising candidate due to its excellent catalytic properties, abundance, and lower price than PGMs[4].

This study evaluates the techno-economic feasibility of replacing conventional Pt/C cathode with MoS_2-based alternatives, specifically MoS_2/Vulcan and MoS_2/RGO in the PEM electrolyzer system. By comparing the LCOH for these alternative catalysts under various electricity price scenarios, this research seeks to determine the economic viability of MoS_2-based catalysts and their potential to reduce the cost of hydrogen production. The analysis considers the impact of system efficiency, operational expenditures (OPEX), and capital expenditures (CAPEX) on the overall cost, providing a comprehensive assessment of the economic performance of these alternative cathode catalysts.

2. MATERIALS AND METHODS

Using a standardized analytical framework, the techno-economic performance of a PEM electrolyzer system is evaluated by comparing two MoS_2-based catalysts, MoS_2/Vulcan and MoS_2/RGO. A 100 kW system is chosen as the representative scenario, selected for its relevance in scalable hydrogen production applications. The catalysts are analyzed based on experimental data obtained from a reference study [4].

The annual operating hours were estimated at 4,000 hours with an expected lifespan of 10 years, and the efficiency values for MoS_2/Vulcan and MoS_2/RGO were assumed to be 75% and 70%, respectively, based on current densities of 0.35 A/cm² and 0.25 A/cm² reported in the reference study[4].

The cost analysis for the MoS_2-based catalysts was conducted by considering various parameters, including catalyst loading, current density, and surface area. These parameters were derived from experimental data and market prices to ensure accuracy and relevance. The detailed cost breakdown is presented in Table 1.

Consequently, the CAPEX for the entire PEM system was calculated by first determining the cost of the system without

the Pt/C electrode, which is assumed to constitute 20% of the total stack price in conventional systems. By subtracting the Pt/C electrode cost of $12,386 from the total system cost of $260,000, we obtained the CAPEX for the system without the electrode [5]. We then added the costs of our alternative MoS_2-based electrodes to this amount to determine the total CAPEX.

Table 1. Cost Analysis Parameters for MoS_2/Vulcan and MoS_2/RGO Catalysts

Parameter	MoS_2/Vulcan	MoS_2/RGO
Loading (mg/cm²)	5 mg/cm²; (47 wt% MoS_2)	3 mg/cm²; (43.8 wt% MoS_2)
Current Density (A/cm²)	0.35 A/cm²	0.25 A/cm²
Surface Area Assumption (m²)	15.87	22.22
Total Cost (USD)	363	756

LCOH is a measure of the cost per unit of hydrogen produced over the lifetime of the production facility[6]. This formula takes into account CAPEX, OPEX, the fixed annual cost rate (FCR), and annual hydrogen production (eq 1) [7].

$$\mathrm{LCOH} = \frac{CAPEX \cdot FCR + OPEX}{Annual\ Hydrogen\ Production}$$

FCR includes depreciation and capital costs. For a 5% interest rate and a 10-year lifespan, the FCR is calculated to be 0.1295. ($FCR = r(1+r)^n / ((1+r)^n - 1)$). The OPEX was assumed as 5% of the CAPEX, and the annual hydrogen production was determined using the lower heating value (LHV) of hydrogen. The electricity prices of $0.03, $0.05, and $0.07 per kWh (representing low, medium, and high renewable energy cost scenarios) were used for both electrodes in all three scenarios.

3. RESULTS AND DISCUSSION

Fig. 1 presents the LCOH values for both MoS_2/Vulcan and MoS_2/RGO systems under various electricity price scenarios. This visual representation emphasizes the substantial influence of system efficiency and electricity costs on the overall economic performance of hydrogen production technologies.

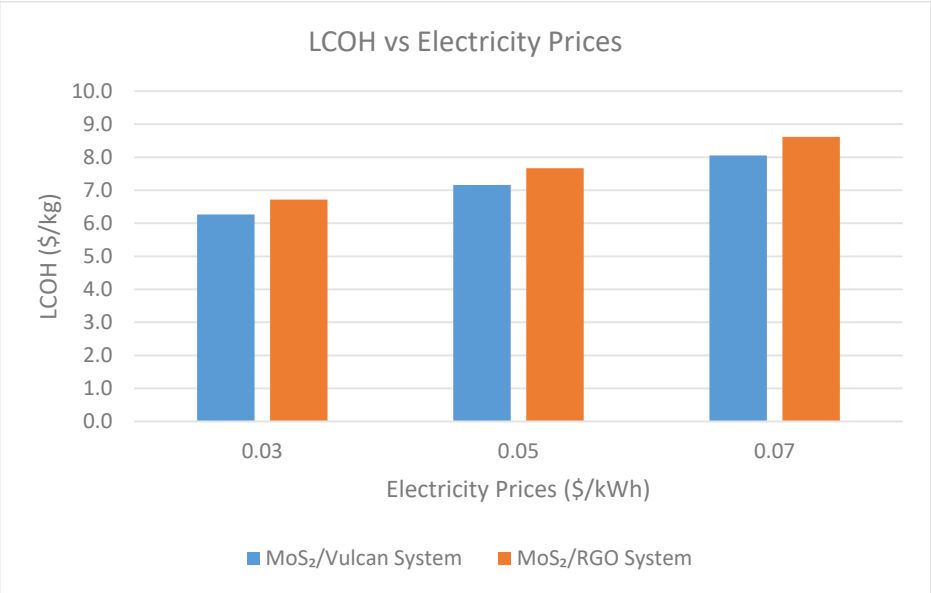

Fig. 1. LCOH values of the PEM electrolyzer with MoS_2/Vulcan and MoS_2/RGO electrodes under different electricity price scenarios

The MoS_2/Vulcan system, with an efficiency of 75%, produced 3,000 kg of hydrogen per year, while the MoS_2/RGO system, with an efficiency of 70%, produced 2,800 kg of hydrogen per year. The LCOH values for MoS_2/Vulcan were found to be $6.27/kg, $7.16/kg, and $8.05/kg for electricity prices of $0.03, $0.05, and $0.07 per kWh, respectively. For MoS_2/RGO, the LCOH values were $6.72/kg, $7.67/kg, and $8.62/kg for the same electricity prices.

The results indicate that the MoS_2/Vulcan system is more cost-effective than the MoS_2/RGO system across all electricity price scenarios. The higher efficiency of the MoS_2/Vulcan system contributes to its lower LCOH, making it a more economically viable option for hydrogen production.

Compared to traditional hydrogen production systems, which have LCOH values ranging from $5 to $7 per kg according to the Department of Energy (DOE) report [8], both alternative systems show competitive potential. However, the MoS_2/Vulcan system, in particular, approaches the lower end of this range, suggesting its feasibility as a viable alternative for cost-effective hydrogen production.

4. CONCLUSIONS

The techno-economic analysis demonstrates that MoS_2-based cathode catalysts can potentially lower hydrogen production costs in PEM electrolyzers. Among the alternatives examined, MoS_2/Vulcan exhibited a lower LCOH than MoS_2/RGO across all electricity price scenarios, making it the more economically viable. However, MoS_2/RGO remains a competitive candidate, and further optimization could enhance its cost-effectiveness. While both catalysts offer significant cost advantages over Pt/C electrodes, future studies should focus on improving long-term stability and assessing large-scale implementation to realize their commercial potential fully.

ABSTRACT

This study proposes a hydrogen supply chain (HSC) design that consider Türkiye's renewable energy targets for the transportation sector. Two models were created within the scope of the study: Model 1, which offers an unrestricted structure, and Model 2, which limits the transfer of primary energy sources by restricting the distance to hydrogen transportation. The results show that Model 2 reduces the total cost by approximately 8.4% but increases carbon emissions by 2.3 times. In Model 2, local production is provided by importing natural gas in regions where local renewable energy resources are insufficient, which increases carbon emissions. In contrast, risk levels are reduced by 58.9% in Model 2, and a more secure and predictable supply chain is created. In addition, the establishment of small and medium-sized SMR facilities at a higher rate in Model 2 encourages the local production and consumption of hydrogen. These findings reveal that HSC can be optimized in terms of cost and risk, but that renewable energy capacity should be increased to improve environmental impacts.

1. INTRODUCTION

Global energy demand is escalating swiftly due to population increase, urbanization, and technological advancements. This scenario results in heightened fossil fuel consumption and exacerbation of environmental issues. The transportation industry is a major contributor to global carbon emissions, accounting for roughly one-fourth of the total emissions. The usage of fossil fuels in passenger and freight transportation constitutes a significant share of these emissions [1]. Consequently, the decarbonization of the transportation sector has emerged as a critical element of the sustainable energy transition. Battery electric vehicles (BEVs) markedly diminish carbon emissions in comparison to fossil fuel vehicles. Nonetheless, range constraints and prolonged charge durations are primary problems hindering the extensive adoption of BEVs. Hydrogen fuel cell vehicles (FCEVs) seek to address these issues through their extended range and rapid refueling benefits.

For FCEVs to achieve widespread adoption, a dependable and sustainable HSC must be developed. The processes of production, transportation, and distribution are crucial in HSC design. In HSC design for the transportation sector, the primary objectives include the efficient conveyance of hydrogen from production sites to end users, while minimizing costs and reducing environmental effect. Research in this domain is expanding, and diverse hydrogen strategies are being executed across numerous nations. The European Union intends to substantially integrate hydrogen into the transportation sector by 2050, while nations like Japan and South Korea are swiftly advancing their hydrogen infrastructure [2, 3].

Türkiye also engages in numerous investigations about the HSC. Güler et al. [4] formulated a multi-period HSC model for Türkiye, which was subsequently adapted by Erdoğan et al. [5] into a single-period and multi-objective framework. Subsequently, these two studies were amalgamated to establish a multi-objective and multi-period HSC design. Subsequently, Özbek et al. [6] introduced a multi-period, multi-objective, and stochastic HSC planning framework for Türkiye to mitigate demand uncertainty by leveraging these findings. Nevertheless, these studies predominantly rely on the current energy infrastructure and inadequately address green hydrogen production and the incorporation of renewable energy sources.

While conventional hydrogen production methods include reforming natural gas or biomass gasification, the focus is increasingly shifting towards green hydrogen production to meet carbon emission reduction goals. Green hydrogen is generated through renewable energy sources like wind, solar, hydroelectric, and geothermal, and is recognized as a carbon-neutral energy carrier. Recent studies indicate that sourcing a significant amount of hydrogen for transportation from green sources is essential for achieving net zero emission targets [7, 8]. Furthermore, the use of surplus renewable energy for hydrogen production enhances energy supply security while simultaneously lowering hydrogen costs [9]. Consequently, Özbek et al. [10] performed a multi-objective and stochastic HSC analysis for 2050, informed by the

findings of Dinçer et al. [11] , which identified the hydrogen potential for Türkiye.

This study proposes an HSC design for the transportation industry, considering Türkiye's actual renewable energy infrastructure and its targeted renewable energy capacity. Türkiye's existing renewable energy capacity is insufficient; yet it possesses significant potential for solar and wind energy, as indicated by the Ministry of Energy's published reports outlining the country's renewable energy targets [12]. In this context, it will be evaluated how hydrogen production and distribution strategies can be optimized by integrating them with renewable energy sources and analysis will be made on how this will change the network in the event of some restrictions in the HSC network.

2. MATERIALS AND METHODS

Özbek et al. [6] have introduced a multi-period, multi-objective, and stochastic HSC network for the years 2025-2055, addressing the uncertainty in hydrogen consumption. In this HSC network, only Türkiye's existing resources were evaluated, disregarding the objectives for enhancing renewable energy. Özbek et al. [10] incorporated CO_2 emissions from primary energy sources (PES) into this model and produced a plan exclusively for 2050. This study integrates two previous studies and proposes a multi-period, multi-objective, and stochastic HSC network plan to address the timeframe of 2035-2065, aligned with Türkiye's actual renewable energy purposes. The demand for Türkiye throughout the three 10-year intervals from 2035 to 2065 is forecasted, with the assumption that FCEVs will constitute 4.5% of BEVs. These forecasts define scenarios based on low and moderate demand levels, where each scenario is represented as a sequence of demand states (e.g., low-medium-low), resulting in a total of eight scenarios across three periods, which then serve as inputs for the scenario-based stochastic model. It is assumed that both renewable and non-renewable energy sources will be utilized for hydrogen production. In the model, renewable energy sources are considered solely as indigenous resources of Türkiye, whilst non-renewable energy sources like natural gas and coal are presumed to be imported. The assessment of these energy sources relies on Türkiye's current power plants and future forecasts [12].

In an effort to quantify demand uncertainty, a scenario-based stochastic programming methodology with two phases is implemented. There are two types of variables in stochastic programming. The values of discrete control (i.e., here-and-now) variables will remain unchanged, regardless of any alterations in the scenario. They illustrate the decisions that must be made at the outset of the issue. An example of this is the decision to establish a plant within a grid. Another option is the quantity of hydrogen that will be transported or produced at this facility. Their values are contingent upon the circumstances. These types of decisions are demonstrated by continuous dispatch variables, which are also known as "wait-and-see" variables. The timeframe from 2035 to 2065 is segmented into three decadal intervals, resulting in the formulation of eight scenarios based on varying demand levels during these times. Furthermore, the Epsilon Constraint Method is utilized to determine the best model that minimizes both cost and CO_2 emissions [13].

Two new constraints have been added to the model to perform sensitivity analysis. The first is the constraint in Eq. (1) that prevents the flow of hydrogen between the grids if there is more than 300 km between the two grids. Since the model aims to minimize cost and CO_2, if the establishment of the hydrogen production plant is not profitable in these respects, it gives results that hydrogen is taken from another grid, even from a considerable distance. The aim of this constraint is to encourage the model to establish production plant by using its own renewable energy resources. The second is the constraint in Eq. (2) that prevents the flow of PES between the grids. The current model permits the transit of power between the grids for use in electrolysis producing facilities. This constraint has been implemented to assess the impact of grids utilizing their own resources on the model. It is important to highlight that if the grid does not have enough renewable PES to produce hydrogen, it will either open coal or natural gas-fired facilities or buy hydrogen from other grids.

$$if\ L^{R}_{lgg'} \geq 300\ , then\ Q_{lgg'ts} = 0 \quad \forall l, g, g', t, s: g \neq g' \tag{1}$$

$$QE_{egg'ts} = 0 \quad \forall\ e, g, g', t, s: g \neq g' \tag{2}$$

3. RESULTS AND DISCUSSION

The model was executed without the aforementioned constraints (Model 1) and with the constraints incorporated (Model 2). The objective function values of the most effective outcomes are displayed in Table 1.

Table 1. Results of Model 1 and Model 2

	Total Cost ($/day)	Total CO_2 (kg/day)	Total Risk (unit)
Model 1	123,133,797	448,439,969	323,722
Model 2	112,728,602	1,025,561,041	133,122

The main difference between Model 1 and Model 2 is that Model 2 imposes a distance restriction on hydrogen transportation and prevents the transfer of PES between different networks. When the results are examined, it is observed that Model 2 reduces the total cost by approximately 8.4% but increases carbon emissions by 2.3 times. This is due to the increase in fossil fuel use in grids where renewable energy sources are insufficient in hydrogen production. Due to the restrictions, the transportation of hydrogen from long distances has been prevented and local production has become mandatory. Although this reduces transportation costs, it has negatively affected the environmental impact by increasing the use of carbon-intensive energy sources such as natural gas in some grids. On the other hand, Model 2 has reduced the total risk by 58.9%, making the HSC more secure and predictable. This is due to the decrease in the risk arising from transportation.

In order to support these results, the numbers of SMR facilities opened under Model 1 and Model 2 are given in Table 2. The percentages in the table show the ratio of SMR facilities opened in a certain size in the relevant period to the total number of facilities opened in that size in that period. For example, in first period, there are 10 large SMR facilities and the total number of facilities opened in that period is 32, so the percentage for large SMR facilities is calculated as 31%. It is important to note that the number of facilities is not changed according to scenarios. Additionally, Table 3 shows the inter-grid hydrogen flows in Model 1 and Model 2 for all scenarios. This table presents a comparative analysis of the effects of constraints on these flows.

Table 2. Numbers and Distribution of SMR Facilities Opened under Model 1 and Model 2

Facility Type	t=1			t=2			t=3		
	Small	Medium	Large	Small	Medium	Large	Small	Medium	Large
Model 1	0	0	10 (31%)	0	0	10 (10%)	0	0	10 (6%)
Model 2	0	1 (100%)	14 (47%)	2 (1%)	3 (38%)	25 (27%)	2 (1%)	3 (33%)	31 (23%)

Table 3. Hydrogen flows (10^6 million liters) between grids under Model 1 and Model 2

	Scenario /Time	1	2	3	4	5	6	7	8
Model 1	1	2	2	2	2	3.3	3.3	3.3	3.3
	2	12.8	12.8	12.8	12.8	10.4	10.4	13.8	13.8
	3	7.7	12.4	12.4	17.5	9.8	15.6	15.6	17.9
	Scenario /Time	1	2	3	4	5	6	7	8
Model 2	1	2.3	2.3	2.3	2.3	3.5	3.5	3.5	3.5
	2	7	7	7	7	5.7	5.7	8.9	8.9
	3	6.5	10.2	10.2	10.5	8.	11.7	11.7	12

As seen in Table 2, since Model 1 has an unrestricted structure, SMR facilities are established on a large scale only in grids with high demand, and the needs of other regions are met by transporting hydrogen from these facilities. This situation shows that a centralized structure prevails, and long-distance transportation increases as demand is met from a single point. On the other hand, in Model 2, due to distance and energy constraints, local production of hydrogen is encouraged, which leads to the establishment of small and medium-sized facilities. In addition, it is noteworthy that the rate of SMR facilities of all sizes is generally higher in Model 2 compared to Model 1. This increase shows that Model 2 enables hydrogen to be produced and consumed regionally by providing more local production. However, in cases where local renewable energy resources are insufficient, natural gas had to be imported to operate these facilities. As seen in Table 1, this situation causes a significant increase in carbon emissions in Model 2. When looking at Table 3, it is seen that thanks to the unrestricted structure of Model 1, hydrogen can be transported to long distances and the total flow rate is higher, but this increases transportation risk. In Model 2, hydrogen flow is limited, local production is encouraged and thus risk levels are reduced. However, the increase in fossil fuel use in cases where renewable energy sources are insufficient has negatively affected environmental impacts. In general, while Model 2 provides some advantages in terms of economy and operation, it is necessary to increase renewable energy capacity and strengthen its integration in order to reduce carbon emissions.

4. CONCLUSIONS

This study evaluated the economic, environmental and operational impacts of constraints in the design of the HSC for the transportation sector in Türkiye. Model 1, with its unrestricted structure, allowed hydrogen to be transported over long distances and increased the total flow rate. However, this situation led to higher costs and risks. On the other hand, Model 2 reduced risks and costs by encouraging local production. However, the increase in fossil fuel use in regions where local renewable energy resources are insufficient has significantly increased carbon emissions. The findings of the study reveal that cost and risk optimization can be achieved in the HSC, but renewable energy integration is a critical requirement to reduce environmental impacts. In the future, the development of renewable energy infrastructure and the promotion of low-carbon production methods will be key elements for the establishment of a sustainable HSC.

ABSTRACT
Recent advancements in battery and electric motor technologies have facilitated the widespread adoption of Unmanned Aerial Vehicles (UAVs). Although electric UAVs offer advantages such as low emissions and ease of use, the limited energy density of batteries poses a significant disadvantage in terms of short flight durations. This study proposes a hybrid propulsion system that integrates hydrogen fuel cells with batteries to address this limitation. Hydrogen-based systems provide longer flight endurance than battery-only systems, achieving this in an environmentally friendly and low-emission manner. Within this scope, a relatively simple and accessible hybrid propulsion system was designed to enhance flight endurance in UAVs in a sustainable manner. Static power tests and tests based on cruise flight profiles were conducted to validate the system's performance. The results demonstrated the potential of the proposed system to significantly and sustainably extend the flight endurance of UAVs.

Keywords: Unmanned Aerial Vehicle (UAV), Hybrid Propulsion System, PEM Fuel Cell, Extended Range

1. INTRODUCTION

Unmanned Aerial Vehicles (UAVs) have become indispensable in both military and civilian applications due to their versatility and efficiency. Electric UAVs, powered by lithium-based batteries, are widely preferred in civilian applications because of their low emissions and operational simplicity. However, the low energy density of batteries poses a significant challenge for applications requiring extended flight durations.

Polymer Electrolyte Membrane (PEM) fuel cells offer a promising solution by providing high power density and generating electricity without emissions. PEM fuel cells generate electricity through an electrochemical reaction between hydrogen and oxygen, producing water and heat as byproducts. With these properties, hydrogen fuel cells emerge as a sustainable energy carrier and a practical way to extend UAV flight endurance [1].

In the open literature, there are existing studies on fuel cell-powered UAVs. Most of these studies have preferred using hybrid systems, with batteries as the secondary power source [2,3]. Typically, passive power distribution systems have been employed, and hydrogen has been stored in tanks (though systems that produce hydrogen on demand also exist) [4,5]. A notable aspect of the reviewed studies is that the designed system architectures are complex and costly [6,7].

This study focuses on developing a simple and accessible hybrid propulsion system utilizing PEM fuel cells as the primary power source and Li-Po (Lithium Polymer) batteries as the secondary power source. A hybrid system architecture was designed within this scope, and a power distribution board was developed. The mathematical model of the system was created in the MATLAB/Simulink platform, and simulation tests were conducted on the model. Subsequently, a static cruise flight power test was performed on the hybrid system, and the results were compared with the simulation outcomes. This study aims to create a system capable of extending the flight durations of electric UAVs while maintaining environmental sustainability.

2. MODELING AND EXPERIMENTAL METHODOLOGY

2.1. System Architecture

The proposed hybrid propulsion system includes PEM fuel cells and Li-Po batteries as power sources. The system architecture is designed to utilize the fuel cell as the primary power source during cruise flight. At the same time, the battery provides secondary support during high-power-demand flight phases, such as takeoff and climb. The goal of this architecture is to utilize the high energy density of the hydrogen to achieve long-range flight during the cruise phase, while the high-power density of the Li-Po battery supports power-intensive phases. The system architecture is illustrated in Figure 1.

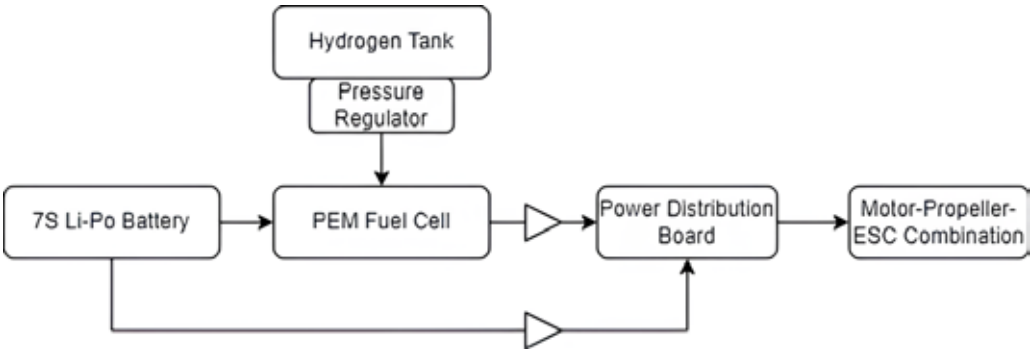

Fig. 1. System Architecture

The fuel cell used in the system is specifically designed for aviation applications and is suitable for hybrid operation. It features an integrated circuit board that enables hybrid operation with a battery. This configuration allows the battery to supplement power demands instantaneously when high power is required within the operational limits of the fuel cell. However, since the circuit board's capacity does not meet the maximum power demand of the motor selected for the system, a power distribution board has been added to the architecture. This board enables the fuel cell to be bypassed, allowing the battery to supply all the required power. The design of the board prioritizes simplicity and accessibility. It operates manually and is controlled via a UAV remote controller switch.

A composite tank with an energy storage capacity of 705 Wh has been selected for hydrogen storage. This tank stores hydrogen as compressed gas and features an ultra-lightweight internal pressure regulator that effectively reduces the hydrogen pressure to 0.5-0.6 bar, supplying the fuel cell. The tank produced by H3 Dynamics has a capacity of 2 liters and operates at pressures of up to 300 bar. The Aerostak A250 PEM fuel cell, manufactured by H3 Dynamics, with a nominal power of 250 W has been selected. A 7-cell Li-Po battery with a capacity of 2200 mAh and a discharge rate of 45C has been used.

2.2. Hybrid System Modeling

To evaluate the performance of the system and simulate its behavior under different scenarios, a system model was developed in the MATLAB/Simulink environment [8]. During the model development process, the components within the architecture were individually modeled and tested to ensure realistic results. The models were refined until the data obtained from the tests matched the results of real-world tests. Once validated, the individual models were integrated to create the overall power system model.

A load model was created based on static motor test data obtained from the motor-propeller combination selected for the architecture to enable realistic simulation tests on the power system. This load model was incorporated into the system model. Simulation tests were then conducted using the complete model, and the flight time achievable at different throttle values was observed. With the simulations, it was decided at which power value the system would operate, and the operating time obtained was compared with the operating time that could be achieved with a only Li-Po battery with the same weight.

2.3. Experimental Studies

To observe the performance of the fuel cell and analyze its behavior under load, both static and dynamic load tests were conducted [9]. A conditioning process allowed the device to reach its optimal performance, ensuring that the power values specified in the manufacturer's documentation were achieved.

Subsequently, the hybrid system was assembled, and tests were conducted under motor load to observe its response to instantaneous load variations. After determining that the observations and results were sufficient, preparations were made for the final test: the cruise flight test, which aimed to evaluate power consumption during cruise flight. The cruise flight test was conducted, and the maximum range achievable with a single hydrogen tank was observed. The cruise flight power test setup is provided in Fig. 2.

3. RESULTS AND DISCUSSION

3.1. Extended Flight Endurance

The hybrid propulsion system has significantly increased flight duration by up to 30% compared to conventional battery-only systems, which is a remarkable achievement. This increase in flight time was achieved without compromising the operational capabilities of the UAV. The PEM fuel cell, used as the primary power source during cruise flight, provides a sustainable solution for long-range operations. At the same time, the Li-Po battery efficiently supports high-power phases, such as takeoff and climb. As a result, the UAV could sustain longer flight times, which is critical for many applications, especially remote monitoring, surveillance, and search-and-rescue missions. The integration of both power sources, optimized for different flight phases, has enabled the system to operate efficiently and effectively, ensuring that the UAV can meet the demands of various mission profiles. This improvement enhances the practical usability of UAVs and presents a strong argument for the broader adoption of hybrid power systems in the aerospace industry, particularly for missions that require extended flight durations. Results of the cruise flight power test are provided in Fig. 3.

3.3. MATLAB/Simulink Simulations

The results obtained from simulations conducted on the hybrid power system model created in the Simulink platform were compared with real-world test results, and it was found that the model provided highly accurate results. In the simulation test, the system was predicted to operate for 193 minutes, while the real-world test showed that the system ran for 195 minutes. Thus, the accuracy rate of the model was determined as 98.9%.The high accuracy of the developed model demonstrates its potential as a solid foundation for future research and development. This accuracy enables further work to investigate how system boundaries may change after modifications are made to the system and its components. By conducting further simulations and adjustments to the model, it will be possible to observe the impact of these changes on the overall system performance. As a result, tests can be performed on the model with high accuracy without the need for real tests, and thus more efficient work can be done in terms of time and computational cost.

4. CONCLUSIONS

In this study, a relatively simple and accessible hybrid power system architecture consisting of a PEM fuel cell and a Li-Po battery has been successfully designed, developed, and implemented. To thoroughly evaluate the system's performance and ensure that the study is grounded in solid mathematical principles, a system model was created using MATLAB/Simulink. After the accuracy of the model was ensured by tests, simulations were performed to see how long the hybrid power system can operate with one tank of hydrogen. As a result of the simulations, it was decided to operate the system at an average value of 220 W. The system was able to operate for 193 minutes at 220 W power value. For comparison, simulations were performed with a only Li-Po battery equal to the weight of the hybrid system and it was observed that the system could operate for 150 minutes.
