Following the simulation phase, real-world tests of the hybrid power system were conducted to validate the results obtained through the simulations. During these tests, the conditioning of the fuel cell was completed, and the system was subjected to a final cruise flight power test. In this crucial step, a possible flight profile for a fuel cell-powered UAV was developed, and the behavior of the UAV was carefully simulated during flight. A significant portion of this profile was dedicated to cruise flight, which allowed for extracting the corresponding power profile that was subsequently applied to the hybrid propulsion system.

The test results indicated that the system performed as expected, showcasing the reliability and accuracy of the simulated results. Additionally, the system demonstrated an extended flight duration compared to conventional battery-only systems while maintaining its operational capabilities. This increase in flight time contributes to environmental sustainability, as it helps to reduce the overall energy consumption and emissions of the UAV. The extended flight duration, in particular, addresses one of the primary challenges modern electric aircraft faces: the relatively limited flight time compared to combustion engine-powered aircraft. This study, therefore, presents a significant advancement in hybrid propulsion systems and lays the foundation for future research and improvements in the field, particularly in the context of long-endurance, environmentally friendly UAVs.

ABSTRACT
Hydrogen is a synthetic fuel. There are many methods of producing hydrogen. The most important of these is electrolysis systems that provide green hydrogen production. It is important to produce accessible electrocatalysts in electrolysis systems and to ensure that the use of hydrogen energy becomes widespread. The biggest factor in the necessity of switching to renewable energy in energy production is the damage caused by fossil fuels to the environment. The reusability of materials that are harmful to the environment due to their production and waste, the reduction of damage to the environment and their contribution to energy efficiency also meet the criteria in the definition of renewable energy. There are many products that can be recycled and used as waste. Recycling of waste zinc-carbon batteries prevents the damage to the environment caused by the heavy chemicals they contain, while also providing economic contribution. For this reason, the catalytic effects of graphite rods obtained from waste zinc-carbon batteries on hydrogen evolution were investigated. Electrochemical Impedance Spectroscopy, Linear Scanning Voltammetry and Cyclic Voltammetry techniques were used to evaluate the electrodes obtained from waste zinc-carbon batteries. The hydrogen efficiency of graphite rods obtained from waste batteries of different trademarks was examined.

Keywords: *Energy, Hydrogen, Catalyst, Waste Battery, Recycling*

1. INTRODUCTION

Energy is one of the indispensable components of life today. The use of fossil fuels in energy production has some negative effects such as greenhouse gas effect, smog effect, acid rain and external dependency[1] Due to these negative effects of fossil fuels, it is important to turn to sustainable and environmentally harmless renewable energy sources in energy production[2]. The use of renewable energy sources means a cleaner environment. However, the use of storage systems has become necessary due to reasons such as the energy obtained from renewable energy sources changing according to climate conditions and the fact that the systems in the facility are not operated due to the full power grid when electricity supply is low and electricity can be produced in energy facilities[3, 4]. Hydrogen systems are leading in energy storage [5]. There are many methods of hydrogen production. The most environmentally friendly of these is electrolysis systems, which enable the production of green hydrogen[6]. Electrocatalyst production is important for widespread use of electrolysis systems.
Waste materials that have completed their lifespan after consumption are recycled to reduce the damage to nature and to contribute to the economy by saving energy. One of the materials that is important to recycle is waste batteries. In addition to the damage that batteries cause to the environment due to their chemical structure, the recovery of the precious metals used contributes to the economy[7]. Batteries are classified in many ways. They are divided into two groups according to their chemical properties: primary (non-rechargeable) and secondary (rechargeable). Secondary batteries (rechargeable) can be used by recharging. However, primary batteries are waste because they cannot be used again after their lifespan is over[8]. Primary batteries are harmful to the environment because their chemical components contain heavy metals. Preventing the environmental damage of waste primary batteries can be possible through recycling processes. In many publications in the literature, recycling is done by applying pyrometallurgical and hydrometallurgical techniques[7, 9-11]. In recycling using pyrometallurgical and hydrometallurgical techniques, mostly metals such as zinc and manganese are obtained. The structure of zinc-carbon batteries includes a zinc plate as the anode, a manganese dioxide-coated graphite rod as the cathode, and ammonium chloride or zinc chloride as the electrolyte. In our study; the waste zinc-carbon battery will be physically broken down, the graphite rod inside will be removed and tested as cathode material in alkaline electrolyzer systems. Electrochemical Impedance Spectroscopy (EIS), Linear Scanning Voltammetry (LSV), Cyclic Voltammetry (CV) Techniques were used to examine the catalytic activity.

2. MATERIALS AND METHODS

Graphite rods were removed from zinc-carbon batteries obtained from recycled battery boxes. Many different rademarks of zinc carbon batteries were examined and this study presents data for the three best commercial trademarks.Potentiostat-galvanostat analyzer was used for electrochemical characterizations. All experiments and

measurements were carried out in a 1.00 M KOH solution at room temperature using a three-electrode method. The platinum, which has a surface area of 2 cm^2, and Ag/AgCl (3.0M KCl) electrodes were used as counter and reference electrodes, respectively. The EIS measurements made using the method were taken by applying 10 mV amplitude in the frequency range of 10^5 -10^{-2} Hz. The LSV graphs were obtained from -1.0 V to -1.8 V at 1 mVs^{-1} scan rate. The CV has been carried out at 100 mVs^{-1} scan rate from -1 V to +0.8 V. All experiments were done in a 1.00 M KOH solution at room temperature.

3. RESULTS AND DISCUSSION

EIS measurements were taken by applying a potential of -1.5 V in the frequency range of 10^5 -10^{-2} Hz and are shown in Figure 1. As seen in the Nyquist curves in Figure 1, the resistance of the graphite rod obtained from the C trademark battery is higher than the others. The resistance of the graphite rod obtained from A trademark, B trademark, C trademark was 13.2, 14.7 and 15.5 $\Omega.cm^{-2}$, respectively.

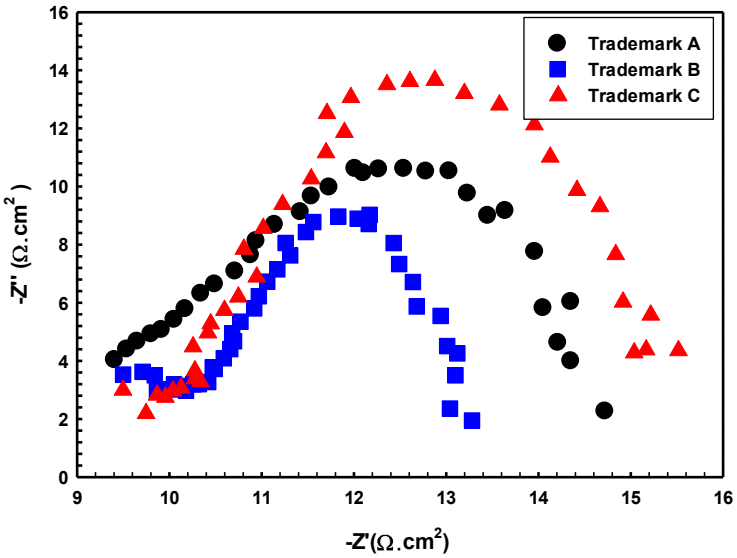

Fig. 1. Nyquist plots Trademark A, Trademark B and Trademark C at in 1 M KOH solution at 298 K

The LSV curves obtained from waste zinc carbon batteries were performed in 1.0 M KOH solution at room temperature of 25°C and are shown in Figure 2. According to the LSV results, the graphite rod obtained from Trademark A exhibited lower onset potential and higher current density for hydrogen evolution than the others.

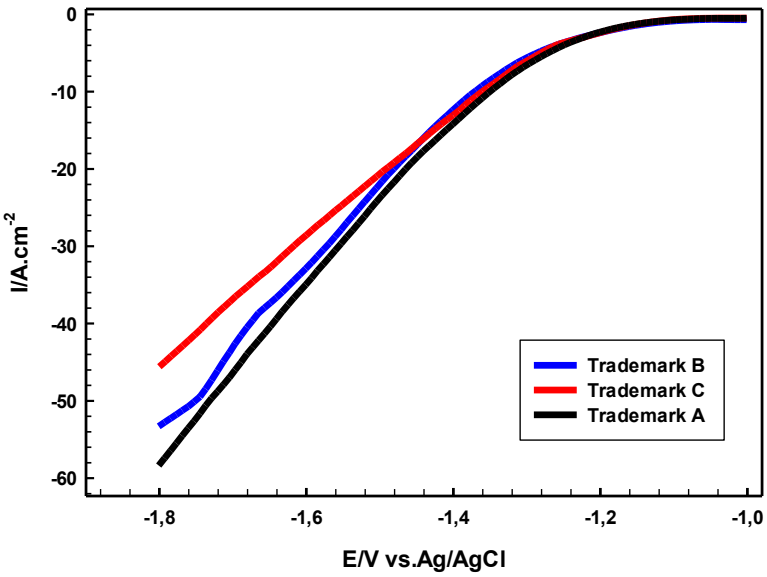

Fig. 2..LSV curves at for Trademark A, Trademark B and Trademark C in 1 M KOH solution at 298 K

The CV curves of graphite rods obtained from waste zinc-carbon batteries were obtained in 1.0 M KOH solution at room

temperature of 25° C and are shown in Figure 3. When the CV results of Trademark A and Trademark B were examined, it was seen that they had peaks at the same potential, which led to the idea that the structure of Trademark A - Trademark B may be the same but the amount of substance in Trademark A is higher. In Figure 3, it is seen that the peaks of Trademark C have peaks at different potentials than the other trademarks. Our characterization studies are continuing.

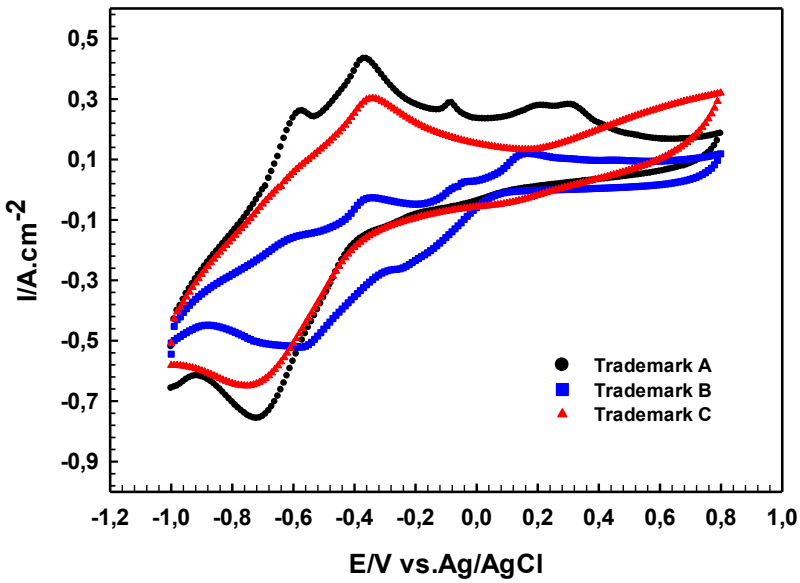

Fig. 3. CV curves at for Trademark A, Trademark B and Trademark C in 1 M KOH solution at 298 K

4. CONCLUSIONS

The catalytic activity of graphite rods obtained from waste zinc-carbon batteries was investigated for hydrogen evolution process.

- EIS shows that graphite rod obtained from Trademark B has less resistance to hydrogen evolution reaction.
- From LSV findings, it was determined that graphite rod obtained from Trademark A has the lowest initial potential and the highest current density.
- According to CV results, led to the idea that the composition of Trademark A and Trademark B may be the same, but the amount of ingredients in Trademark A is greater. Graphite rod obtained from Trademark A has the largest current increase and the highest peak.

We think that graphite rod obtained from waste zinc-carbon batteries can be used as cathode material and contribute to Hydrogen Evolution Reaction. We suggest that among the graphite rods obtained from waste batteries, graphite rod belonging to Trademark A can be used as an effective electrocatalyst for hydrogen production.

ABSTRACT
Clean fuels must be used in high-temperature manufacturing processes to make the transition to sustainable energy systems. The possibility of using non-premixed hydrogen combustion as a substitute for traditional hydrocarbon fuels is examined in this study through numerical investigation in an industrial ceramic furnace. A two-dimensional numerical domain of the furnace was created using a discrete ordinates approach for radiative heat transfer, finite-rate chemistry for combustion, and turbulent flow dynamics through the k-ε model using computational fluid dynamics simulations. The analysis focuses on flame configuration, temperature distribution, heat transfer and mitigation of CO_2 emissions under different hydrogen mixing ratios such as H5, H10 and H15. Air-fuel ratios and burner configuration are held constant to understand the effects of the hydrogen addition. The results reveal key insight into the stability of non-premixed hydrogen flames mixing with methane, temperature distribution on the combustion domain, homogeneous heating of the ceramic material and lower CO_2 emissions. Comparative analysis with pure methane reveals approximately 5 K enhancement in average furnace temperatures and a 7% reduction in CO_2 emissions. The use of hydrogen in industrial ceramic furnaces will be very beneficial in terms of efficiency, environment, and decarbonization. Future studies can be performed for different furnace geometries and boundary conditions.

Keywords: Non-premixed combustion, hydrogen, ceramic furnace, CFD, CO_2 emissions, decarbonization

1. INTRODUCTION

In recent years, various alternative fuel technologies have been developed to reduce the use of fossil fuels and transition to sustainable energy sources. The use of fossil fuels causes the emissions of carbon dioxide (CO_2), nitrogen oxides (NO_x) and other harmful pollutants into the atmosphere, leading to problems such as global climate change and air pollution. As a solution to these problems, hydrogen is considered as an alternative fuel with its high energy density, clean combustion products and zero carbon emission potential. Drying, sintering and even cooling are essential process steps in producing ceramic products in industry [1]. Industrial-type furnaces are mainly used for firing and heating ceramics. Using hydrogen as an alternative fuel in these furnaces is seen as an innovative approach that can significantly reduce environmental impacts.

There are many studies on industrial-type industrial furnaces in the literature. Balli et al. conducted a numerical and experimental study on energy efficiency, fuel consumption and CO_2 emissions reduction on an industrial prototype furnace used in ceramic production [1]. Schüttensack et al. analyzed the furnace system with a mixture of hydrogen and natural gas fuel, which causes less emissions instead of electric furnaces used in steel production industries. This study found that it causes less CO_2 emissions than electric furnaces [2]. Mayrhofer et al. investigated the application of natural gas/hydrogen mixtures as an alternative fuel in industrial heat treatment furnaces and the economic potential for reducing CO_2 emissions in this application area [3]. Daurer et al. numerically modeled a semi-industrial furnace in an oxy-fuel combustion chamber. In their study, the effect of hydrogen on flame temperature and combustion characteristics was investigated [4].

There are few studies on analyzing systems using hydrogen as a fuel for ceramic production. In this study, unlike the others, the effect of the hydrogen-methane mixture on the ceramic product and combustion characteristics was investigated. It aims to explore the impact of alternative fuels on heat dissipation and emission reduction by examining the thermal behavior of an industrial prototype gas furnace for ceramic production. In this study, the flue gas outlet temperatures, temperature distributions and emissions were investigated using hydrogen with methane gas at different molar ratios in industrial-type furnaces.

2. MATERIALS AND METHODS

A 2D numerical model was established to evaluate the combustion performance of alternative fuels in industrial furnaces.

The model is mainly based on the traditional natural gas and hydrogen co-combustion model. A CFD numerical simulation study was carried out in the numerical model using ANSYS Fluent software [5,6] with a non-premixed combustion model. The computational domain is given in Fig. 1.

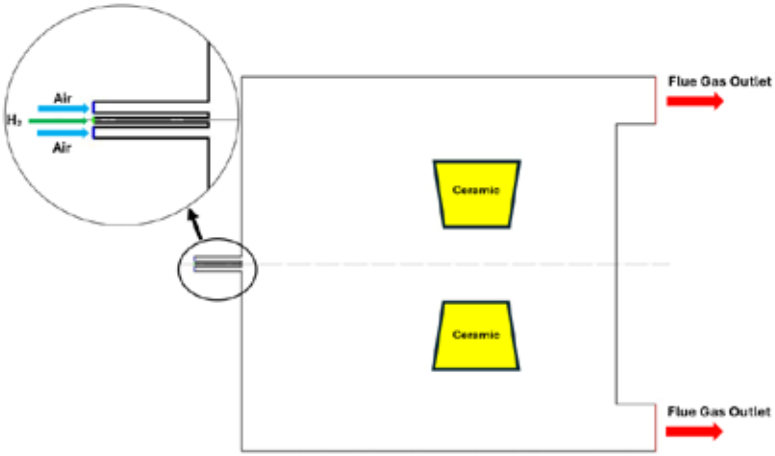

Fig. 1. Computational domain with inlets and outlets

The numerical model evaluated the effect of hydrogen natural gas co-combustion on the temperature in the combustion chamber, ceramic temperature change, and CO_2 emissions. The main boundary conditions used in the study are mass fuel mass flow inlet, air mass flow inlet, adiabatic wall, and pressure outlet boundary conditions. A pressure-based solver is used as the general solver, and a RANS-based *k*-ϵ turbulence model is used [7]. The primary combustion statement is expressed by Eq. (1) [8].

$$xCH_4 + yH_2 + \frac{a_s}{\phi}(O_2 + 3.76N_2) \rightarrow Products \quad (1)$$

Equations *x* and *y* are the methane and hydrogen molar ratios, respectively. The a_s and The ϕ are the F/A stoichiometry and equivalence rate, respectively. The boundary conditions and combustion parameters used in the study are given in Table 1.

Table 1. Boundary conditions and combustion parameters

Boundary conditions	Unit	Value and condition
Fuel and air Inlets	kg/s	Mass flow inlet
Outlet		Pressure outlet
Inner wall	-	Non-slip boundary, DO radiation model [9]
Outer wall	-	Adiabatic wall
Ambient temperature	K	300
Furnace dimensions (L x D)	mm	440 x 400
Fuel blends	vol%	D100 D95-H5 D90-H10 D85-H15

3. RESULTS AND DISCUSSION

In this study, combustion temperature and CO_2 emissions were calculated numerically according to different hydrogen blends in industrial furnaces. In the results of the study, it was observed that hydrogen addition increased the furnace temperature and decreased CO_2 emissions. Reduced CO_2 emissions are due to the non-existence of carbon atoms in hydrogen fuel. CO_2 decreases from 0.0585 (H0) to 0.0560 (H15), indicating that higher hydrogen ratios correlate with reduced CO_2 emissions. This aligns with expectations, as hydrogen combustion produces no CO_2 emissions. Due to the low ignition temperature and high calorific value of hydrogen, the temperatures in the furnace increased with hydrogen addition. Fig. 2. shows the furnace outlet temperature, ceramic surface average temperature and CO_2 emissions for different ratios of hydrogen addition to natural gas.

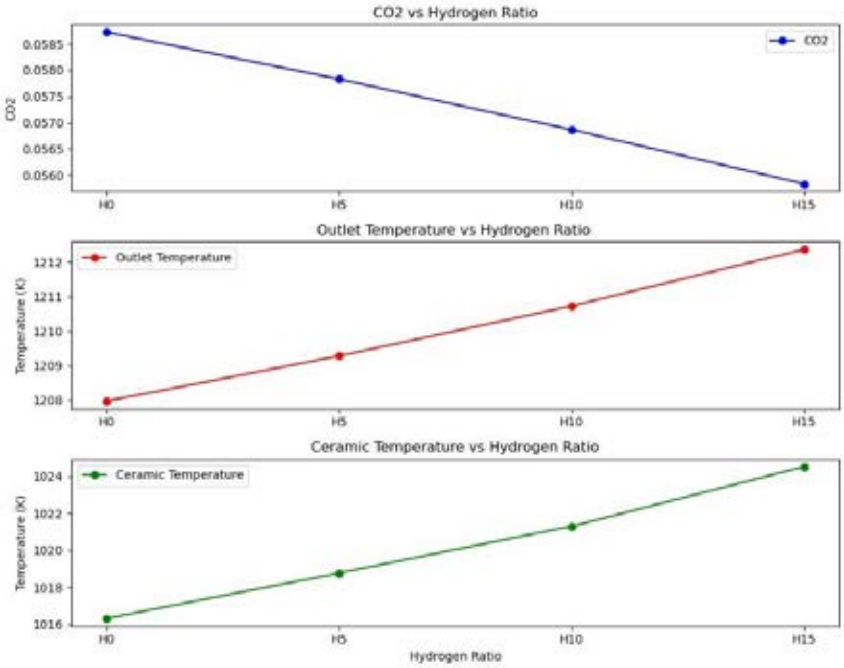

Fig. 2. Variation of temperature and emissions for hydrogen ratio

Fig. 3 shows the furnace's temperature distribution for the co-combustion of hydrogen and natural gas at different hydrogen ratios.

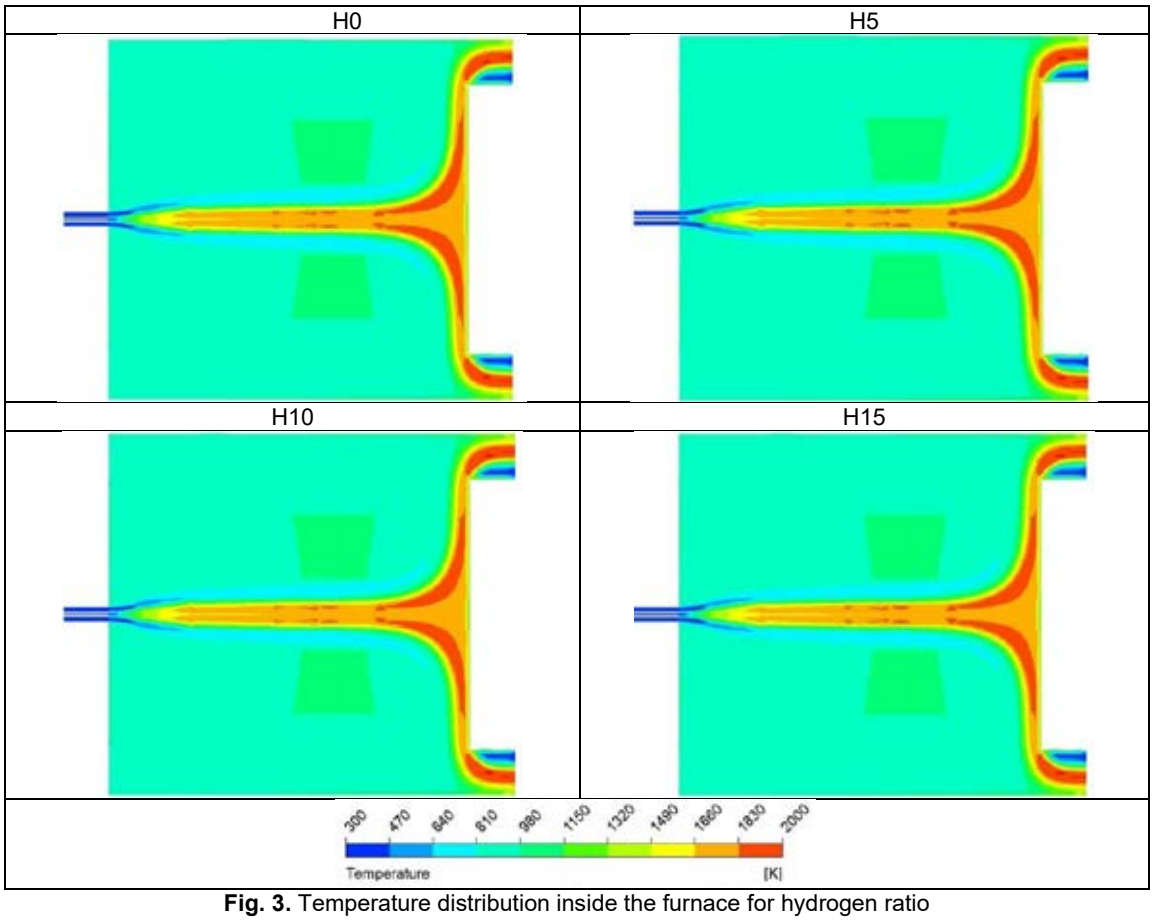

Fig. 3. Temperature distribution inside the furnace for hydrogen ratio

Due to the furnace's geometrical structure, the temperature distribution is in the same direction as the blower velocity gradient. The temperatures inside the furnace reach up to 2015 K values, while the average furnace and ceramic material temperatures are around 1000 K levels.

4. CONCLUSIONS

In this study, the temperature and emission parameters of industrial furnaces with different hydrogen additives were investigated numerically. The main findings of the study are as follows.

- Within the scope of the study, a non-premix combustion numerical combustion model was created.
- It was determined that CO_2 emissions decreased by approximately 7% with increasing hydrogen addition.
- Increasing hydrogen addition elevates temperatures inside the combustion chamber and on the ceramic surface. This is due to hydrogen's high ignition and thermal value.
- Approximately 5 K enhancement was observed in average furnace temperatures

Hydrogen is a carbon-free energy vector with high thermal potential. Therefore, system performance studies can be examined using different burner and geometric structures. In addition, with the emission restrictions imposed, hydrogen obtained from clean energy sources has a high potential for future use.

ABSTRACT
Using hydrogen as an energy vector is one of the key drivers of the shift away from fossil fuels. This study numerically investigated the effect of a hydrogen and natural gas blend on furnace temperature and emissions. It analyzed D100 pure natural gas and H100 pure hydrogen combustion with 5%, 10%, and 15% hydrogen addition. In addition, parametric studies were carried out for different equivalence ratios. The study determined that increasing hydrogen addition increases the combustion chamber temperature and decreases CO_2 emissions. Approximately 1% temperature increase was observed between D100 fuel and H100 fuel. CO_2 mole fractions were found to be approximately 5.1%, 5.0%, 4.9% and 4.8% for D100, H5, H10 and H15 fuel blends. With the study, the combustion performance of the use of hydrogen, an energy vector, in ceramic furnaces

Keywords: Hydrogen, combustion, CO_2 reduction, furnace, sustainability

1. INTRODUCTION
The development of low-carbon or zero-carbon combustion technology is crucial for the energy sector, given the swift implementation of carbon-neutral policies and technologies. Hydrogen is thought to be a superior alternative fuel among several renewable fuels. In addition to absorbing excess renewable energy from sources like wind and solar power and reducing grid instability, hydrogen also has the benefit of having a high calorific value per mass, which allows it to be burned directly and used in internal engines, boilers, and gas turbines [1,2]. Cofiring natural gas with hydrogen, however, lowers carbon emissions while aggravating the production of nitrogen oxide, another air pollutant, particularly at high hydrogen-blending concentrations. Advanced hydrogen-enriched methane combustion technologies must be developed to effectively and economically limit source NO_X production to comply with the strict NO_X emission requirements [3].

Sintered materials can be heated in conventional natural gas furnaces up to 2000 K, although greater temperatures are frequently needed to produce dense refractory ceramics. Therefore, correct combustion and fuel selection are essential in the firing process of ceramics. Using hydrogen as an alternative to natural gas fuel is one crucial step for sustainable systems [4]. Different studies have been carried out on the combustion processes of furnaces in the literature. Kang et al. [5] experimentally and numerically investigated the heat transfer performance of a ceramic honeycomb regenerator in oxy-fuel combustion. Daurer et al. [6] tested the high pulse oxy-fuel combustion of pure H_2 in an industrial environment based on experiments, theoretical calculations and RANS simulations. Li et al. [7] modeled the effect of hydrogen-rich fuel injection on combustion characteristics, thermo-chemical behavior, and coke dynamics in a three-dimensional blast furnace duct at the particle level using the computational fluid dynamics-discrete element method (CFD-DEM). Ren et al.[8] numerically investigated the effects of hydrogen content in the co-injection gas on the combustion characteristics in the duct.

Studies in the literature have generally examined low-temperature combustion and oxyfuel combustion processes. However, the combustion conditions of hydrogen with natural gas at different ratios and 100% hydrogen combustion conditions have been studied very little. In addition, the combustion conditions of hydrogen with air density are also among the main issues to be examined in the literature. In this study, 100% diesel and 100% hydrogen combustion conditions were numerically investigated and the flame appearance in the furnace was investigated. The effect of 5%, 10% and 15% hydrogen natural gas mixture on combustion chamber temperature and emissions were determined. The effect of 15% hydrogen natural gas mixture on combustion and emissions at different air excess coefficients was evaluated parametrically. The study was conducted under a computational fluid dynamics model using non-premix combustion conditions. Thus, it is expected to make significant contributions to the literature by reducing CO_2 emissions against global warming and enabling the modeling of sustainable combustion processes.

2. MATERIALS AND METHODS

A two-dimensional numerical model was developed to assess the performance of hydrogen natural gas combustion in industrial furnaces. The conventional natural gas and hydrogen co-combustion model is the primary foundation. Using ANSYS Fluent software [9,10] and non-premix combustion model, a CFD numerical simulation investigation was conducted using the numerical model. Fig. 1 shows the computational domain. The study was carried out for the test furnace and ceramics in the Çanakcılar Ceramic Industry and Trade Co. factory.

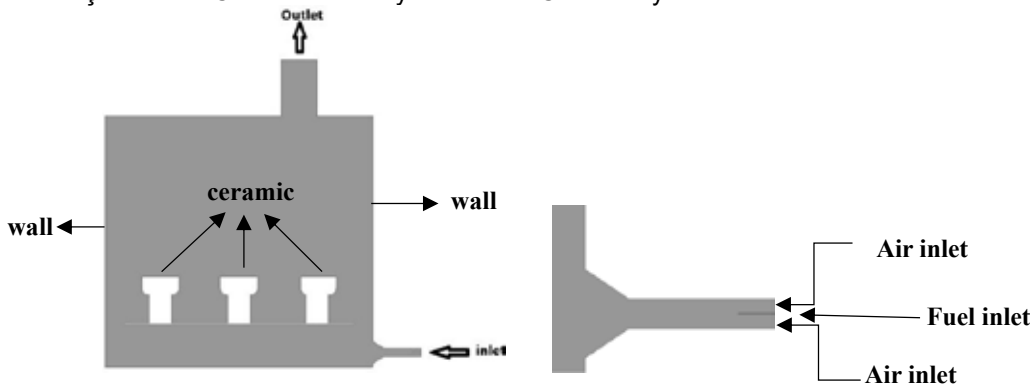

Fig. 1. Computational domain

The numerical model assessed how the co-combustion of hydrogen and natural gas affected the combustion chamber's temperature, the change in ceramic temperature, and CO_2 emissions. The study's primary boundary conditions are the adiabatic wall, pressure outlet, air mass flow intake, and mass fuel mass flow inlet. The general solver is pressure-based, while the k-ϵ turbulence model is based on RANS [9]. Eq. (1) expresses the primary combustion statement. [11].

$$xCH_4 + yH_2 + \frac{a_s}{\phi}(O_2 + 3.76N_2) \rightarrow Products \quad (1)$$

Equations *x* and *y* are the methane and hydrogen molar ratios, respectively. The a_s and the ϕ are the F/A stoichiometry and equivalence rate, respectively. Table 1 gives the boundary conditions and combustion parameters used in the study. The study used the ϕ equivalence ratio with variables x and y.

Table 1. Boundary and initial conditions

Boundary conditions	Unit	Value and condition
Inlets	kg/s	Mass flow inlet
Outlet		Pressure outlet
Inner wall	-	Non-slip boundary, DO radiation model [12]
Outer wall	-	Adiabatic vall
Ambient temperature	K	300
Furnace dimensions (L x D)	mm	1430 x 1340
Case studies	vol%	D100 H5 H10 H15 H100
ϕ	-	0.6 0.8 1.0

3. RESULTS AND DISCUSSION

Fig. 2 shows the flame temperature distribution for 100% natural gas (D100) and 100% hydrogen (H100) combustion. The flame distribution formed by hydrogen combustion spreads over more expansive areas compared to natural gas. In addition, combustion chamber temperatures are higher in hydrogen combustion than in natural gas combustion. In addition, the adiabatic flame temperature increases in the combustion process with hydrogen fuel. This is one of the main reasons for the temperature increase.

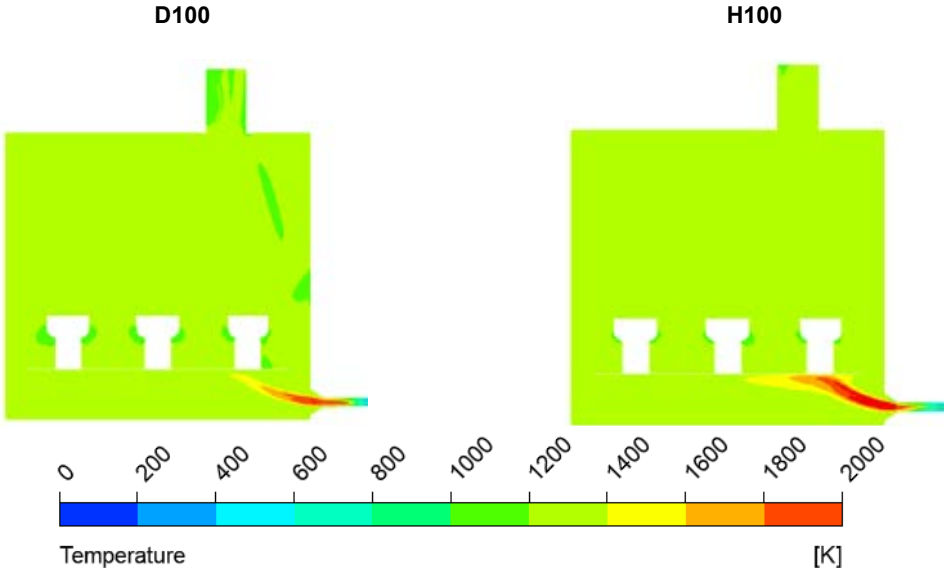

Fig. 2 Flame distribution of hydrogen and natural gas

Fig. 3 shows the distribution of combustion chamber temperature with hydrogen addition for different hydrogen ratios and equivalence ratios. It was determined that increasing hydrogen addition increased the combustion chamber's average temperature. In addition, the decrease in the equivalence ratio decreases the combustion chamber temperatures. The decrease in the equivalence ratio leads to an increase in the air-fuel ratio.

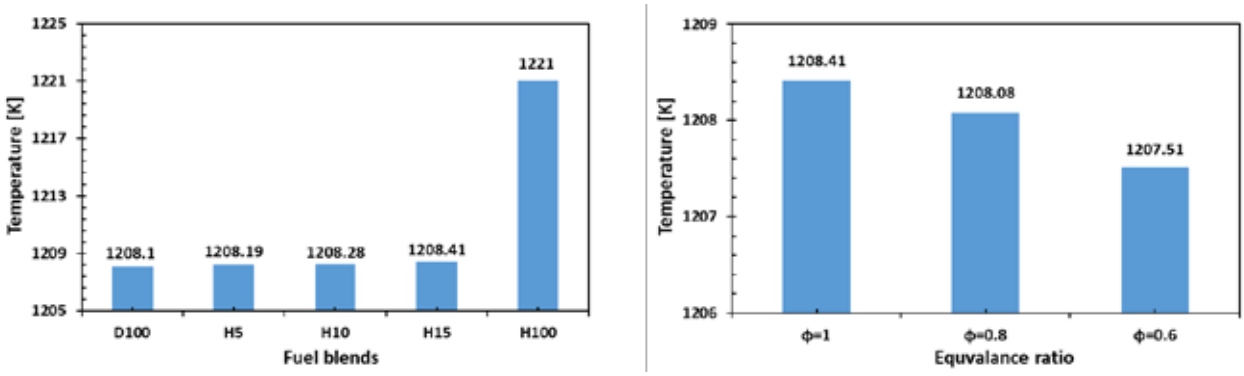

Fig. 3 Temperature of the combustion chamber for variable fuel blends and equivalence ratio

Fig. 4 shows CO_2 emissions for different hydrogen addition and equivalence ratios. It was determined that CO_2 emissions decreased with increasing hydrogen addition. In addition, the reduction in the equivalence ratio also reduces the hydrogen ratio. This is mainly because hydrogen is a carbon-free fuel.

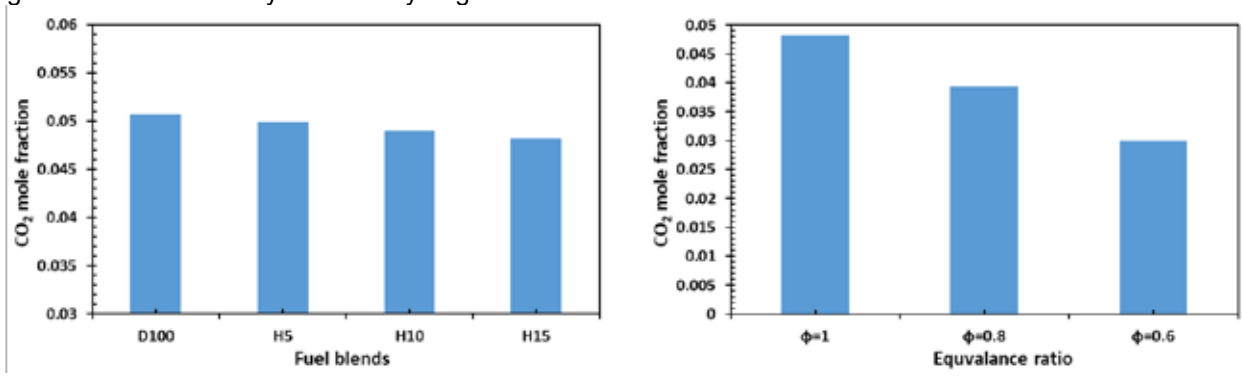

Fig. 4 CO_2 mole fraction of variable fuel blends and equivalence ratio

4. CONCLUSIONS

The fact that hydrogen is a carbon-free fuel with high energy efficiency will bring about its widespread use in energy systems. Within the scope of the study, the ceramic ceramic combustion process for different hydrogen addition and equivalence ratios was carried out parametrically. The results of the study are briefly as follows.

- With increasing hydrogen addition, combustion chamber flame and temperature values increase. The combustion temperature was approximately 1208 K for D100 fuel and 1221 K for H100, respectively.
- Combustion chamber temperature and emission values increase with increasing equivalence ratio.
- The fact that hydrogen does not contain carbon atoms is the main reason for reducing CO_2 emissions in combustion processes.

ABSTRACT
Enhancing the efficiency of catalysts for dry reforming of methane (DRM) requires optimizing their structural and electronic properties to maximize activity and minimize coke formation. This study investigates the effect of substituting Sr for La in $La_ySr_{1-y}Ni_{0.5}Mg_{0.5}O_3$ perovskites (y=0, 0.5 and 1) to enhance catalytic performance. Structural analysis confirms high crystallinity, with Sr incorporation optimizing oxygen mobility, CO_2 adsorption, and carbon resistance. The interplay between La and Sr influences Ni reducibility, with Sr-induced oxygen vacancies delaying low-temperature reduction and La enhancing Ni accessibility. Catalytic testing reveals that La-rich samples (y = 1) achieve the highest CO_2 and CH_4 conversion (85% and 75% at 750 °C), whereas Sr-rich samples (y = 0) exhibit relatively lower conversions at higher temperature but greater oxygen vacancy formation. Overall, $La_{0.5}Sr_{0.5}Ni_{0.5}Mg_{0.5}O_3$ achieves the best balance of oxygen mobility and catalytic efficiency, providing insights into perovskite catalyst design for syngas production.

Keywords: Dry Reforming of Methane, Perovskite Catalysts, Strontium Substitution, Oxygen Mobility

1. INTRODUCTION

The growing global demand for energy, driven by rapid industrialization, calls for sustainable alternatives that reduce environmental impact while remaining economically viable [1]. The heavy reliance on fossil fuels has significantly contributed to greenhouse gas emissions, intensifying climate change and highlighting the urgent need for cleaner energy solutions [2]. Among various methane reforming processes, DRM,Eq.(1) has gained attention due to its ability to convert both CO_2 and CH_4 and into syngas [3]. Compared to partial oxidation (POM) and steam reforming (SRM), DRM is more sustainable as it utilizes CO_2 instead of water, promoting carbon capture and utilization [4]. However, challenges such as catalyst deactivation due to sintering and carbon deposition hinder its large-scale implementation [5].

$$CO_2 + CH_4 = 2CO + 2H_2 \qquad \Delta H^o = +247.3\ kJ.mol^{-1} \qquad (1)$$

Catalysts play a crucial role in DRM by lowering activation energy, enhancing reaction rates, and improving selectivity [6]. Perovskite-based catalysts have attracted significant interest due to their structural flexibility, high thermal stability, and ability to accommodate multiple metal elements [7]. Perovskites containing transition metals at the B-site, along with La, Sr, or Ce at the A-site, have shown promising results in methane reforming applications [8]. These materials act as precursors to highly dispersed active metal species, improving catalytic efficiency and resistance to deactivation.
Strontium (Sr) substitution in perovskites has been explored for its ability to modify catalyst properties, influencing activity and stability [9]. Sr incorporation can enhance CO_2 adsorption, promote oxygen mobility, and mitigate coke formation by facilitating carbon oxidation [10]. Additionally, Sr can improve Ni dispersion on the catalyst surface, increasing the number of active sites and boosting overall performance [11]. Previous studies have demonstrated that Sr interacts synergistically with other components, such as La and Ni, to create more effective catalytic sites [12].
Building upon our previous findings, where $LaNi_{0.5}Mg_{0.5}O_3$ exhibited the highest DRM performance [13], this study investigates the effect of Sr substitution for La in the perovskite structure. We explore $La_ySr_{1-y}Ni_{0.5}Mg_{0.5}O_3$ catalysts (y=0, 0.5 and 1) with varying Sr content to evaluate its influence on structural properties, methane and CO_2 conversion, syngas production, and coke resistance. By analyzing the impact of Sr incorporation, we aim to develop highly efficient and stable catalysts for DRM, contributing to more sustainable energy solutions.

2. MATERIALS AND METHODS

$La_ySr_{1-y}Ni_{0.5}Mg_{0.5}O_3$ perovskite catalysts were synthesized using the solution combustion method (SCS) with glycine as the fuel, ensuring homogeneous mixing and controlled composition. The precursors were calcined at 700 °C to achieve the desired perovskite phase, followed by reduction in a hydrogen-containing atmosphere to activate the catalytic sites. Various characterization techniques were employed to analyze the structural properties, elemental composition, surface chemistry, and reducibility of the catalysts before and after the reaction.
The catalytic performance was evaluated in a tubular flow reactor under atmospheric pressure, using a 1:1 CO_2/CH_4 feed at a flow rate of 50 sccm. The reaction was conducted across a temperature range of 100–750 °C, and the gaseous products were analyzed via gas chromatography to determine CO_2 and CH_4 conversion, as well as syngas yield. The impact of Sr substitution on catalytic activity and stability was assessed by correlating structural and reduction properties with reaction performance.

$$CO_2 Conversion = (CO_{2,in} - CO_{2,out})/CO_{2,in} \quad (2)$$
$$CH_4 Conversion = (CH_{4,in} - CH_{4,out})/CH_{4,in} \quad (3)$$

3. RESULTS AND DISCUSSION

Fig. 1 illustrates the catalytic performance of $La_ySr_{1-y}Ni_{0.5}Mg_{0.5}O_3$ perovskites in terms of CH_4 and CO_2 conversion across different temperatures. The results show a general increase in conversion with temperature, consistent with the endothermic nature of DRM. Among the catalysts, the y=1 sample exhibited the highest CO_2 conversion, reaching approximately 85% at 750 °C. Similarly, CH_4 conversion was most efficient for the y=1 sample, exceeding 75% at the same temperature, highlighting the role of La in enhancing methane activation. The superior activity of the y=0 catalyst at lower temperatures is attributed to its higher Sr content, which enhances oxygen vacancy formation and mobility, facilitating CO_2 and CH_4 activation.

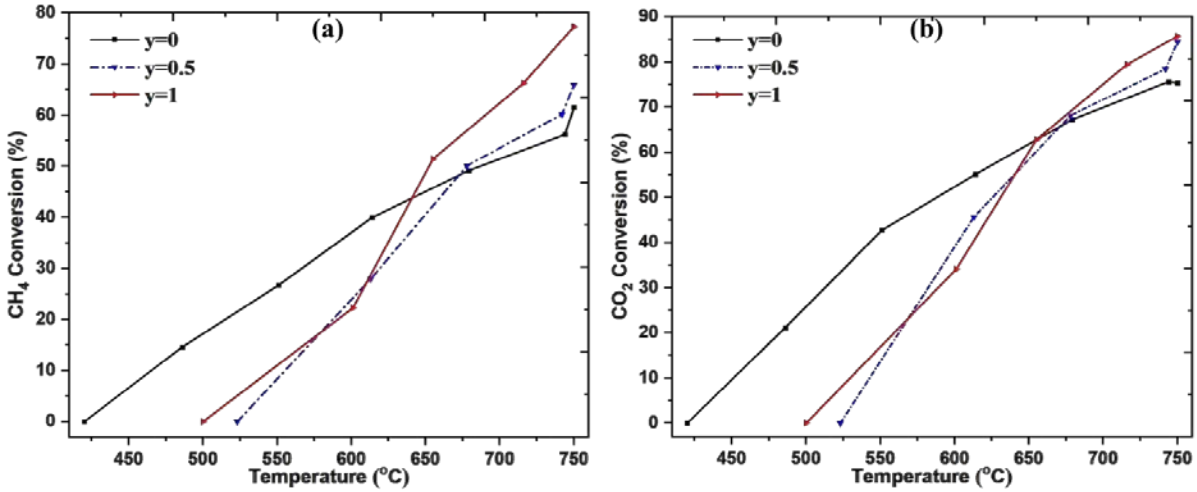

Fig. 1. $La_ySr_{1-y}Ni_{0.5}Mg_{0.5}O_3$ perovskites activity (a) CH_4 and (b) CO_2

Fig. 2a exhibits the TPR profiles of the perovskites, highlighting the influence of the La/Sr ratio on reduction behavior. A broad peak above 800 °C is attributed to lattice oxygen reduction, influenced by Sr and La substitution [14]. Increasing Sr content weakens the low- and mid-temperature peaks, indicating reduced Ni reducibility due to enhanced oxygen vacancy formation and stronger lattice oxygen binding [15, 16]. In contrast, higher La content stabilizes Ni in higher oxidation states, promoting easier reduction at lower temperatures [17].

The XRD patterns of $La_ySr_{1-y}Ni_{0.5}Mg_{0.5}O_3$ perovskites (Fig. 2b) reveal insights into phase composition, crystallinity, and structural evolution. $SrNiO_3$ is the dominant crystalline phase, with characteristic peaks in all samples except for y = 1. Additional peaks indicate secondary phases influenced by La incorporation and Mg substitution. Sharp diffraction peaks at 29°, 32°, 38°, 44°, 43°, and 63°confirm high crystallinity, matching the perovskite-type $SrNiO_3$ (PDF#28-1242) [18]. La^{3+} substitution alters the structure, with SrO peaks appearing in lower y samples and increasing with Sr^{2+} content, indicating phase segregation. At higher y values, La^{3+} stabilizes the perovskite structure. NiO (ICSD 24018) is also present, with cubic phase reflections confirming crystallinity [19]. The $Sr_9Ni_7O_{21}$ phase forms due to incomplete Sr^{2+} and Ni^{2+} incorporation, typically appearing at 19°, 57°, and 68° [20]. Its presence affects active site distribution and catalytic stability [21], influenced by synthesis conditions. Strontium segregation occurs via moisture absorption, leading to $Sr(OH)_2{\cdot}8H_2O$ formation, which reacts with CO_2 to produce $SrCO_3$. Peaks at 26.1°, 46.8°, and 50° correspond to $SrCO_3$ (JCPDS card no. 01-0556) [22], with a 2θ = 26° peak overlapping with carbon species [23]. In Sr-rich samples, increased $SrCO_3$ intensity suggests CO_2 interaction with SrO [24].

Fig. 3 presents FESEM images of some selected perovskite before and after the DRM reaction. Fresh $SrNiO_3$ has a rod-like structure, which sinters post-DRM, likely due to Sr-based perovskites' lower thermal stability [25]. Mg incorporation (Fig. 4a) disrupts this structure, forming a porous, granular morphology. Post-DRM (Fig. 3c), filamentous carbon appears, suggesting Mg improves stability but does not prevent carbon accumulation.La substitution (Fig. 3b) creates a porous-clustered morphology, enhancing stability and reducing carbon deposits post-DRM (Fig. 3d) due to improved oxygen mobility [26]. These findings highlight the need for an optimal La/Sr ratio to balance stability and carbon resistance during DRM.

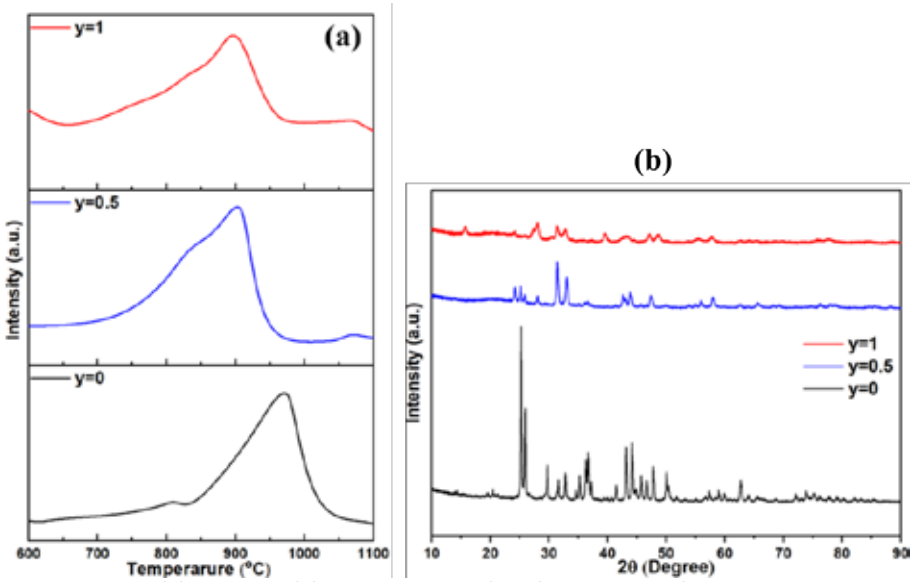

Fig. 2. (a) TPR and (b) XRD patterns of $La_ySr_{1-y}Ni_{0.5}Mg_{0.5}O_3$ perovskites

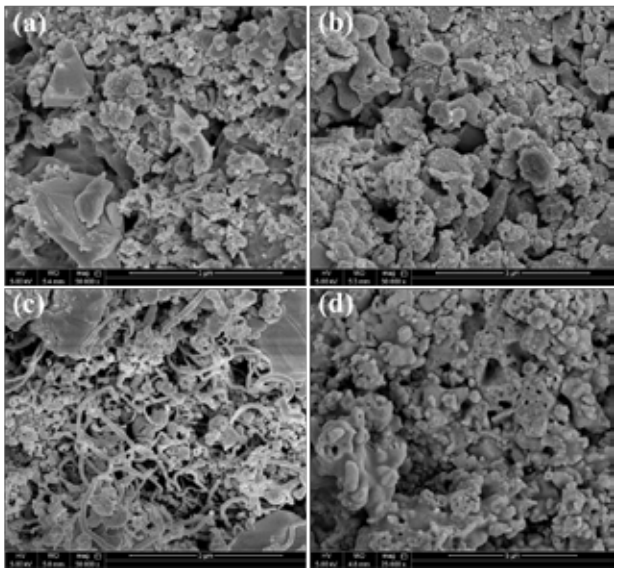

Fig. 3. FESEM images of (a,e) $SrNi_{0.5}Mg_{0.5}O_3$, and (b,f) $La_{0.5}Sr_{0.5}Ni_{0.5}Mg_{0.5}O_3$; (a,b) before and (e,f) after DRM reaction

CHN analysis aligns with FESEM results, showing increased carbon content post-DRM for $SrNi_{0.5}Mg_{0.5}O_3$ from 1.17 to 4.05, indicating higher carbon deposition. In contrast, $La_{0.5}Sr_{0.5}Ni_{0.5}Mg_{0.5}O_3$ exhibits reduced carbon content (1.71% vs. 1.93% fresh), suggesting enhanced carbon removal via oxygen mobility [27]. Carbon in fresh samples likely stems from precursor residues, with La-containing catalysts showing slightly higher values due to carbonate species formation during synthesis [28].

4. CONCLUSIONS

Sr incorporation improved catalytic activity at high temperatures, with the $La_{0.8}Sr_{0.2}Ni_{0.5}Mg_{0.5}O_3$ catalyst achieving the highest CO_2 and CH_4 conversion rates of 88% and 75%, respectively, at 750 °C. In contrast, Sr-only catalysts exhibited much lower activity, with 27% CO_2 and 20% CH_4 conversion at 500 °C. Sr substitution hindered the reducibility of Ni species by promoting oxygen vacancy formation, which stabilized the lattice and delayed reduction. XPS analysis confirmed that $La_{0.8}Sr_{0.2}Ni_{0.5}Mg_{0.5}O_3$ had the highest Ni^0 content post-DRM, correlating with its superior catalytic performance. While $SrCO_3$ formation in Sr-rich catalysts reduced catalytic activity by altering the active phase, the presence of Mg stabilized the active phase, promoting CO_2 adsorption and improving performance. Mg also modified the catalyst morphology, increasing surface area and active sites but potentially encouraging methane cracking and carbon deposition at high temperatures. Overall, $La_{0.5}Sr_{0.5}Ni_{0.5}Mg_{0.5}O_3$ exhibited the best balance of oxygen mobility and active surface oxygen, making it the most efficient catalyst.

ABSTRACT
To mitigate the intermittency and unpredictability of renewable energy sources (RES) energy storage systems are becoming increasingly essential. This paper analyzes a hybrid energy storage system H_2-CAES, based on the integration of two storage subsystems: a hydrogen production-storage-use one and a diabatic compressed air energy storage (CAES) plant fed by hydrogen. The proposed hybrid system aims to meet the energy demand of a medium-sized municipality, maximizing the self consumption of the energy produced by a PV plant. The H_2-CAES system utilizes RES excess energy production to store energy through both compressed air and hydrogen and then releases it during periods of low production to minimize reliance on the electrical grid. The results confirm the great potential of the H_2-CAES system and the validity of integrating these storage technologies. The hybrid system exhibits good performance, high flexibility, no pollutant emissions, and allows successfully balancing RES seasonal storage. However, some issues with hydrogen storage and use are present, and energy losses are significant.

Keywords: Hydrogen, Compressed Air Energy Storage, Renewables, Hybrid Systems

1. INTRODUCTION
The increasing share of electricity production from RES has led to a significant reduction of pollutant emissions, but has introduced considerable technical challenges. The intermittency and unpredictability of RES make the development of adequate energy storage systems a priority [1]. These systems, by providing ancillary services and applications, stabilize the electrical grid and enable a further growth of renewable energy production. There are various storage technologies, divided into categories, depending on the physical principle of exploitation: mechanical (pumped hydro, compressed air energy storage (CAES), flywheels), electrochemical (batteries), electrical (supercapacitors), thermal and hydrogen [1].
In this paper a hybrid storage system based on the integration between a CAES plant and hydrogen technologies is proposed. CAES plant is a mechanical storage technology that used excess energy to compress air and store it in a natural or artificial reservoir [2]. During peak demand periods, the compressed air is expanded in a gas turbine to generate electricity. CAES plants can be classified into two categories: Diabatic CAES (equipped with a combustion chamber to heat compressed air) and Adiabatic CAES (equipped with a thermal energy storage system to accumulate the compression heat). CAES plant offer large storage capacities, flexibility, reliability, and low maintenance costs. However, overall efficiency is relatively low, and its spread is limited by the need for suitable air storage unit. Two large diabatic CAES plant were in operation since last century: the Huntorf one (Germany) and the McIntosh one (Alabama, US). Hydrogen is an energy carrier that can be used as an alternative to fossil fuels, since it shows a great calorific value and does not produce polluting emissions. Hydrogen has large applications, ranging from the transport sector to energy production, though some issues remain [3]. Though hydrogen is currently produced mainly from fossil fuels, via methane steam reforming, coal gasification, partial oxidation, or biomass pyrolysis, “Green Hydrogen” can be produced through water electrolysis exploiting renewable energy sources.
Hybrid systems integrating CAES and hydrogen have recently been evaluated. Most analyses focus on the use of hybrid H_2-CAES systems to balance the intermittency and instability of RES [4-6]. However, also the integration of these hybrid systems with thermoelectric generation and power-to-X [7-8], has also been discussed. The main function of such hybrid systems is time shifting/peak shaving or the seasonal storage of large amounts of energy. The hybridization of the two systems makes feasible and advantageous to consider a medium to small-sized CAES plant [4]. The presence of a hydrogen-based storage system would still allow for substantial storage capacities, and the hydrogen produced could be used both for electricity generation via a fuel cell and to power the combustion chamber of the CAES.

2. RES PRODUCTION AND USER DEMAND
The proposed hybrid system was studied supposing to feed a medium town of about 40000 inhabitants, with an industrial area. The total annual energy consumptions of the user are slightly lower than 270 GWh and are partially satisfied by a large photovoltaic (PV) plant. The PV plant was sized imposing an annual production equal to the user requirements. A simulation model was developed through the commercial software SAM to evaluate the PV production curve using meteorological data obtained from the NREL database.
Fig. 1 shows both the typical load profile of the user for a week (continuous line) and a weekend day (dashed line), and the typical hourly power PV production for a summer (continuous line) and winter day (dashed line). Fig. 2 shows the monthly PV energy production, user energy demand, and PV energy production directly sent to the user. .

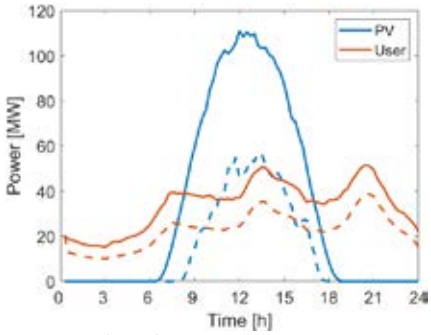

Fig 1. User load profile of a week day and a weekend day and hourly PV production for a summer and winter day

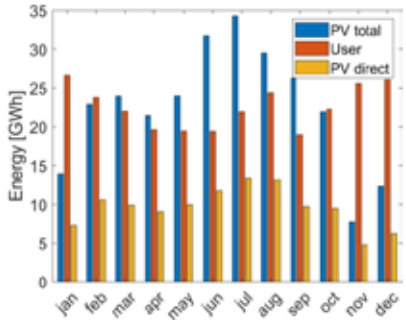

Fig 2. Monthly PV production, user demand and PV directly sent to the user

From Fig. 1 emerges as the user demand is higher during the weekday showing a peak of about 50 MW in both the afternoon and the evening. The PV production exceeds the user demand around noon, especially in summer. Fig. 2 shows that the monthly PV production is higher on summer and ranges between 7.6 and 34.3 GWh. The user demand is slightly higher in winter ranging between 19.0 and 26.6 GWh. Without any storage system, the PV plant can meet just 42.7% of the yearly user demand (115.4 of 270.0 GWh), with the grid demands being particularly high during the winter months. This situation calls for the introduction of an adequate storage system.

3. SYSTEM CONFIGURATION

The proposed energy storage system is a H_2-CAES hybrid system composed of two subsystems: a) a diabatic CAES subsystem fed by hydrogen, b) a hydrogen production, storage and use subsystem. The main objective of the storage system is to increase the share of the user energy demand directly or indirectly satisfied by the PV plant. The storage system accumulates the excess production from the PV and releases it during periods of low production to minimize the contribution of the electrical grid. The hydrogen is produced on-site by using a proton exchange membrane (PEM) electrolyzer. The H_2 subsystem also handles hydrogen storage and is equipped with a PEM Fuel Cell (PEMFC) capable of generating additional electricity. The general layout of the hybrid system H_2-CAES is shown in Fig. 3.

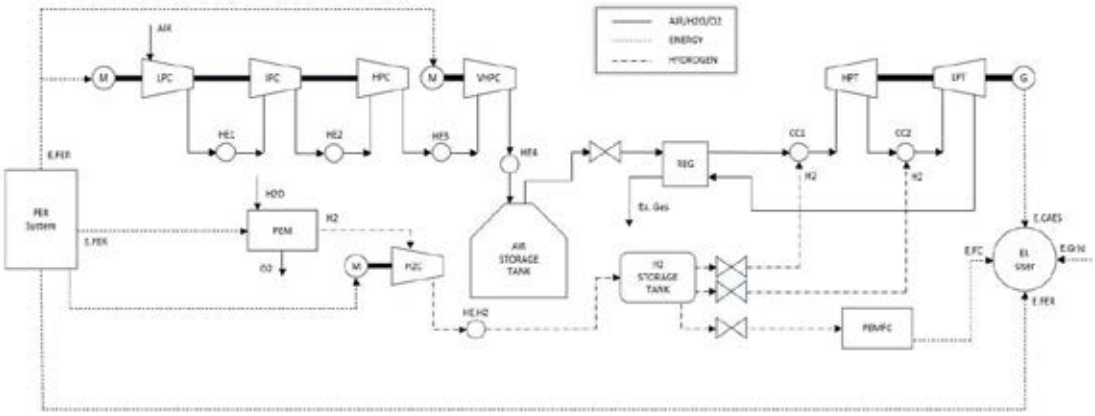

Fig. 3. Functional scheme of the H2-CAES energy storage system

3.1. The CAES subsystem

In the charge phase the CAES is fed by ambient air that is pressurized by four compressors in series: a low- (LPC), a intermediate- (IPC, a high- (HPC), and a very high- pressure (VHPC) ones. The compressed air is stored in a dedicated reservoir at a pressure ranging from 70 to 100 bar, depending on the reservoir charge level, and at a constant temperature of 35°C. The first three compressors operate at a constant pressure ratio β with an isoentropic efficiency of 0.86, while the VHPC regulates the pressure inside the reservoir by varying its rotational speed. During the discharge phase the compressed air is processed by the turbines producing electrical energy. The turbine section consists of two axial turbines on the same shaft, operating at a constant β: a high-pressure (HPT) and a low-pressure (LPT) one. The isentropic efficiency of both turbines was set equal to 0.9, while the mechanical efficiency of the plant was assumed equal to 0.97. To assure a constant operating pressure to the turbines, the air exiting the storage tank is throttled by a valve, ensuring an operating pressure of 70 bar, corresponding to the minimum pressure of the reservoir. Firstly, the airflow is preheated in a regenerative heat exchanger (REG), exploiting the residual heat from the LPT exhausts, and

then reaches 1200 °C in a combustion chamber (CC1), that is fed by hydrogen. Then the hot gas expands in the HPT and is sent to the CC2 combustion chamber, where is reheated to 1200 °C. Finally, the hot gas expands in the LPT.

3.2. The H_2 subsystem

The H_2 subsystem consists of three subsections for the production, storage, and direct use of hydrogen. The hydrogen is produced through the PEM at a pressure of 35 bar and a temperature of 25°C. The hydrogen, compressed up to 250 bar and cooled, is stored in a dedicated tank (H_2 Storage Tank) for feeding the hybrid system, while the oxygen is supposed to be released. Assuming a PEM efficiency of 0.60, the hydrogen energy density of 33.3 kWh/kg allows to produce 18.2 kg of hydrogen for each MWh absorbed. Despite the high storage pressure inside the tank, the compressor shows a quite low energy consumption, about 2% of the PEM requirements. A volume of the H_2 Storage Tank of 4920 m³ was set, imposing a maximum storage capacity of 100 tons of hydrogen. PEM fuel cells operate at relatively low temperatures, around 60-80 °C, allowing a faster start-up than other high-temperature fuel cell technologies. PEM also offers numerous advantages, including high power density, low pollutant emissions and quiet operation. A PEMFC efficiency of 0.55 was assumed in this study. Given the energy density of hydrogen, a hydrogen consumption of 0.054 kg/kWh was estimated. The role of the PEMFC in the hybrid system is to support the CAES discharge phase. The fuel cell operates to covered user energy deficits too low to be satisfied by the CAES or in case the deficit is sufficiently high to require the operation of both the subsystems. As a consequence, the size of the PEMFC is closely related to the minimum power deliverable by the CAES.

3.3. Cases studied

Three cases characterized by a different size of the main components have been analyzed. In particular, a parametric analysis of the size of the PEM electrolyzer was carried out. Table 1 summarizes the three selected cases:

Table 1. Cases analyzed

		Case 1	Case 2	Case 3
$P_{CAES,ch}$	MW	11.5-12.3	19.2-20.6	20.7-28.6
$P_{CAES,dis}$	MW	15.0	25.0	35.0
P_{PEMFC}	MW	7.5	12.5	17.5
P_{PEM}	MW	30.0-90.0	30.0-90.0	30.0-90.0

Each set was designed starting from the distribution of the residual energy expressed as the difference between the PV production and the user demand. Several sizes of the CAES subsystem were analyzed ranging from a minimum discharge power of 15 MW to a maximum of 35 MW. Since the PEMFC covers the user demand values lower than the activation threshold of the CAES turbines, (set to 50% of the nominal power) a PEMFC power equal to 50% of the CAES discharge power was selected. The variation of the size of the CAES during discharge also affects the size of the compressor unit. The PEM was finally be evaluated over a wide range of power in all cases.

4. RESULTS AND DISCUSSION

4.1. Performance Indices

To evaluate the performance of the H_2-CAES hybrid system, several performance indexes has been defined.
The Self Consumption (SC) index assesses the amount of energy produced by the PV plant E_{PV} consumed by hybrid system $E_{C,CAES} + E_{PEM}$ or directly by the user $E_{PV,dir}$ without being sent into the electrical grid. The closer this index is to 1, the more effective the storage system is in utilizing the PV energy.

$$SC = \frac{E_{C,CAES}+E_{PEM}+E_{PV,dir}}{E_{PV}} \quad (1)$$

The Self Support (SS) index evaluates the degree of satisfaction of the load demand. This index relates the energy provided directly by the PV plant $E_{PV,dir}$ and the by hybrid system components $E_{T,CAES} + E_{PEMFC}$ to the energy required by the user E_{User}.

$$SS = \frac{E_{T,CAES}+E_{PEMFC}+E_{PV,dir}}{E_{User}} \quad (2)$$

4.2. Cases studied

The operation of the H_2-CAES hybrid system strictly depends on the hourly behavior of the PV production and user request. The operation hours of the CAES charge phase range between 600 and 1600 per year. The value increases with the PEM size thanks to a greater hydrogen availability and decreases with the CAES size. Higher values of the operating hours (2500-3000) can be noticed for the PEM, with a reduction strictly related to its size. In the discharge phase both the CAES and the PEMFC increase operation hours with PEM size due to a greater availability of hydrogen and decreases with the hybrid system size do to the activation thresholds. The CAES discharge phase shows value of the operating hours ranging between 1200 and 3100, whereas the PEMFC shows lower values (550-2650 h).
Fig. 4 and Fig. 5 show the yearly energy consumption during the charge phase and the yearly energy production during the discharge phase in function of the electrolyzer size for the three different cases considered. Fig. 6 shows both the

self-consumption and the self support index as a function of the PEM size for the three cases.

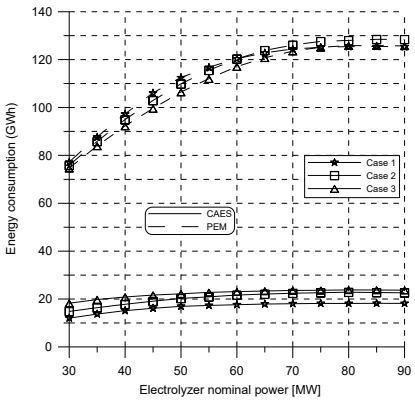

Fig. 4. Energy consumption in the charge phase as a function of PEM size

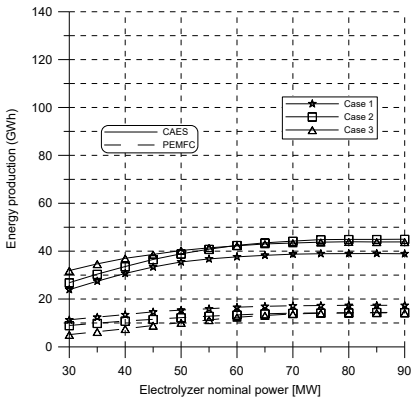

Fig. 5. Energy production in the discharge phase as a function of PEM size

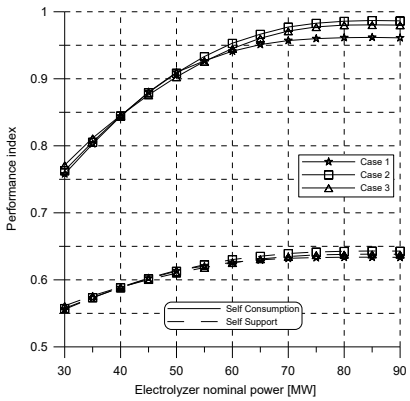

Fig. 6. Self consumption and self support indexes as a function of PEM size

Both energy consumption and energy production increase with the PEM size, due to the greater production and availability of hydrogen. For the CAES a greater size leads to a higher energy production and consumption despite a lower operating hours, but difference between case 2 and case 3 are negligible, especially at the highest PEM sizes. Small-size PEMFC assures a greater contribution to energy production thanks to a higher operation period. Globally, the H_2-CAES hybrid system contributes to satisfy the user requirements from a minimum value of about 35 MW (P_{PEM} = 30 MW) to a maximum value slightly lower than 60 MW (P_{PEM} = 90 MW).

SC index notably increases as the PEM size increases. A larger electrolyzer enhances the absorption of PV excess energy producing more hydrogen. The increase of the SC index peaks with a 80 MW PEM. Negligible differences are noticed among the three cases except for the highest PEM sizes, with case 2 showing best performance. Lowest H_2-CAES sizes do not allow to accurately exploit PV excess energy, whereas largest H_2-CAES size causes many energy deficit lower than the activation threshold. The SS index increases with the PEM size from 0.55 to 0.64. No significantly difference are noticed with the cases, with a slightly higher SS index for the case 2.

5. CONCLUSIONS

The ever increasing use of renewable energy sources makes the role of energy storage systems deeply significant as these systems overcome the limits of intermittency and non-programmability of RES. A hybrid storage system based on the integration of a CAES plant and a hydrogen production, storage, and use system was proposed. The system was integrated with a medium size city allowing to increase the self support index up to 10-20 percentage points, depending on the H_2-CAES size, starting from a reference value of 42.7%. Three different cases were analyzes in function of the H_2-CAES size with the intermediate one showing best performance. To better analyze the hybrid system behavior and identify the system size that guarantee the best performance an economic analysis is planned to be performed.

ABSTRACT
This study focuses on the development of Ni-based methanation catalysts with enhanced CO conversion, CH_4 selectivity, and stability under unconventional feed conditions (H_2/CO<3) by integrating methanation and WGS reactions. Various Ni-based catalysts were synthesized and evaluated to understand the effects of promoters, supports, and metal-support interactions (MSI) on catalytic performance. Among the synthesized catalysts, 5%Ce-10%Ni/γ-Al_2O_3 demonstrated the highest performance, maintaining CO conversion above 95% while minimizing carbon deposition. XPS, XRD, SEM, HR-STEM, and Raman analyses revealed that Ce incorporation enhanced Ni reducibility, improved MSI, and suppressed carbon accumulation at higher temperatures (673 K), while lower temperatures (523 K) promoted deactivation due to carbon buildup. Despite a slight reduction in metal dispersion, Ce addition improved catalyst stability and activity over prolonged operation. SBA-15-supported catalysts exhibited balanced MSI and favorable dispersion, while 5%Ce-10%Ni/ZrO_2, despite its high TOF values, exhibited lower CO conversion and CH_4 selectivity, along with stability issues at 400 °C, underscoring the complex role of MSI in catalytic performance. Stability tests confirmed that 5%Ce-10%Ni/γ-Al_2O_3 was the most durable formulation, maintaining high activity over time. Overall, these findings highlight the importance of promoter selection and MSI tuning in designing efficient and stable Ni-based methanation catalysts.

Keywords: CO Methanation, Synthetic Natural Gas, Ce-Promoted Catalysts, Ni-Based Catalysts

1. INTRODUCTION

The growing global demand for cleaner energy sources has driven extensive research into alternative fuels, like synthetic natural gas (SNG). While natural gas (primarily CH_4) is considered an efficient and environmentally friendly fossil fuel due to its high energy density and clean combustion profile, its uneven distribution and finite reserves have led to an increasing focus on SNG production via syngas methanation [1].

The conventional SNG production process begins with the gasification of coal or biomass to produce syngas (a mixture of H_2, CO, CO_2, CH_4 and minor hydrocarbons), followed by purification and methanation reactions [2]. Both methanation reactions (CO and CO_2 methanation) are exothermic, making temperature control crucial to avoid catalyst deactivation via sintering or carbon deposition. The TREMP (Topsoe Recycle Energy-efficient Methanation Process) developed by Haldor Topsøe is a widely used industrial system that employs adiabatic reactors operating at progressively lower temperatures to optimize CH_4 yield [3]. However, conventional processes typically require an H_2/CO ratio of ~3, limiting their flexibility with feedstocks exhibiting lower ratios [4].

Recent research efforts have focused on developing novel methanation catalysts capable of operating efficiently under lower H_2/CO ratios and varied reaction conditions. Ni-based catalysts are widely studied for their high activity, cost-effectiveness, and stability. However, issues like carbon accumulation, sintering, and limited high-temperature stability require further improvements [1,4]. To overcome these challenges, recent studies have investigated Ni catalysts modified with promoters such as Ce, La, Mg, and Mn, which aim to improve metal-support interactions, catalyst dispersion, and overall performance [5-10]. Si et al. [5] showed that La_2O_3 improves the catalytic activity of Ni/ZrO_2 by limiting NiO particle growth and enhancing Ni dispersion. Similarly, Hu et al. [6] demonstrated that MgO, when used as a promoter in Ni/Al_2O_3 catalysts, significantly enhances stability. Researchers have also investigated Mn-promoted Ni/Al_2O_3 catalysts, which exhibit superior CO methanation performance compared to unmodified catalysts [7,8]. Furthermore, CeO_2 has been recognized as an effective support and promoter in methanation reactions, particularly in improving CO conversion and CH_4 selectivity [9,10].

This study focuses on design and development of Ni-based methanation catalysts that integrate water-gas shift (WGS) and methanation reactions to achieve efficient methane production even under unconventional feed conditions (H_2/CO<3). By exploring a range of promoters and supports, this work seeks to maximize catalytic activity, selectivity, and stability.

2. MATERIALS AND METHODS

2.1 Catalyst Preparation

Sixteen Ni-based catalysts were synthesized via the incipient wetness impregnation, incorporating Ce, La, Mg, and Mn

as promoters and using γ-Al_2O_3, SBA-15, and ZrO_2 supports. Commercial γ-Al_2O_3 and ZrO_2 were used directly, while SBA-15 was synthesized hydrothermally with Pluronic P-123 and TEOS. For bimetallic catalysts, sequential impregnation was applied, with the promoter introduced prior to Ni loading. The samples were dried overnight at 383 K and subsequently calcined at various temperatures.

2.2 Performance Evaluation

Catalyst performance was evaluated in a fixed-bed quartz microreactor for 6 hours under H_2/CO ratios of 3, 2, and 1 at temperatures ranging from 473 to 673 K. The feed gas composition and flow rates were controlled using mass flow controllers (Brooks 5850E), and products were analyzed by gas chromatography (Agilent 6850, TCD, HayeSep D column). Stability tests were conducted for 72 hours to assess long-term performance.

2.3 Catalyst Characterization

Catalysts were analyzed using H_2-chemisorption (Micromeritics 3Flex) for dispersion and TOF, SEM (Philips XL 30 ESEM-FEG) and HR-STEM (Hitachi HF5000 200kV) for morphology and dispersion, XRD (Bruker D8 Discover) for crystalline phases, XPS (Phi 5000 VersaProbe III) for oxidation states and electronic interactions, and Raman spectroscopy (Renishaw inVia, 514 nm laser) for coke formation on spent catalysts.

3. RESULTS AND DISCUSSION

3.1 Effect of H_2/CO Ratio

CO methanation reactions were conducted at 673 K for H_2/CO ratios of 3, 2, and 1. At H_2/CO = 3, most catalysts exhibited high CO conversion values (93–99%), except for 5%Ce-10%Ni/ZrO_2 (86.5%). The highest CH_4 selectivity (76.2%) was observed for 5%Ce-10%Ni/SBA-15-550. Reducing the H_2/CO ratio to 2 led to a drop in CO conversion for 1%Mg-10%Ni/γ-Al_2O_3 (92.9%→84.2%) and 15%Ni/SBA-15-750 (92.7%→72.6%), while other catalysts showed little change in performance. At H_2/CO = 1, both CO conversion and CH_4 selectivity declined for all catalysts. The highest CO conversion (84.6%) was observed for 1.7%Mn-15%Ni/γ-A_2O_3 (Fig.1).

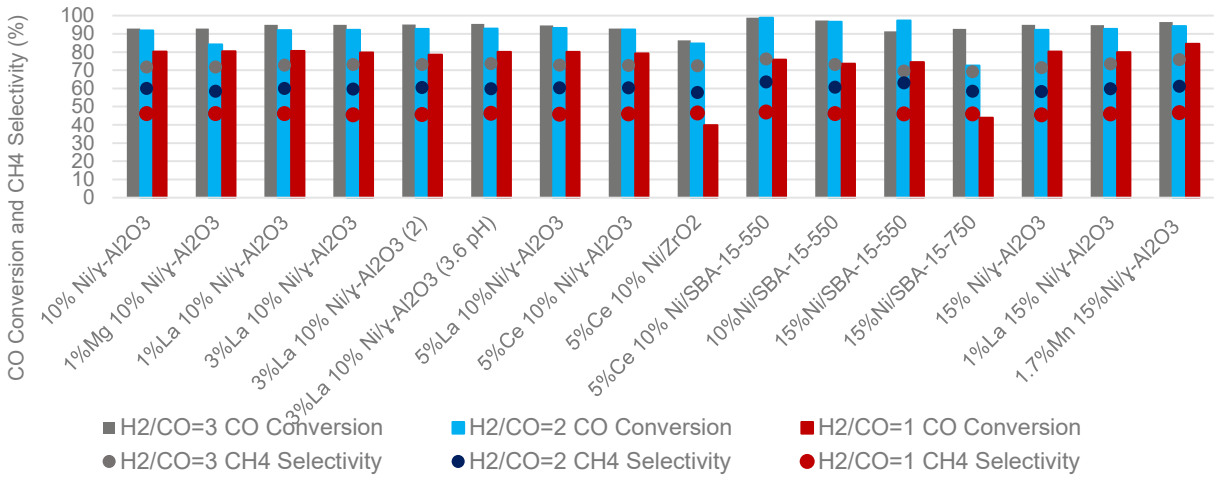

Fig. 1. Average CO conversion and CH_4 Selectivity values for 6-hour experiments conducted at 673 K for three H_2/CO ratios of 3, 2, and 1.

To evaluate the effect of temperature, six-hour performance tests were conducted with an H_2/CO ratio of 3 at five different temperatures: 473 K, 523 K, 573 K, 623 K, and 673 K. As discussed, the CO conversion value was highest for 5%Ce-10%Ni/SBA-15-550 at 673 K. When the temperature was reduced to 623 K, the CO conversion of 15% Ni/SBA-15-750 catalyst decreased significantly, from 92.7% to 45.2%. In contrast, the performance of other catalysts remained stable, maintaining high CO conversion values. At 573 K, both 10% Ni/SBA-15 and 15%Ni/SBA-15-750 exhibited the lowest performance, with CO conversion dropping to 36.6% and 7%, respectively. Other catalysts showed moderate declines in activity but maintained acceptable performance levels. At 523 K, only six catalysts demonstrated measurable CO conversion (Fig. 2). These catalysts were further tested at 523 K with an H_2/CO ratio of 2, confirming the superior performance of the 5%Ce-10%Ni/γ-Al_2O_3 catalyst (Fig. 3).

The stability of 5%Ce-10%Ni/γ-Al_2O_3 was evaluated under different conditions. At 673 K and H_2/CO ratios of 3 and 2, the catalyst maintained stable CO conversion (94% and 90%, respectively) over 72 hours. However, at 523 K with an H_2/CO ratio of 2, CO conversion declined from 95% to 79%, indicating activity loss due to carbon deposition.

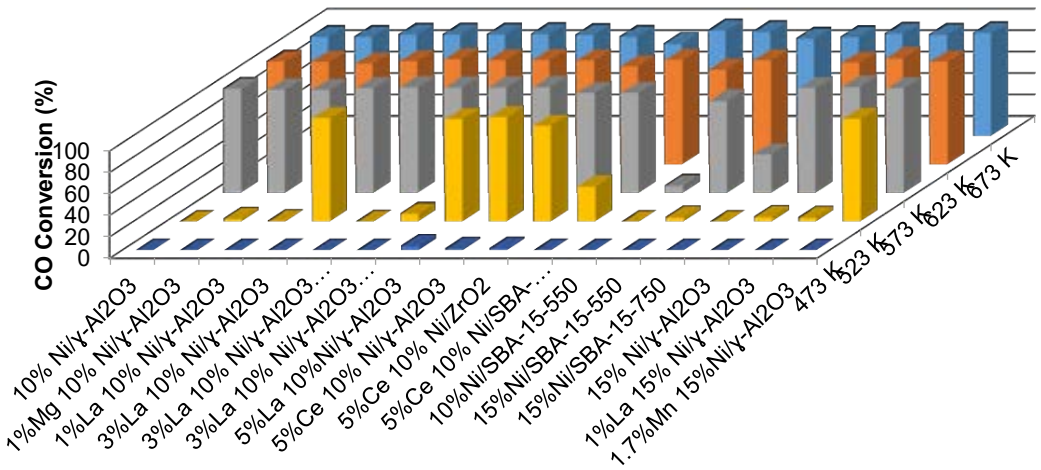

Fig. 2. Average CO conversion values for 6-hour performance tests conducted with H2/CO=3 at 5 different temperatures for all catalysts.

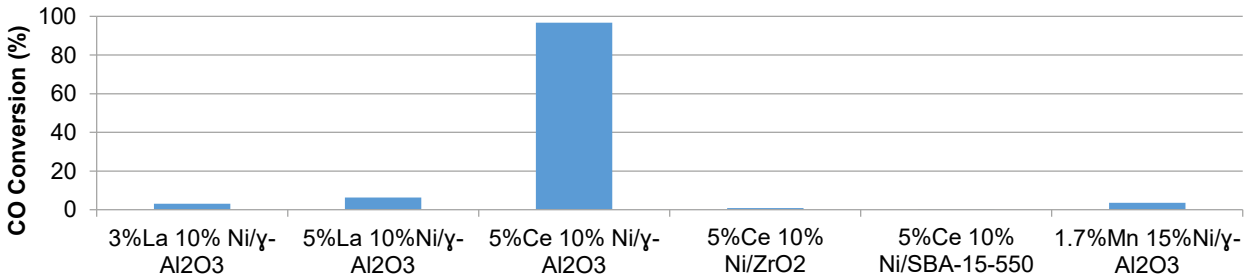

Fig. 3. Average CO conversion and CH4 yield values for 6-hour performance tests conducted with H2/CO=2 at 523 K.

3.3 Characterization

Given its superior CO methanation performance, 5%Ce-10%Ni/γ-Al_2O_3 was selected for detailed characterization alongside 5%Ce-10%Ni/SBA-15-550, 5%Ce-10%Ni/ZrO_2, and 10%Ni/γ-Al_2O_3.

SEM imaging revealed that Ni dispersion and particle distribution were significantly influenced by the support type. On γ-Al_2O_3, Ni clusters were unevenly dispersed, with cracks that could facilitate reactant diffusion. Contrary to expectations, Ce incorporation decreased Ni dispersion, as confirmed by H_2 chemisorption results, with Ce-Ni interactions evidenced in high-magnification SEM images. The ZrO_2-supported catalyst displayed an irregular Ni-Ce distribution, suggesting strong MSI that may stabilize Ni but restrict its accessibility. In contrast, SBA-15 exhibited a well-defined mesoporous structure, which favored higher Ni dispersion and enhanced reactant diffusion. STEM-EDS mapping confirmed these findings, showing that Ce preferentially decorated Ni particles, particularly in Ce-promoted γ-Al_2O_3 catalysts, thereby influencing stability and electronic interactions.

XRD confirmed metallic Ni as the active phase. $NiAl_2O_4$ formation was observed in γ-Al_2O_3-supported samples, potentially impacting reducibility. XPS indicated that Ce altered Ni's electronic environment, enhancing its reducibility and oxygen mobility, thus stabilizing Ni during methanation. Raman spectroscopy revealed carbon deposition as a major deactivation factor, with higher coke formation at 523 K compared to 673 K, further supporting the role of temperature in mitigating deactivation.

3.4 TOF Analysis

TOF values were calculated at multiple temperatures to assess the intrinsic activity of Ni sites in Ce-promoted catalysts. While 10%Ni/ γ-Al_2O_3 exhibited the highest dispersion (6.99%), 5%Ce-10%Ni/ZrO_2 had the lowest (3.33%), indicating that the support material significantly influenced metal distribution. The SBA-15-supported catalyst (6.23%) achieved a balance between dispersion and activity due to its mesoporous structure. Despite the reduction in Ni dispersion with Ce addition, Ce-containing catalysts exhibited higher TOF values, highlighting the role of MSI in enhancing reaction rates, which is consistent with SEM and HR-STEM findings (Fig. 4).

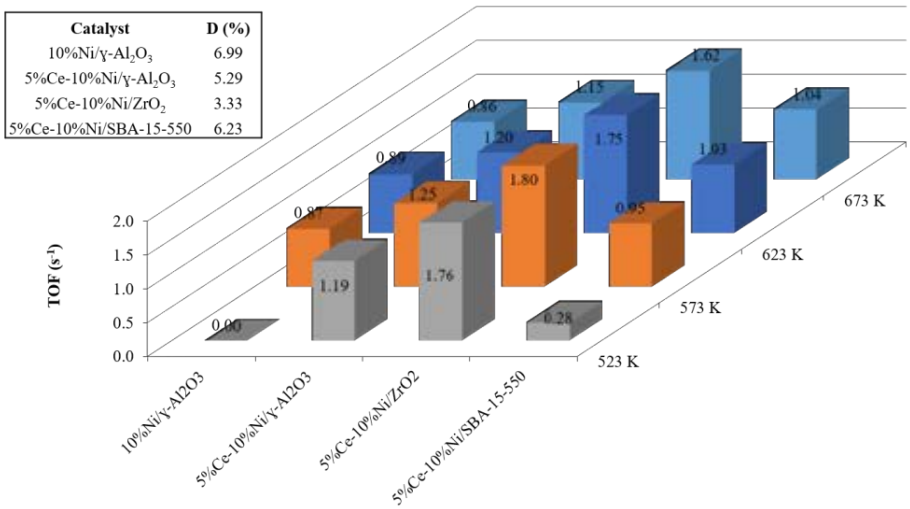

Fig. 4. TOF values for 6-hour performance tests conducted with H2/CO=3 at 4 different temperatures

4. CONCLUSIONS

This study focused on developing high-performance Ni-based methanation catalysts, enabling efficient methane production under unconventional feed gas compositions. Various catalysts were synthesized with different metal compositions, precursor types, loadings, and preparation methods. Among them, 5%Ce-10%Ni/SBA-15-550 demonstrated the highest CO conversion at 673 K for H_2/CO ratio of 3, while 5%Ce-10%Ni/ZrO_2 exhibited the lowest conversion. Additionally, at 523 K and reduced H_2/CO ratio of 2, the 5%Ce-10%Ni/ γ-Al_2O_3 catalyst demonstrated superior catalystic performances, reinforcing its stability and effectiveness under challenging reaction conditions.

Comprehensive characterization of 5%Ce-10%Ni/γ-Al_2O_3, 5%Ce-10%Ni/SBA-15-550, 5%Ce-10%Ni/ZrO_2, and 10%Ni/γ-Al_2O_3 provided key insights into structure-activity relationships. XPS analysis identified metallic Ni, NiO, and Ni^{2+} species, with Ce incorporation shifting binding energies, reducing NiO peaks, and enhancing Ni reducibility. XRD analysis revealed the presence of $NiAl_2O_4$ formation in Ce-promoted catalysts, while Raman spectroscopy confirmed that lower temperatures (523 K) accelerated carbon deposition, impacting catalyst durability. SEM and TEM demonstrated distinct Ce-Ni clustering, highlighting the role of metal-support interactions in Ni dispersion and catalytic efficiency. TOF analysis demonstrated that Ce promotion enhanced catalytic activity despite a slight decrease in Ni dispersion, underscoring the significance of MSI. While 5%Ce-10%Ni/ZrO_2 exhibited the highest TOF values, its overall CO conversion remained the lowest, indicating that strong MSI can improve reaction rates but may also limit overall catalytic efficiency depending on the support material.

ABSTRACT
The dry reforming of methane (DRM) is a promising route for syngas production and greenhouse gas mitigation. However, its high-temperature requirement (700–1000°C) presents challenges for industrial implementation. This study investigates low-temperature DRM (≤500°C) over a Ru-La/ZrO_2 catalyst using *operando* DRIFTS-MS to elucidate reaction mechanisms and identify active intermediates. The results reveal a strong correlation between linearly adsorbed CO on Ru^0 sites (1980 cm^{-1}) and catalytic activity, suggesting CO-Ru^0 as a key active intermediate. Temperature-dependent experiments (440–480°C) indicate a mechanistic shift around 450°C, attributed to enhanced reverse water-gas shift (RWGS) reaction contributions. Deconvolution of DRIFTS spectra confirms that CO-Ru^0 peak intensities align with methane conversion trends, highlighting their role in the reaction pathway. These findings provide crucial insights into “surface group-activity” relationships and pave the way for optimizing catalyst design for efficient low-temperature DRM.

Keywords: *Operando* DRIFTS-MS, low temperature DRM, reaction mechanism, active intermediate, surface group-activity relations

1. INTRODUCTION

The dry reforming of methane (DRM) has been widely investigated due to its substantial environmental and industrial benefits. From an environmental perspective, DRM facilitates the concurrent conversion of two potent and thermodynamically stable greenhouse gases, CO_2 and CH_4, thereby mitigating their atmospheric impact. Industrially, this process is highly advantageous as it generates synthesis gas, a crucial feedstock for the production of valuable hydrocarbons via Fischer-Tropsch synthesis.

Due to its highly endothermic nature, the DRM reaction conventionally necessitates high temperatures to achieve optimal performance. Most studies on DRM catalyst development have focused on reaction temperatures ranging from 700°C to 1000°C [1]. However, the requirement for such elevated temperatures presents a considerable challenge, particularly in industrial applications, where maintaining these conditions demands substantial energy input, making the process both energy-intensive and economically less viable. This highlights the critical need to lower the operating temperature to facilitate the broader industrial adoption of DRM [2].

In response to the challenges associated with the high-temperature DRM process, there has been a growing focus on low-temperature DRM studies in recent years. These studies, typically conducted at reaction temperatures below 500°C (or 550°C), are characterized by significantly lower conversion levels, primarily due to thermodynamic and kinetic limitations. To address these issues, researchers are actively investigating methods to enhance catalyst activity at reduced temperatures while ensuring stable performance. The incorporation of noble metals, either as promoters or active metals, has become a common strategy for improving catalyst efficiency in these low-temperature DRM reactions [1,3,4].

Understanding the complex mechanisms occurring on low-temperature DRM catalysts is essential, as such insights could provide valuable information for addressing the challenges associated with slow reaction kinetics at lower temperatures. *Operando* spectroscopic techniques are particularly well-suited for probing reaction characteristics, such as surface species and active intermediates, while concurrently monitoring the catalyst's performance. This approach enables the establishment of “surface group-activity” relationships, a critical step in elucidating the catalyst properties that govern its overall performance.

Operando DRIFTS studies provide critical insights into the reaction pathway, the nature of active sites, the role of catalyst components, and reactant activation mechanisms, among other factors. While such information has been extensively explored for conventional DRM temperatures, the mechanisms at low temperatures remain largely unexplored. This study aims to systematically investigate the catalytic mechanisms and identify active intermediate species in the low-temperature DRM reaction over a bimetallic Ru-La/ZrO_2 catalyst, utilizing advanced *operando* and transient techniques with an integrated DRIFTS-MS system.

2. EXPERIMENTAL

2.1. Catalyst Preparation

The preparation procedure begins with crushing and sieving monoclinic ZrO_2 pellets (Alfa Aesar, >95%) into particles

with a size range of 125-250 µm (60-120 mesh). The support is then calcined at 800 °C for 4 hours in air using a muffle furnace. The La loading step precedes the Ru impregnation process for catalyst preparation. Initially, 5 g of the calcined support is placed in a Büchner flask, and the pores of the support are evacuated under a vacuum of 0.82 atm for 30 minutes prior to impregnation. Meanwhile, a precursor solution is prepared by dissolving 1 g of $La(NO_3)_3 \cdot 6H_2O$ (Alfa Aesar, 99.9%) in 3 ml of deionized water. Once the support pores have been adequately evacuated, the precursor solution is introduced at a rate of 0.75 ml/min. After impregnation, the sample is placed in an ultrasonic bath for 90 minutes to ensure uniform distribution. The concentration of the precursor solution is calculated to achieve a 6 wt% La loading on the freshly reduced sample. The resulting sample is then dried overnight at 110 °C, followed by calcination at 500 °C for 4 hours in air using a muffle furnace. The same procedure is repeated for Ru loading, where 2.56 ml of $Ru(NO)(NO_3)_3$ (Alfa Aesar, 15.5 g of Ru per liter of solution) precursor solution is added to 4.27 g of the La/ZrO_2 sample. This volume corresponds to a targeted Ru loading of 0.92 wt%. Finally, the bimetallic catalyst is reduced in-situ before each experiment at 500 °C with 25% H_2 in an inert atmosphere.

2.2. Deconvolution DRIFTS Spectra

The deconvolution procedure was performed using OriginPro 2023b software. Initially, baseline correction was applied to the spectrum. To address the low signal-to-noise ratio, smoothing was conducted using a 17-point Savitzky-Golay algorithm with a second-order polynomial. Peak identification was achieved through local maxima and second derivative analyses. The selected peaks for fitting were modeled as Voigt profiles. The fitting procedure was carried out using the Levenberg-Marquardt algorithm.

3. RESULTS AND DISCUSSION

3.1. Elucidating the Mechanism

Among the various *operando* DRIFTS-MS experiments conducted, linearly adsorbed CO on metallic Ru sites (observed around 1980 cm^{-1} in the DRIFTS spectra) consistently correlated with catalytic performance, similar to what has been reported in previous studies [5]. The experimental results presented thus far are sufficient to establish a qualitative correlation between MS data and the intensity of this specific peak. To investigate this relationship further, the CO-Ru^0 peak was analyzed during the initial stages of its progression under feed flow. A total of 80 spectra were recorded at a rate of 3.6 seconds per spectrum, with MS focusing exclusively on CO analysis, reducing its cycle time to 1.1 seconds. Fig. 1 displays the 80 spectra obtained using this approach.

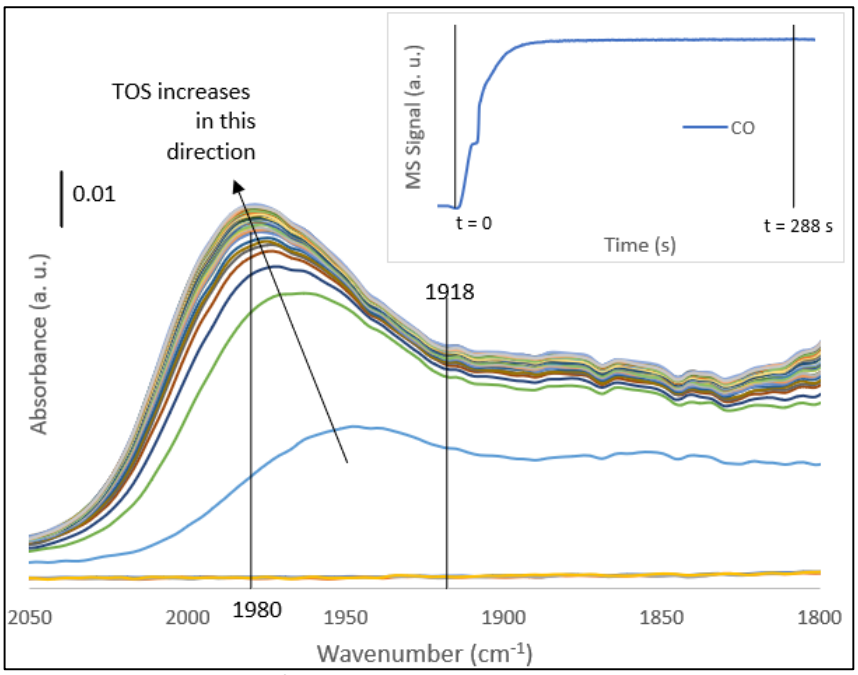

Fig. 1. Evolution of CO-Ru^0 peak within 288 seconds after initial contact with feed.

The region between 2100 cm^{-1} and 1800 cm^{-1} shown in Fig. 1 was found to be adequately represented by two distinct peaks: one at approximately 1980 cm^{-1} and a shoulder at 1918 cm^{-1}, as depicted in Fig. 1. The peak at 1980 cm^{-1} is the primary focus, as it correlates with the activity trends observed from MS measurements. The shoulder at 1918 cm^{-1} must also be considered in the analysis, as its influence needs to be differentiated from the evolution of the linearly adsorbed

CO-Ru peak. Notably, Fig. 1 demonstrates how, as the time on stream (TOS) analysis progresses, the intensity of the linearly adsorbed CO-Ru peak increases, while shifting to higher wavenumbers. To isolate the effects of these two peaks, peak deconvolution was performed on the 16 spectra that span the transient phase. Fig. 2 shows the relationship between activity and the deconvoluted peak areas.

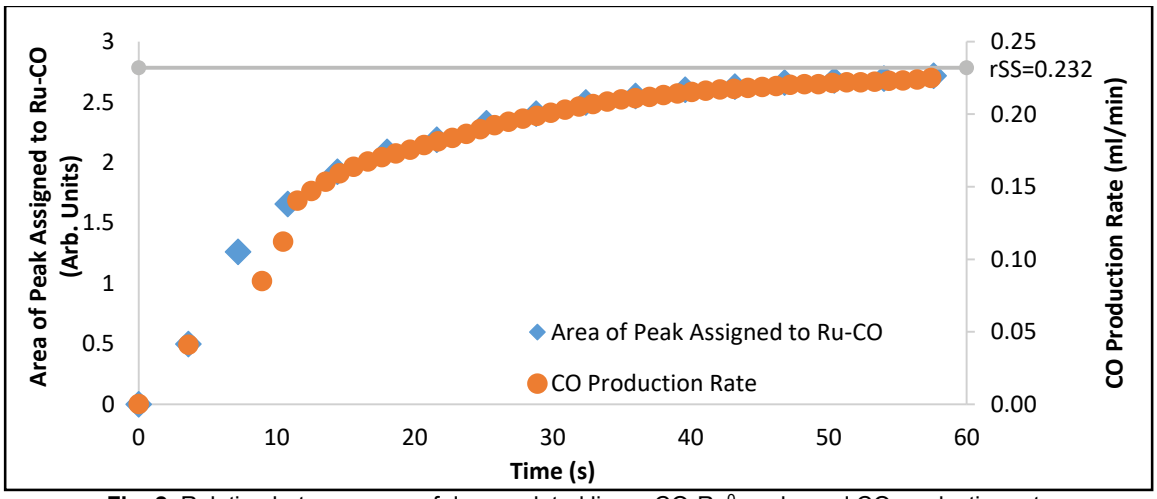

Fig. 2. Relation between area of deconvoluted linear CO-Ru^0 peaks and CO production rate

Fig. 2 confirms that the rapid *operando* measurements support the qualitative observations from earlier experiments, showing a strong correlation between the evolution of the linearly adsorbed CO-Ru peak and catalytic activity. The areas of the deconvoluted CO-Ru peaks exhibit an increase, though the rate of this increase slows over time on stream. This behavior is qualitatively reflected in Fig. 1, where the initial rapid rise in CO-Ru peak intensity for the first few spectra is followed by a more gradual and diminishing increase until the peak stabilizes at a steady-state value.
A similar methodology to that used in this study was applied to investigate Au active sites on Au/TiO_2 catalysts [6], where band fitting of carbonate, formate, and carbonyl region peaks facilitated the identification of the active intermediate. The authors argue that if a surface species is an active intermediate, its peak areas in the deconvoluted spectra over time should correlate with the observed catalytic activity. Based on this principle, the alignment between the deconvoluted areas of the linearly adsorbed CO-Ru^0 peaks and the CO production rate (as shown in Fig. 2) provides compelling evidence that CO-Ru^0 species act as active intermediates in the reaction.

3.2. Temperature Investigation

The mechanism was further investigated at temperatures ranging from 440°C to 480°C in 10°C intervals. Fig. 3 combines activity measurements (via MS) with the intensities of peaks attributed to linearly adsorbed CO on metallic Ru sites at different temperatures, illustrating the mechanism shift that occurs around 450°C.

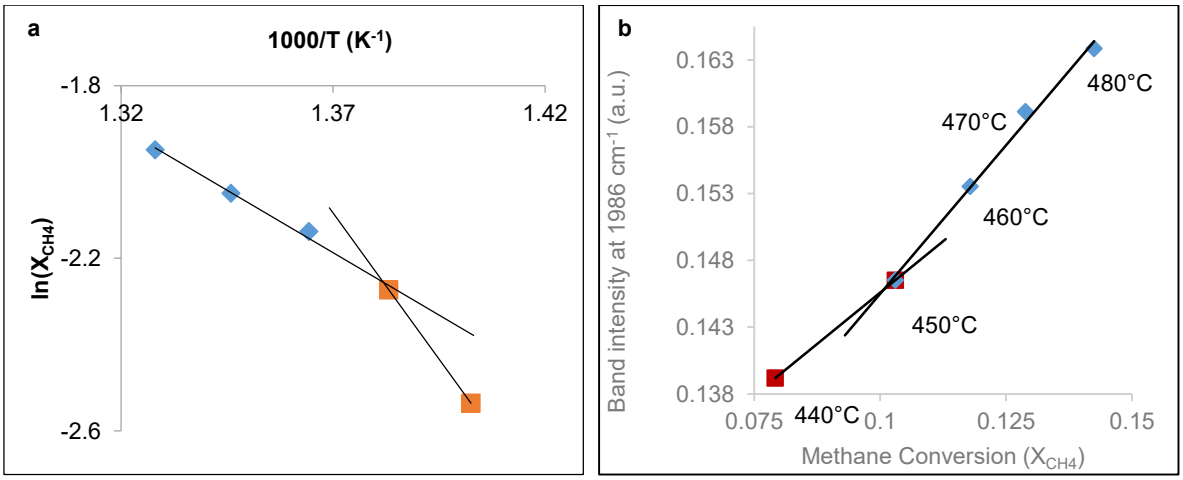

Fig. 3. Natural logarithm of observed methane conversion values versus reciprocal of temperature (in K) values (a) and CO-Ru^0 related peak intensities at observed methane conversion values (b) at 440-480°C.

Fig. 3a resembles an Arrhenius plot and demonstrates that MS readings at five different temperatures indicate a shift in activation energy near 450°C. *Operando* experimental conditions confirmed this observation through DRIFTS spectra band intensities. The strong correlation between the CO-Ru^0 peak and DRM progression (established in this study) is utilized in Fig. 3b. The results show that the behavior of CO-Ru^0 intensities in relation to methane conversion exhibits distinct patterns below and above 450°C. The change in slope around 450°C can be attributed to the increased effectiveness of the RWGS reaction at lower temperatures. CO produced via RWGS, rather than methane conversion, would result in lower band intensity for a given conversion, which is exactly what is observed in Fig. 3b at lower temperatures.

4. CONCLUSIONS

Operando FTIR-DRIFTS-MS experiments have revealed a correlation between the linearly adsorbed CO-Ru peak and measured catalytic activity. The areas of the deconvoluted peaks from FTIR-DRIFTS spectra and the CO production rate recorded by MS were integrated and analyzed comparatively to elucidate surface group-activity relationships for the bimetallic Ru-La/ZrO_2 catalyst. The strong alignment between the deconvoluted peak areas and CO production rates provides compelling evidence designating linearly adsorbed CO-Ru^0 species as the active intermediate for the low-temperature DRM reaction under the studied conditions. Temperature-variant *operando* DRIFTS-MS experiments conducted between 440°C and 480°C revealed methane conversion trends that indicated a mechanism shift around 450°C. This observation was further supported by concurrent DRIFTS spectra, which showed a change in the evolution of CO-Ru^0 related peak intensities, with a notable alteration in slope near 450°C.

ABSTRACT
Operando FTIR-DRIFTS-MS was employed to elucidate the CO_2 methanation mechanism over Ni-La/γ-Al_2O_3 catalysts under conditions mimicking methane-to-hydrogen fuel processor (FP) systems, specifically focusing on low H_2/CO_2 feed ratios, such as 1:1. The study provided insights into reaction pathways and active intermediates, revealing that CO_2 methanation primarily proceeds via H-assisted CO_2 dissociation, with weakly bridged CO species identified as critical intermediates for CH_4 formation. The study quantitatively and qualitatively assessed the dynamics of surface intermediates, emphasizing the crucial role of weakly bridged CO in CH_4 production, while formate species were found to act as spectators. These results offer significant insights into the catalytic behavior of Ni-La/γ-Al_2O_3 under non-stoichiometric conditions, enhancing our understanding of the underlying mechanisms in CO_2 methanation. This work further contributes to the development of more efficient catalysts for CO_2 utilization in FP-PEMFC systems, advancing strategies for carbon capture and utilization to mitigate CO_2 emissions and support sustainable energy solutions.
Keywords: CO_2 Utilization, CO_2 Methanation at Low H_2/CO_2 Ratio, Operando DRIFTS, Active Intermediate

1. INTRODUCTION

CO_2 methanation, the catalytic conversion of CO_2 into methane, represents a promising strategy for mitigating CO_2 emissions, particularly in fuel processor (FP)-PEMFC systems. However, the characteristic low H_2/CO_2 feed ratio in these systems presents a significant challenge for achieving efficient methanation. The catalytic performance of Ni-La/γ-Al_2O_3 catalysts was rigorously assessed through both experimental investigations and computational modeling approaches tailored to these specific conditions [1]. Operando DRIFTS, a powerful technique for probing reaction mechanisms, was utilized in this study to elucidate the CO2 methanation mechanism under non-stoichiometric H_2/CO_2 feed ratios. The literature identifies two primary reaction pathways for Ni-based catalysts on Al_2O_3 supports: the H-assisted CO formation route and the direct dissociation of CO_2 into surface-bound CO, both of which subsequently undergo hydrogenation [2,3]. Furthermore, alternative mechanisms, such as the formate- and CO-routes, have been proposed to account for surface reaction dynamics under varying conditions [4,5]. In this study, operando DRIFTS, combined with FTIR and MS, was applied to investigate the CO_2 methanation mechanism over Ni-La/γ-Al_2O_3 catalysts under low H_2/CO_2 feed ratios, mimicking conditions found in FP-PEMFC systems.

2. EXPERIMENTAL

2.1. Catalyst Preparation

The high surface area γ-Al_2O_3 pellets (commercial Alfa Aesar) were used as the support material in this study. These pellets were crushed and sieved to a particle size of 0.250-0.354 mm (45-60 mesh), and the sieved γ-Al_2O_3 was directly tested as a support in preliminary experiments. To prepare the support for catalyst synthesis, the sieved γ-Al_2O_3 was calcined at 600 °C for 3 hours. For catalyst preparation, Ni was impregnated onto the support via the incipient wetness impregnation method. A $Ni(NO_3)_2{\cdot}6H_2O$ precursor was dissolved in deionized (DI) water to achieve the desired 15 wt.% Ni loading. Following impregnation, the sample was dried at 110 °C for 12 hours and subsequently calcined at 600 °C for 4 hours to obtain the Ni/γ-Al_2O_3 catalyst. In the case of promoted catalysts, La was introduced by impregnation with $La(NO_3)_3{\cdot}6H_2O$ prior to Ni addition. The wet sample was dried at 110 °C for 12 hours and calcined at 600 °C for 4 hours to obtain the La/Ni/γ-Al_2O_3 catalyst.

2.2. FTIR-DRIFTS-MS System and Operando DRIFTS Experiments

The FTIR-DRIFTS-MS system integrates feed preparation, FTIR-DRIFTS, and gas analysis components. The desired gas mixture is introduced into a Pike Technologies DRIFTS cell with a ZnSe window, and the temperature is controlled by a PIKE Technologies temperature controller. Absorbance spectra are recorded using a Bruker Vertex 70V FTIR instrument, coupled with a Mercury-Cadmium-Telluride (MCT) detector. Outlet gas analysis is conducted using a Hiden Analytical HPR-20 R&D mass spectrometer, allowing real-time tracking of gas concentration changes alongside FTIR measurements. A 4-way valve ensures flexible feed stream transitions for dynamic experimental conditions.
DRIFTS experiments were conducted on γ-Al_2O_3, La/γ-Al_2O_3, Ni/γ-Al_2O_3, and Ni-La/γ-Al_2O_3 samples in the FTIR-DRIFTS-MS system to investigate the CO_2 methanation reaction mechanism under low H_2/CO_2 feed ratios. Samples were mixed with CaF_2 powder to enable accurate FTIR spectra measurements at 350 °C, overcoming the dark color of reduced Ni catalysts. The mixture was crushed to a homogeneous consistency and placed into the ceramic sample holder of the DRIFTS cell, which is equipped with a ZnSe window to facilitate IR beam penetration.

In-situ reduction was performed from room temperature to 600 °C under H_2 flow, followed by cooling to the experimental temperature in an inert He flow. Each experiment included a 30-minute He flush at the beginning and end. FTIR spectra were recorded in the 4000-800 cm^{-1} range with a resolution of 4 cm^{-1}, using a background spectrum from the initial He flush step. Two methods were employed: the standard method, with steady-state evaluations and 128 scans recorded at intervals (1, 3, 5, 10, 20, and 30 minutes), and the quick measurement method, recording spectra every 3.6 seconds for the first 5 minutes to capture transient behavior. The product stream in these experiments was monitored using MS analysis. DRIFTS experiments with standard measurements were conducted to investigate CO, CO_2, and H_2 adsorptions, as well as low H_2/CO_2 reactions, while quick measurements were employed to study CO_2 adsorption and reactions under both low and stoichiometric H_2/CO_2 feed ratios, including specific sequential and stepwise adsorption or reaction tests. All experiments were conducted with a total flow rate of 50 ml/min and each step lasting 30 minutes to reach steady-state conditions.

2.3. Peak Deconvolution for FTIR Spectra

The carbonyl region of the spectra obtained during the reaction experiment with an H_2/CO_2 feed ratio of 1:1 was qualitatively assessed to explore a potential correlation between weakly bridged CO species and CH_4 production. Peak deconvolution was performed in the 2110-1740 cm^{-1} range, focusing on linearly bonded CO, weakly bridged CO, and strongly bridged CO species. Using OriginPro 2023b software, non-linear fitting with a Voigt function model was applied to optimize the peak locations and calculate the weakly bridged CO peak area. The MS signal for CH_4 was converted to CH_4 production rates using calibration, and a potential relationship between the surface concentration of weakly bridged CO species and CH_4 production was analyzed.

3. RESULTS AND DISCUSSION

3.1. DRIFTS Evaluation for Adsorption and Reaction Experiments

The FTIR-DRIFTS-MS system was utilized for quick measurements alongside standard experiments, particularly to examine transient phenomena in the reaction over the Ni-La/Al_2O_3 catalyst, in addition to experiments on reactant adsorptions. DRIFT spectra recorded at 350°C for the first 36 seconds in Fig. 1a revealed key surface transformations. The initial spectrum (0th) corresponded to the final He flush, while the 1st spectrum remained unchanged due to system dead-volume effects. By the 2nd spectrum, surface modifications became evident, marked by the dominance of carbonyl species (linearly bonded, weakly bridged, and strongly bridged CO species adsorbed on Ni sites as peaks at 2023 cm^{-1}, 1915 cm^{-1}, and a shoulder at 1841 cm^{-1}, respectively) in the absence of gaseous CH_4 at 3016 cm^{-1}. Additionally, carbonate species were identified at 1504 cm^{-1}, 1391 cm^{-1}, and 1655 cm^{-1}, whereas characteristic peaks of bicarbonate and formate were initially undetected. This absence suggested a rapid transformation of bicarbonate into formate and subsequently into carbonyl species, though definitive mechanistic conclusions required further evidence. By the 3rd spectrum, formate species emerged at 1590 cm^{-1} and 1382 cm^{-1}, alongside bicarbonate at 1641 cm^{-1} and 1224 cm^{-1}, indicating their presence on the catalyst surface. Notably, the gaseous CH_4 product was detected at 3016 cm^{-1} and 1305 cm^{-1} from the 3rd spectrum onward, marking its formation in the reaction pathway. A comparative DRIFTS analysis of steady-state reaction experiments on Al_2O_3, La/Al_2O_3, Ni/Al_2O_3, and Ni-La/Al_2O_3 revealed distinct surface species behavior during CO_2 methanation in Fig 1b. Gaseous CO_2 peaks (3750–3590 cm^{-1}) were present in all samples, while OH species (3562 cm^{-1}, 3523 cm^{-1}) formed over all but Al_2O_3. The CH_4 peak (3016 cm^{-1}) appeared exclusively over Ni catalysts, confirming their methanation activity. Notably, La/Al_2O_3 exhibited the most intense formate peaks (2908 cm^{-1}, 3003 cm^{-1}), whereas Ni catalysts showed overlapping formate and CH_4 peaks. In the carbonyl region, only Ni-containing samples generated adsorbed CO (2023 cm^{-1}, 1915 cm^{-1}, 1841 cm^{-1}), supporting the role of Ni active sites in facilitating formate-to-carbonyl conversion. The absence of bicarbonate species on La/Al_2O_3, Ni/Al_2O_3, and Ni-La/Al_2O_3 suggested their rapid transformation into formates, while Al_2O_3 retained bicarbonate peaks (1411 cm^{-1}, 1225 cm^{-1}) due to lower catalytic activity. The higher OH consumption over Ni catalysts, indicated by a stronger negative OH peak at 970 cm^{-1}, further corroborated their role in formate production.

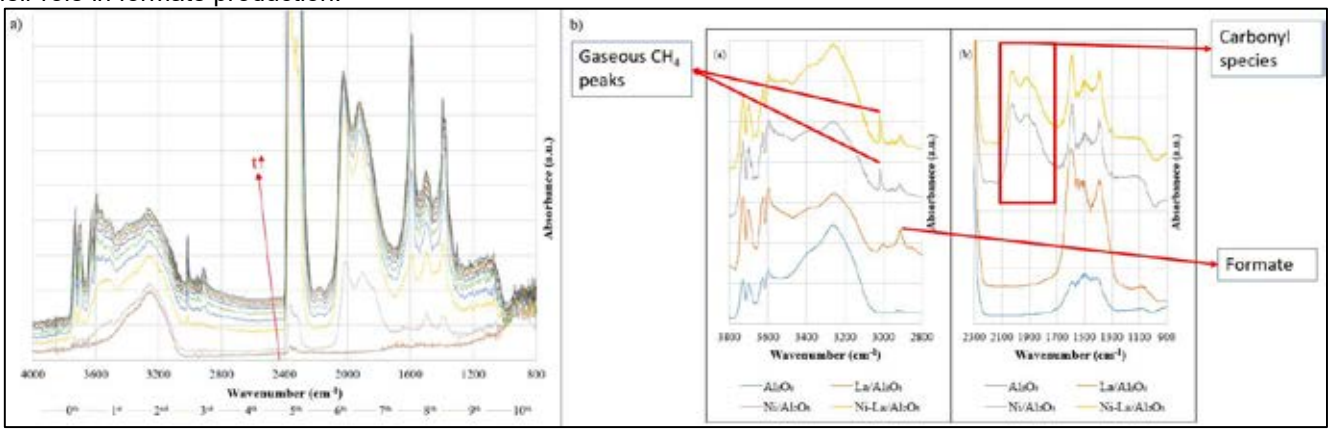

Fig. 1. DRIFT spectra of (a) reaction experiment with quick measurments (3.6 s each) and (b) catalyst and supports for comparison

3.2. Operando DRIFTS Evaluation for Consecutive Adsorption and Stepwise Removal of CO_2 and H_2

A consecutive adsorption experiment was performed over Ni-La/Al_2O_3 at 350°C using the FTIR-DRIFTS-MS system, following a sequence of He, CO_2, H_2, CO_2, and H_2 introductions with a 1:1 H_2/CO_2 feed ratio, concluding with a He flush. The first H_2 adsorption and the second CO_2 adsorption steps are illustrated in Fig. 2a and 2b, respectively. In Fig. 2a, the carbonyl region exhibited a rapid increase, reaching maximum intensity within just 7.2 seconds after which it gradually diminished. During this decline, the relative intensities of linearly bonded CO (2023 cm^{-1}) and weakly bridged CO (1920 cm^{-1}) showed different patterns in their growth and decay phases. While linearly bonded CO was the most intense during the progression phase, weakly bridged CO became dominant as the peaks diminished, suggesting its potential role in CH_4 formation in the reaction. Meanwhile, the main formate peak (1590 cm^{-1}) continued to accumulate as carbonyl species decreased, implying that formate species might act as spectators rather than direct intermediates in the reaction mechanism. In Fig. 2b, during consecutive CO_2 adsorption, the weakly bridged CO peak (initially at 1901 cm cm^{-1}, shifting to 1915 cm^{-1}) was the most intense among carbonyl species but exhibited a slower increase compared to its behavior during H_2 adsorption. Notably, it was the first to diminish, starting after 36 seconds, suggesting a direct involvement in H-related surface reactions. In contrast, the formate peak (1592 cm cm^{-1}) continued to accumulate as carbonyl species declined, reinforcing its role as a spectator spieces. Overall, the strongest quantitative correlation in methanation over Ni-La/Al_2O_3 was observed between CH_4 production and weakly bridged CO, rather than surface formate. This qualitative correlation was further substantiated by an experiment involving the stepwise elimination of reactants (not shown here).

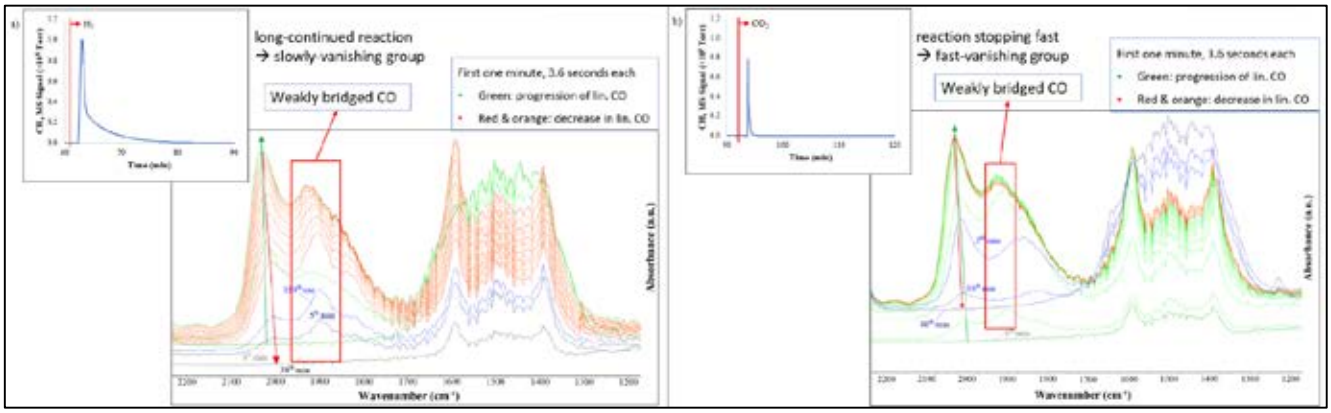

Fig. 2. DRIFT spectra of (a) the first H_2 adsorption and (b) the second CO_2 adsorption over Ni-La/Al_2O_3 at 350 °C

3.3. Quantitative Relationship between Surface Species and CH_4 Production

Building on experiments involving varying H_2/CO_2 feed ratios, consecutive reactant adsorption, and stepwise reactant removal, this section quantifies the relationship between weakly bridged CO species and CH_4 production. DRIFT spectra obtained during reaction with a 1:1 H_2/CO_2 ratio (Fig. 3a) were deconvoluted into three main peaks (Fig. 3b): linearly bonded CO (2023 cm^{-1}), weakly bridged CO (1915 cm^{-1}, shifting to 1905 cm^{-1}), and strongly bridged CO (1841 cm^{-1}). While potentially undetectable overlapping peaks may exist, the most visible peaks were analyzed to establish a quantitative correlation (Fig 3c). Simultaneous MS measurements showed that CH_4 production stabilized after approximately one minute, with the first steady-state spectrum recorded as the baseline for peak deconvolution. Ultimately, a strong correlation between weakly bridged CO and CH_4 production was identified, reinforcing its role as a key active intermediate in CO_2 methanation, while formate species were confirmed as spectators involved in secondary reaction steps.

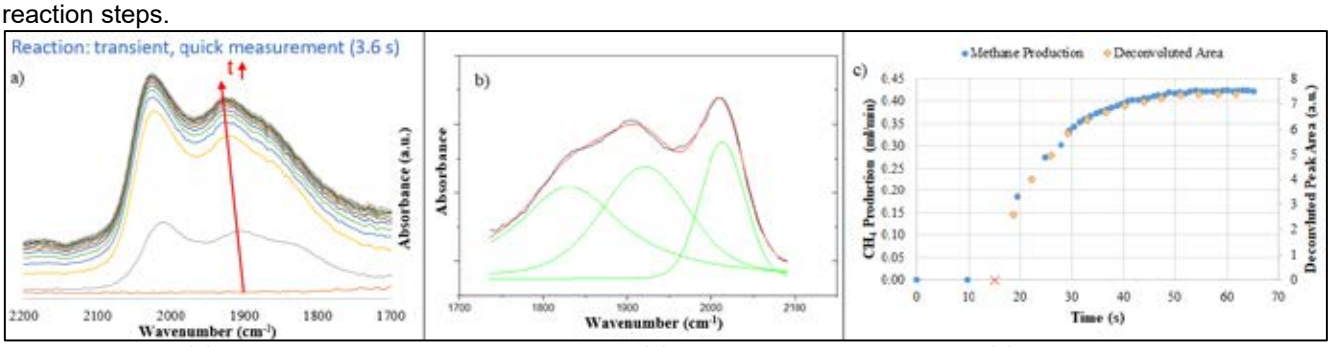

Fig. 3. (a) DRIFT spectra obtained during reaction, (b) illustrative deconvolution, and (c) quantitative correlation

4. CONCLUSIONS

In situ and operando FTIR-DRIFTS-MS reaction experiments at 350 °C with an H_2/CO_2 feed ratio of 1:1 revealed that formate and carbonyl species were stable intermediates during CO_2 methanation, leading to CH_4 production. The

transient behavior analysis, enabled by quick measurements providing spectra every 3.6 seconds, showed that carbonyl species formed before formate accumulation, indicating their role in the early stages of the reaction. Furthermore, weakly and strongly bridged CO species were identified as the most relevant to CH_4 production. The study proposed a qualitative relationship between weakly bridged CO and CH_4 production, suggesting that weakly bridged CO is the active intermediate, while formate species are spectators in the reaction. Additionally, a quantitative correlation between bridged CO species and CH_4 production was established, supporting the qualitative findings.

ABSTRACT

Methane decomposition is a key process for the production of high-purity hydrogen. Among various reactor configurations, an aerosol flow reactor utilizing concentrated solar energy is considered a highly suitable option for this process. In this study, computational fluid dynamics (CFD) methods were employed to investigate methane decomposition in an aerosol flow reactor, incorporating gas flow dynamics, chemical reaction mechanisms, heat transfer via radiation and convection, and discrete-phase interactions. Developing a generalized model that accurately describes the decomposition process and provides reliable predictive data is of critical importance. CFD modeling offers an effective approach for simulating such complex reactions, enabling faster and more precise predictions. To enhance the accuracy of the model, experimental and theoretical data from previous studies on methane decomposition in an aerosol quartz reactor were utilized. The improved CFD model accounts for methane decomposition rates and simulates the distribution of decomposition products, including hydrogen, carbon, and unreacted methane, under varying methane and carbon feed rates and temperature conditions.

Keywords: Methane decomposition, Flow Reaction, CFD Modelling

1. INTRODUCTION

Methane is a highly favorable gas for hydrogen production due to its high hydrogen density, the highest among all gases. Additionally, pure black carbon can be produced through methane decomposition methods. The methane decomposition process has been applied in industrial plants to produce both black carbon and hydrogen. Numerous studies have focused on understanding and improving the decomposition mechanism, developing stable catalysts, and enhancing reactor efficiency. The aim of this study is to analyze the reaction process, explore the aerosol reactor concept, and conduct an energy analysis. Moreover, the feasibility of solar energy conversion is closely related to the efficiency of thermochemical reactions. Various methods exist for hydrogen production, but methane decomposition is a direct process that does not involve additional reactants in its reaction mechanism. This makes it an important topic in chemical conversion, where heat and mass transfer play crucial roles. Key factors influencing heat transfer include radiation-convection mechanisms and chemical reaction kinetics. There are numerous solar-assisted methods for hydrogen production and solar energy storage as chemical energy, including steam reforming, carbon dioxide reforming, and methane cracking. Among these, the aerosol reactor is a promising candidate for methane decomposition due to its ability to directly absorb solar radiation via black carbon catalysts and gas-phase particles. The aerosol reactor, a quartz tubular reactor, allows direct absorption of solar energy by the fluid and particles, leading to a high heat transfer rate. During methane decomposition, hydrogen gas and solid carbon are produced [1,2]. As a result, the hydrogen obtained has high purity, making purification easier. Therefore, using a quartz reactor is a reasonable choice for methane decomposition to produce hydrogen. Both carbon feeding at the inlet and the carbon produced during the reaction catalyze methane decomposition. Several researchers have contributed significantly to this field. Snoeck conducted experimental and theoretical studies on the kinetic aspects of Ni-based catalysts [3]. Deutschmann investigated partial methane oxidation using finite element methods and developed computational fluid dynamics (CFD) models for both two-dimensional and three-dimensional reaction mechanisms [4]. Matowich conducted experimental research on methane decomposition in an aerosol reactor [5].

2. APPROACH AND METHODOLOGY

This study aims to provide a comprehensive understanding of the methane decomposition mechanism by examining key parameters such as chemical reactions, radiation heat transfer, and two-phase flow dynamics. Additionally, it investigates the effects of these parameters in a two-dimensional reactor model. Previous studies, such as Dahl's [1], have used one-dimensional energy balance equations to offer quick insights for engineers. While these models provide valuable approximations, reactor design engineers require a deeper understanding of how parameter distributions across the reactor cross-section influence system performance. However, ensuring mathematical consistency in simulation data remains a significant challenge. To address this, the finite element method is employed, as it allows for the simultaneous solution of multiple interacting parameters while maintaining numerical accuracy. Hydrogen production via solar-driven methane decomposition in an aerosol reactor is highly advantageous due to its efficient

production process, direct utilization of solar energy, and simplified purification requirements. Methane decomposition in an aerosol reactor involves heterogeneous chemical reactions, where complex interactions between gas-phase chemistry, discrete-phase flow, and radiation modeling play a critical role.

3. METHANE DECOMPOSITION

There are a lot of studies to explain reaction mechanism for the decomposition of hydrocarbons, especially natural gas, propane, ethylene and methane. Steinberg is one of the major proponent researchers about the thermal decomposition mechanism of CH_4 process for H_2 production [1]. Methane (CH_4) is dissociated to carbon (C) black and H_2 according to chemical mechanism below :

$$CH_4 \longrightarrow C + 2H_2 \qquad H_{298K} = 74.9 \text{ kJ/mol}$$

$$CH_4 \rightarrow C + 2H_2 \qquad \Delta H_{1000K} = 89{,}8 \text{ kJ/gmol}$$

Cantelo was the first scientist who studied theorical and experimental decomposition methane mechanism in 1927. He reported that the starting point of decomposition is 400 C and ending point is 1500 C. It is reported that methane completely is decomposed at 1500 C [10]. In another study, Holmen reported the activation energy as 370 kj/mol between 1770-2270 K [11]. Tessner determined that the activation energy of carbon nuclei formation during methane's thermal decomposition (316.8 kj/mol) is higher than activation energy of carbon crystallites growth [12]. Activation energies are reported 356- 402 kJ/mol at 2000-3000 ^oK temperature ranges for shock tubes reactors. Steinberg is reported that activation energy is 131 kJ/mol between 973- 1173 K and 28-56 atm [1]. There are a lot of studies carried out on the effects of different catalysts on the decomposition of methane. Recent studies were performed by Muradov and Wiemer co-workers. Muradov have studied carbon catalysis for methane decomposition He developed a model that describes the effect of different carbon catalysts and dimensional parameters on the methane decomposition at fluidized bed reactor according to experimental data [13,14]. Dahl and co-workers studied on a solar aerosol reactor and developed a mathematical model that describes methane decomposition [1]. Another study of them is investigating a aerosol reactor that can be used for product applications at pilot dimension [2]. In this paper, we developed a two dimensional numerical model that describes the methane decomposition process in the aerosol quartz reactor that is used by Matowich.

4. REACTOR MODEL

In this study, an aerosol reactor is used with dimension that is used by Matowich' experiments so that results could be checked via another studies results. This reactor is 0,914 m in length and has an inside diameter of 0,076 m as shown in Fig.2. Methane is fed into the top of reactor at five different amounts. Carbon particles is fed with methane so that carbon particles enhance reaction rates. The rates of CH_4 dissociation is determined by measuring the thermal conductivity of the effluent gas after filtering the carbon black particles from the sample[1,2].

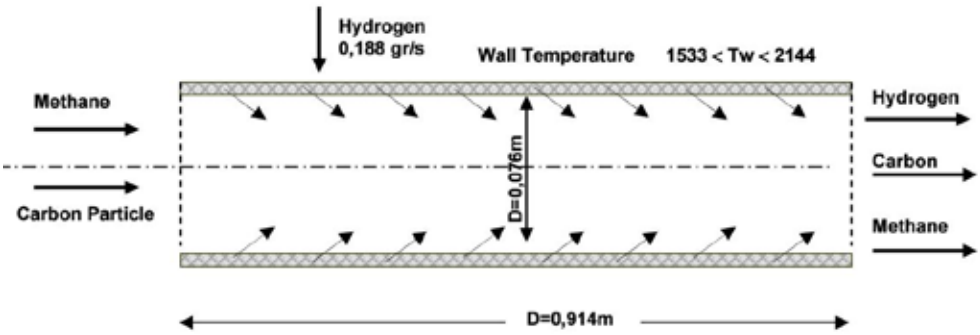

Fig. 1. Schematic representation of aerosol reactor

5. NUMERICAL MODEL

Numerical model is established CFD solutions to supply integrating mechanism elements and displaying conversion distribution in tube as two dimensional. Former studies were only based on experimental research and one-dimensional numerical solutions. We defined proper governing equations such as energy, mass and momentum conservations and species transport equations and also required boundary conditions such as radiation, diffusion and particulate movement BCs to establish numerical model of methane decomposition at the aerosol reactor. Methane decomposition mechanism includes chemical reaction, mass transfer, heat transfer, discrete phase effect,

thermophoresis effect and also lifting effect (Fig.2). On the other hand, defining of chemical conversion mechanism is very important and bringing of accompanying governing equation is one of the difficult subject. Flow in the tube is two phase flow that includes solid carbon particles and continuous methane gas flowing. Solid carbon particles enter to the tube inlet section as a mixture with methane. During the reaction of methane decomposition, carbon particles will be formed along the aerosol tube flow. Discrete phase flow is defined to model of the flow of carbon particles, methane and hydrogen gases during the conversion mechanism along the aerosol tube. Thermophoretic force and lifting effects were also added to our numerical model of aerosol reactor.

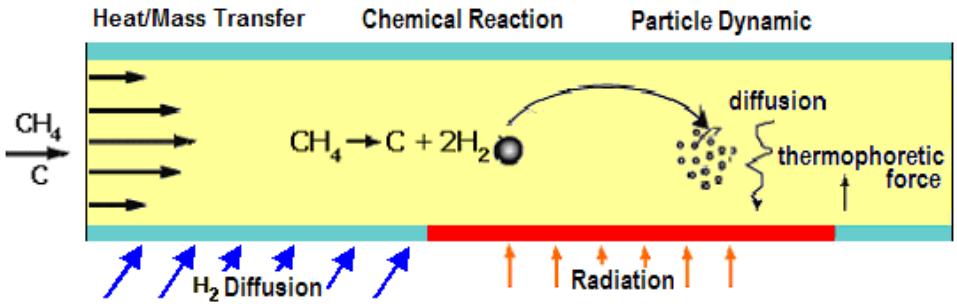

Fig. 2. Schematic representation of numerical model

6. RESULTS AND EVALUATION

Numerical model consists of mass flow, energy conversion, reaction kinetics, radiative heat transfer, discrete phase equations. Model meshing is obtained by using GAMBIT.2.1 for two-dimensional horizontal rectangle shaped reactor. This model is tried to improve the best and the most optimized solution. Using parameters for solving and simulating the reactor are indicated in table-1. These parameters are mostly closest Matovich's experiment and also Dahl and group's simulations. The numerical simulations are based on CFD codes in FLUENT 6.0.12. It solves the conservation equations that is momentum, species, energy, discrete phase and reaction by using a control volume. The methodology used for the 2-D simulations and some of the numerical issues have been explained in elsewhere. FLUENT solves the governing (momentum, species and enthalpy) equations using a control volume based finite difference method. Also the viscosity, specific heat, absorption rate, and the thermal conductivity of the mixture as well as the diffusion coefficient of species are solved simultaneously with governing equations in the mixture depending on the local composition and temperature.

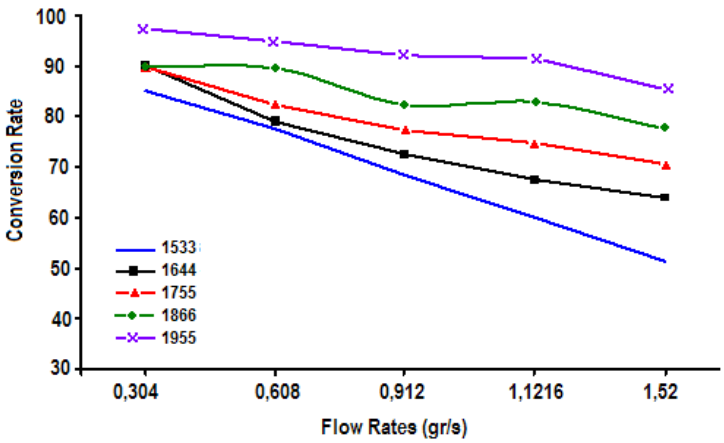

Fig. 3. Molar conversion rates for different mass flow rates and different wall temperatures

Changing of methane conversion rates through reactor related to wall temperatures and flow rates are shown in figure-4. Molar methane conversion rates are indicated for six different temperatures at five different flow rates in the figure. Methane decomposition begins at first length=3-20 cm from beginning of the reactor for all flow rates and 1533 K wall temperature. The latest starting flow rate of decomposition is 1.52 gr/s and the firstest starting flow rate is 0,304 gr/s. This condition can be explained that reaction's activation energy can not be sufficiently supplied for this wall temperatures. So, heat transfer rate is getting insufficient to complete reaction, when flow rates are increasing. Similarly, methane decomposition begins about 0-20 cm for 1644 K wall temperature. Decomposition curves resembles to 1533 K wall temperature's curves. For this reason, it can be said that all decomposition expanding characteristics are similar for these temperatures. Methane decomposition occurs at the beginning away of the reactor

for the other wall temperatures. Conversion curves inclination rises with increasing wall temperatures. As shown at Fig.4, decomposition inclination decrease with remaining flow rates.
Figures-5 indicates methane conversion rates depend on wall temperatures for three flow rates (0,304-0,912-1,52 gr/s) that are periodic difference. According to this figure, while wall temperatures are rising, conversion rate becomes considerably independent from flow rates. Methane decomposition is completing for all flow rates at 2144 K wall temperature. In conclusion, it is obvious that temperature is the most designated factor at methane decomposition mechanism for this reactor. Since carbon particles are a catalyst in the reaction, it is needed to understand the relationship between temperatures of carbon particle and gas phase. Figure-6 is a plot of comparative phase and particle temperatures. Particle temperature is bigger than phase temperature at the first 20 cm of length. After the first length of 20 cm, these temperatures approximate each other and approximately become equal values at the end of the reactor.

7. CONCLUSION

The investigated CFD model for methane decomposition mechanism includes flow-heat-chemical reaction, discrete phase flow and complex mathematical operations in detail. Different parameters' effects on flow reaction can be analysed in different aspects of engineering as well chemical, mechanical, reacting etc. CFD application by using different engineering disciplines is very useful for this type flow reacting problems. It is very useful to investigate new models and also to develop applicable reactor examining. Methane decomposition and kinetic values are another important direction that includes a lot of related intensive and extensive parameters. For example, one of these is activation energy that varies with characteristics of catalysts, particulate geometry, micro chemical structures etc. Therefore, there is not a constant value for kinetic features and chemical reaction kinetics definition is very difficult for this type heterogeneous reaction. As another conclusion from study this modelling enable characteristics of the parameters to understand and define by examining different direction application in aspect of the high way engineering. The fact is that the expanded analysis and solution also can be obtained.

ABSTRACT
Synthetic gas bench data is presented related to the performance of the catalytic NOx reduction using NH_3-SCR process on Cu/zeolite washcoated monolithic reactor for the aftertreatment systems of H_2 internal combustion engine under a wide variety of feed H_2O (1-20%) and O_2(1-14%) and including inlet H_2 (500 ppm) concentrations at a wide temperature window (150-490 ℃). Data showed significant NH_3 uptake (109 g/m^3 and 66 g/m^3) at varied H_2O concentrations (1-20%) and H_2O feed concentration dependent SCR performance at low (150-250℃) and high (400-490℃) temperature ranges and N_2O by-product formation, however obtaining >99.9% deNOx performance in the 250-400 ºC range irrespective of H_2O feed at a space velocity of 60000 h^{-1}. H_2 co-feed to the main SCR feed was found to affect the deNOx slightly at higher temperatures but not significantly at 150-400 ℃ range. According to the results of the study, the well-established NH_3-SCR technology for diesel engine aftertreatment deNOx could be a promising technology for the ATS of H_2-ICE, despite the intrinsic challenges.

Keywords: hydrogen internal combustion engine, aftertreatment system, selective catalytic reduction, NOx, Cu/SSZ-13

1. INTRODUCTION

Hydrogen internal combustion engines (H_2-ICEs) are attracting increasing attention as a promising way to meet stringent Euro 7 emission regulations while addressing global carbon neutrality goals. These engines produce near-zero CO_2 emissions and represent a sustainable alternative to traditional fossil-fuel-based internal combustion engines. However, the high NOx concentrations[1], elevated water vapor content (10–20%)[2], and probable slip of unburned H_2 in the exhaust gas of H_2-ICEs[3] pose significant challenges for the effective performance and durability of selective catalytic reduction (SCR) systems. Compared to diesel aftertreatment systems, which typically operate under a feed water concentration of ~5%, H_2-ICE exhaust contains significantly higher water vapor, potentially affecting catalyst performance. Although there have been studies analyzing the performance of SCR under varying H_2O concentrations[4, 5], most of the literature have focused on the diesel engine conditions, particularly low water and oxygen concentrations in the feed stream. This study explores the performance of a commercial Cu-zeolite SCR catalyst under conditions representative of H_2-ICE exhaust. In this work, effect of water on NH_3 storage, NH_3 Oxidation, NOx conversion efficiency and N_2O formation during Standard SCR (Feed $NO_2/(NO+NO_2)$=0) and effect of H_2 at the inlet of reactor to the Standard and Fast SCR (Feed $NO_2/(NO+NO_2)$=0.5) reactions were experimentally evaluated in a wide range of conditions .

2. MATERIALS AND METHODS

The catalyst in this work was Cu/SSZ-13 washcoated onto a cordierite monolith (600 CPSI - 3 mils). The experiments were conducted on a synthetic gas bench. Cylindrical cores with 2.6 cm length and 1.8 cm diameter were wrapped with ceramic fibre paper and loaded in a quartz tube and positioned in the isothermal zone of an electric tubular furnace (Thermo Scientific Lindberg Blue M). The reaction temperature was recorded using J-type thermocouples located 0.5 cm upstream of the catalyst. H_2, NH_3, NO, NO_2, O_2 and N_2 were introduced via calibrated mass flow controllers (Brooks Instruments) whereas H_2O was delivered using a controlled evaporator mixer (CEM W202A, Bronkhorst). The lines before and after the reactor was heated to 230 °C and 190℃, respectively. Moreover, a furnace was utilized to preheat the O_2, H_2O and N_2 to 170 ℃. The species concentrations at the reactor outlet were monitored with an online FTIR spectrometer (MKS Multigas 2030) equipped with a view cell with a path length of 5.11 m and a liquid nitrogen cooled HgCdTe (MCT) detector. Detailed information on the synthetic gas bench can be found in our previous studies[6]. Hydrothermal aging was performed at 480℃ and with a feed of 20% H_2O, 14%O_2 with balance N_2 for 50h. Standard SCR reaction was conducted in 150-480℃ with a feed of 350 ppm NO, 350 ppm NH_3, 14% O_2 and various H_2O concentrations with balance N_2. For the second experiment set, O_2 concentration was varied (1-8-14%) at low temperatures (150-170-200℃).

3. RESULTS AND DISCUSSION

Investigations on impact of feed water concentration on NH_3 storage capacity of copper chabazite catalysts have revealed distinct behaviors. While NH_3 storage capacity of Cu-SAPO-34 was found to be enhanced due to increased acidity of Bronsted acid sites[7], Cu-SSZ-13 was found to encounter opposite effect[8]. In particular, due to competitive adsorption on active sites, increasing water feed concentration is known to have an inhibiting effect on NH_3 storage

capacity of the catalyst. In this study, TPD runs were conducted with water concentration ranging from 0 to 20%, after mild hydrothermal aging as described in the experimental procedure, under conditions of H_2-ICE exhaust. In Figure 1, NH_3 outlet concentration measured at the downstream of SCR catalyst was shown, during the TPD phase of the experiments, for different feed water concentrations, while keeping the other parameters unchanged. The results showed that the NH_3 storage capacity decreased from 109 molNH_3/m^3 to 66 molNH_3/m^3 due to increasing inlet H_2O concentration from 0% to 20%. NH_3 oxidation is a side reaction occurring on copper zeolite systems during Selective Catalytic Reduction, which becomes significant at temperatures higher than 300 ℃. The extent of oxidation determines the surface

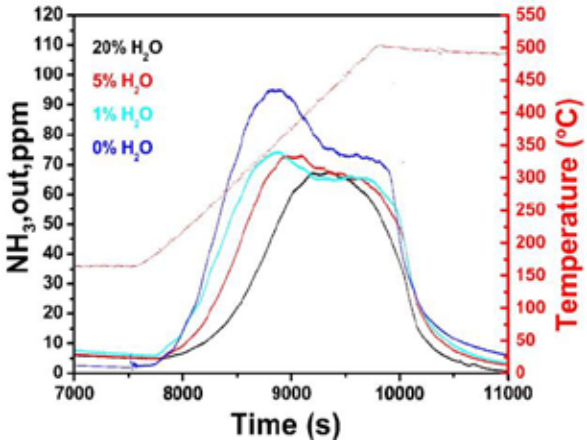

Fig. 2, NH_3 Outlet Concentrations during Temperature Programmed Desorption Phase of NH_3 Adsorption and TPD Experiments at varied H_2O feed concentrations during NH_3 adsorption step (500 ppm NH_3, 0-1-5-20% H_2O, balance N_2, 150℃, 60.000 h^{-1} space velocity).

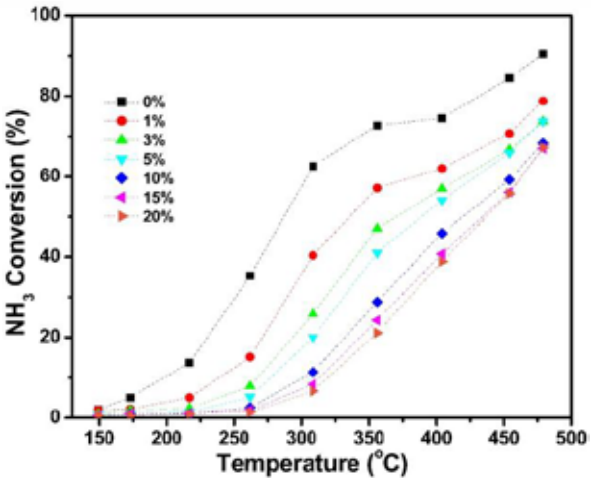

Fig. 1, Temperature vs. NH_3 Conversion via the NH_3 Oxidation Reaction with H_2O inlet ranging from 0% to 20% (Feed conditions: 500 ppm NH_3, 14% O_2, 0-20% H_2O, Balance N_2, 60.000 h^{-1} space velocity)

NH_3 availability for SCR reactions; high oxidation rate is not usually preferred due to depletion of NH_3 bounded active sites. In Figure 2, NH_3 conversion due to NH_3 oxidation at different temperatures were plotted, for inlet water concentrations ranging from 0 to 20%. Conversion of NH_3 during NH_3 Oxidation was also influenced by inlet H_2O concentration: gradually decreasing from 57% to 20% with increase of H_2O concentration from 1% to 20% at 350℃. Data for typical diesel engine outlet H_2O concentration (~5-10%) showed consistent conversion behavior with the literature [9], with minimal conversions up to 300℃, and increasing gradually to ~70% at 490℃. The results suggested that increasing the H_2O concentration to 15 and 20% decreases the NH_3 conversion for all temperatures under investigation. In particular, NH_3 conversion was about 50% at 400 ℃ with H_2O feed concentration of 10% of, and it decreased to 40% when the water concentration in the feed increased to 20%. With more significance, decreasing the inlet water concentration increased the NH_3 conversion and brought the light of to as low as 200℃ at dry conditions. These results suggested that at higher temperatures, high water feed concentrations in a H_2-ICE exhaust might have positive effects on SCR reactions due to possible presence of increased surface NH_3 sites.

Figure 3 shows the (a) steady state NO conversions and (b) N_2O formations under Standard SCR conditions (350 ppm

NO, 350 ppm NH_3, 14% O_2, Variable H_2O, balance N_2) at different temperatures. Furthermore, Figure 3a includes an inset figure which magnifies the high temperature region (T>400℃). It can be observed that NO conversion in the 150-250℃ region decreased with increasing H_2O concentration in the feed stream, whereas no significant change was observed in the 250-400℃ region, in which almost complete NO conversion was reached. However, further increase in temperature resulted in an opposite behavior than in the low temperature region: higher water concentrations promoted the NO conversion by Standard SCR. This observation is in agreement with the findings for NH_3 Oxidation in Figure 2. In Figure 3b, it can be seen that the N_2O formation during Standard SCR had a peak at around 250℃, consistent with the literature [10]. Even though the dependence of low temperature N_2O formation on water concentration was examined by several researchers, high water content as in H_2-ICE was not studied previously. The data in Figure 3b showed that as the H_2O concentration increased to typical values during operation(10-20%), the N_2O formation significantly increased at both 200 and 250 ℃, whereas no significant effect was seen for 150 and 175 ℃. After 350 ℃, the decrease in N_2O concentration was substantial and at 400 ℃ & 450 ℃, the N_2O concentration with 10 and 15% water concentration were almost identical with diesel conditions (when 3-5% water was present in the feed); however, with 20% water, the outlet concentration of N_2O was significantly higher.

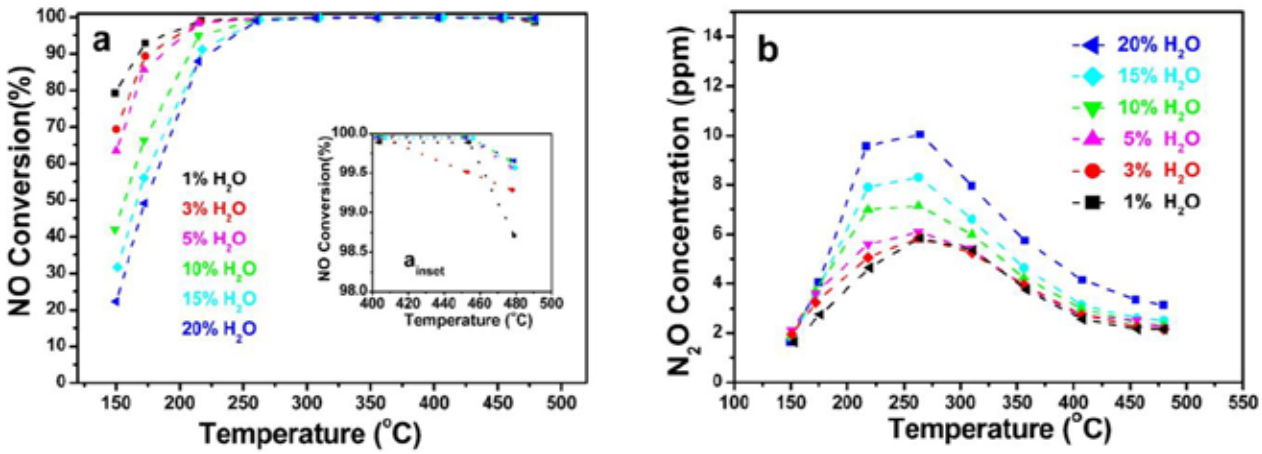

Fig. 3. (a) NO conversion and (b) N_2O Formation under Standard SCR conditions with varying water content (Feed conditions: 350 ppm NO, 350 ppm NH_3, 14% O_2, 1-20% H_2O, balance N_2, 60.000 h^{-1} space velocity).

As mentioned previously, there may be unburned hydrogen in the exhaust gas stream of the H_2-ICE that slips into the aftertreatment system. The possible effect of this H_2 on NH_3-SCR of NOx was studied experimentally, by switching a 500 ppm H_2 feed stream on and off during SCR reaction. Figure 4 shows the resulting behavior of the NO and NO_2 outlet concentrations during (a) Standard (b) Fast SCR reactions. At temperatures of 170 and 350 ℃ the feed of H_2 had no significant effect on NOx conversion, whereas at 450℃ the NOx outlet concentrations depended on the feed of H_2. Hence, the transient concentrations of NO and NO_2 for high temperature region were given in Figure 4. For Fast SCR (b) O_2 concentration were varied and the effect of H_2 inlet was found to be significant. Upon addition of 500 ppm H_2, although the total NOx conversion was not significantly changed, ~3 ppm NO_2 was detected at the outlet gas stream.

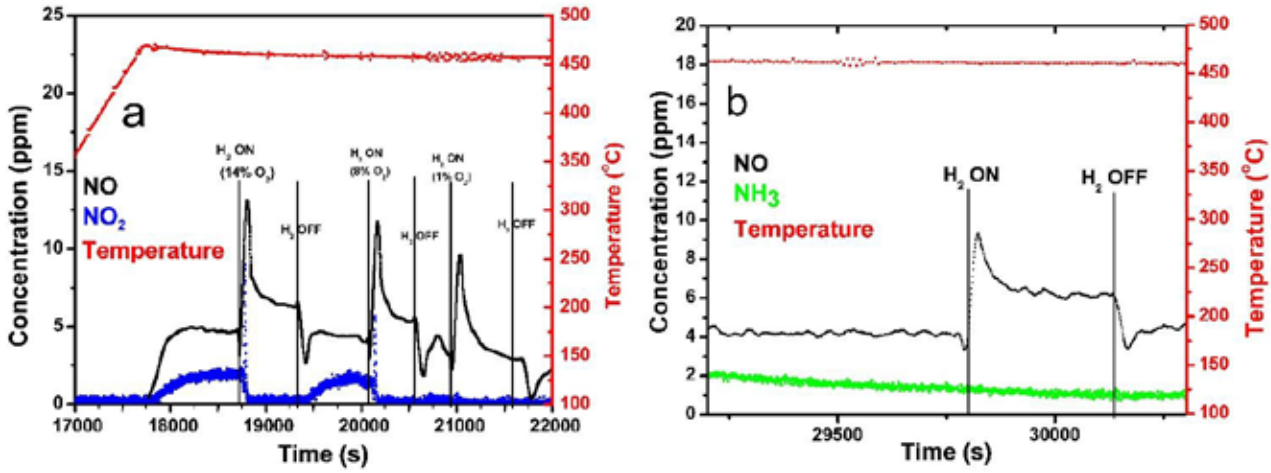

Fig. 4. NO & NO_2 outlet concentrations with H_2 Inlet for (a) Fast SCR (b) Standard SCR

4. CONCLUSIONS

This study examined the impact of water content and unburned hydrogen on NH_3-SCR performance for H_2-ICE aftertreatment. Increased H_2O concentration reduced NH_3 storage due to competitive adsorption but also suppressed NH_3 oxidation, potentially enhancing SCR reactions at higher temperatures. NOx conversion decreased at low temperatures (150–250 ℃) with rising H_2O concentration but increased above 400 ℃. N_2O formation peaked at 250 ℃, with higher water content increasing emissions at low temperatures while having minimal impact at high temperatures. Although further research in modeling and calibration is underway in our laboratory, these findings highlight key challenges and optimization opportunities for SCR systems in H_2-ICE applications, guiding catalyst design and operational strategies to meet NOx regulations efficiently.

ABSTRACT
The maritime industry is under increasing pressure to adopt sustainable propulsion technologies to reduce greenhouse gas emissions and comply with stringent environmental regulations. This study conducts a comparative life cycle carbon emissions assessment of diesel and hydrogen fuel cell propulsion for a high-speed catamaran ferry operating in İzmir Bay. The results show that replacing diesel with hydrogen fuel cells can reduce life cycle carbon emissions by 87.82%, with the largest emission source in hydrogen utilization arising from the electrolysis production phase (65.88%). Notably, while hydrogen combustion itself is emission-free, the life cycle carbon emissions on renewable electricity for hydrogen production contribute to residual emissions. Additionally, the study finds that the emissions from long-distance hydrogen transportation remain only 5.17% of the hydrogen life cycle emissions. The findings underscore the critical role of green hydrogen in maritime decarbonization and provide valuable insights for policymakers, ship operators, and industry stakeholders in transitioning toward sustainable shipping solutions.

Keywords: Marine vessels, Hydrogen, Life cycle carbon emissions assessment, Decarbonization, Marine engineering

1. INTRODUCTION
This study explores hydrogen fuel cells as an alternative propulsion system for catamaran ferries in İzmir Bay to reduce emissions. It highlights the technology's efficiency, safety, and emission reduction potential. Although hydrogen-powered ferries have higher operating costs than diesel, technological advancements and renewable hydrogen production may improve cost-competitiveness by 2025–2030. Hybrid systems and green hydrogen production further enhance sustainability, though challenges in cost and infrastructure remain.

2. SYSTEM DESCRIPTION
This study examined a high-speed ferry with a capacity of 400 passengers, with characteristic features 39 meters in length and 12 meters in width, and having a gross tonnage of 486 GT, operating for 12 hours a day on the Bostanlı - Konak route. The power requirements and the daily fuel consumption of the ferry are provided in Table 1.

Table 1. The power characteristics of the examined ferry

Designated ferry particular information	Data	Unit
Working hours per day	9.67	hours/day
Installed propulsion engine power at 100% MCR (maximum continuous rating)	3,680 (1840×2)	kW
Required diesel generator (DG) power for auxiliary equipment and hoteling	55	kW
Average daily diesel fuel consumption (m_{diesel})	1,680	kg/day

The ferry operates on a steady schedule on the designated route. Fig. 1 shows the vessel's speed profile, including the daily navigation, maneuvering, and port stay periods. The vessel operates at 12 knots on navigation and 4 knots during maneuvering operations. A total of 9 hours and 40 minutes of active operation takes place with the vessel in a day.

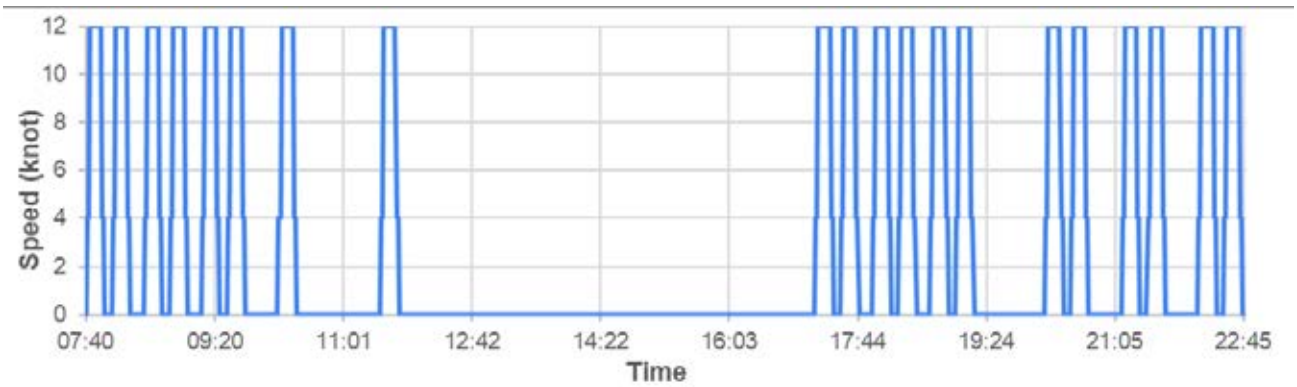

Fig. 1. Speed profile of the vessel during the one-day service period

The existing ferry operates by consuming diesel oil. A comparative life cycle carbon emissions assessment is carried out, considering that an electric motor has replaced the propulsion engine. It is assumed that the electric supply for the propulsion engine and auxiliary power requirements are provided by using hydrogen through proton exchange membrane fuel cells (PEMFCs) placed on the ferry. The specifications of the reference PEMFC are provided in Table 2.

Table 2. The specifications of the reference PEMFC to be used on the ferry [1]

Specifications	Data
Net Power (DC Supply)	200 kW_e
Gross output (rated power)	580 V / 400 A
Heat output	< 320 kW
Fuel quality	Pure hydrogen: ISO14687:2019
IP classification	IP44

The hydrogen demand for the PEMFCs was determined based on the performance curves supplied by the manufacturer, as depicted in Fig. 2. These curves provide essential insights into the relationship between power output, efficiency, and hydrogen consumption under varying operating conditions. Furthermore, an analysis was conducted to accurately estimate the power and current requirements of the PEMFC system according to the vessel's operational load profile. This analysis considers fluctuations in energy demand during different operating scenarios to ensure optimal performance and fuel efficiency.

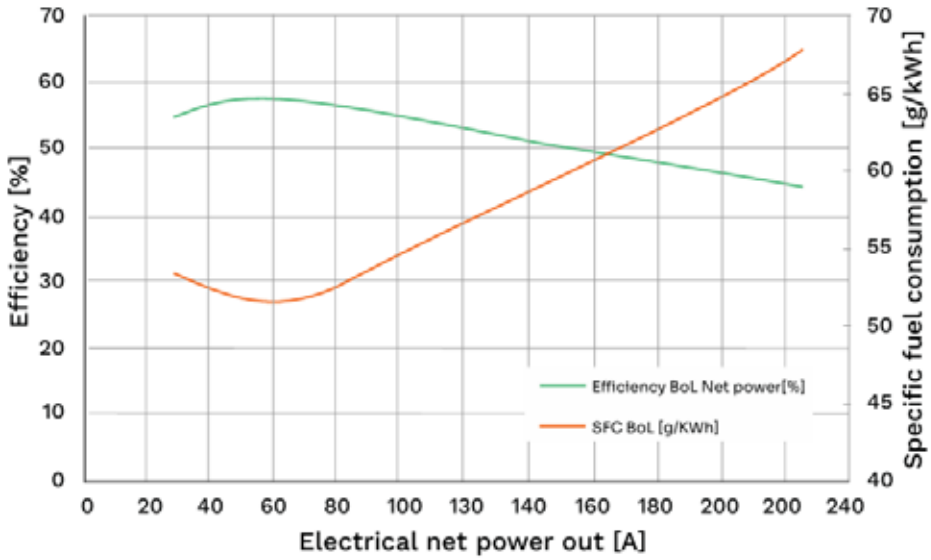

Fig. 2. Performance curve of PEMFC [1]

It is determined that the vessel operates at 35% MCR engine load during navigation while consuming 1,288 kW of power. The engine load decreases to 10% MCR during departure and docking maneuvers, which corresponds to 368 kW engine power. The engine load varies between 0% and 5% MCR while waiting at the dock according to passenger loading/unloading or standstill conditions. In all operation modes, the electric power required for the auxiliaries and hoteling needs is acquired as 55 kW.

3. METHODOLOGY

Greenhouse gas (GHG) emissions are represented as CO_2-equivalent (CO_{2eq}) by applying the 100-year global warming potential (GWP_{100}) to convert emissions of gases other than CO_2. The conversion coefficients for CO_2, CH_4, and N_2O are sourced from the IMO's 2024 LCA Guidelines [2] and IPCC's Fifth Assessment Report [3].

The emissions resulting from the ferry's daily diesel fuel consumption are calculated using the emission conversion factors from Table 3 by Eq. (1).

$$g_i = m_{diesel} \times C_{f,i} \tag{1}$$

where m_{diesel} is the mass of the diesel fuel consumed by the ferry per day, i represents CO_2, CH_4, and N_2O emissions for burning diesel oil as fuel, g_i is the emissions from the propulsion system's exhaust gas for ith emission and C_f represents the emission conversion factor.

Table 3. Initial default emission factors per fuel pathway code [2]

Properties	Marine Diesel / Gas Oil max. 10% Sulphur)	Hydrogen	Unit
Well-to-Tank (WtT) GHG intensity ($\boldsymbol{GHG_{CO_{2eq},WtT}}$)	17.7	0	gCO_{2eq} / MJ
Lower Calorific Value (LCV)	0.0427	0.12	MJ / g fuel
$\boldsymbol{C_{f,CO_2}}$	3.206	0	gCO_2 / g fuel
$\boldsymbol{C_{f,CH_4}}$	0.00005	0	gCH_4 / g fuel
$\boldsymbol{C_{f,N_2O}}$	0.00018	0	gN_2O / g fuel

$g_{CO_{2eq},TtW,diesel}$ is expressed as Tank-to-Wake (TtW) CO_{2eq} emission using GWP_{100} values to convert emissions of gases equivalent CO_2 emission basis, based on the factors provided in the IPCC's Fifth Assessment Report [3] for CO_2, CH_4, and N_2O and calculated using Eq. (2).

$$g_{CO_{2eq},TtW,diesel} = \sum(GWP_{TtW,i} \times g_i) \tag{2}$$

where GWP_{TtW} represents the Tank-to-Wake GWP_{100} values and taken as 1 gCO_{2eq} / per g of fuel burned for CO_2, 28 gCO_{2eq} / per g of fuel burned for CH_4, and 265 gCO_{2eq} / per g of fuel burned for N_2O (IMO, 2024).

The Well-to-Tank (WtT) CO_{2eq} emission from daily diesel fuel consumption is calculated using Eq. (3).

$$g_{CO_{2eq},WtT,diesel} = m_{diesel} \times LCV_{diesel} \times GHG_{CO_{2eq},WtT,diesel} \tag{3}$$

The Well-to-Wake (WtW) CO_{2eq} emission from consuming marine diesel oil in the ferry is determined by using Eq. (4).

$$g_{CO_{2eq},WtW,diesel} = g_{CO_{2eq},TtW,diesel} + g_{CO_{2eq},WtT,diesel} \tag{4}$$

The calculation methodology for the WtW CO_{2eq} emission for hydrogen fuel involves electrolysis, conditioning (liquefaction or compression), transport, and distribution stages contributing to the life cycle carbon emissions of the hydrogen fuel used in the ferry. The WtW CO_{2eq} emission for hydrogen fuel ($g_{CO_{2eq},WtW,hydrogen}$) is calculated using Eq. (5) for each stage.

$$g_{CO_{2eq},WtW,hydrogen} = m_{hydrogen} \times \sum(E_j \times EF_{electricity}) \tag{5}$$

where j represents emission production stages of electrolysis, conditioning, transport, and distribution of hydrogen. E_j is defined as the energy required for the jth stage and $EF_{electricity}$ is the emission factor for the electrical energy from renewable energy sources.

- $E_{electrolysis}$: Energy required for electrolysis - 51.2 kWh / kg H_2 [4]
- $E_{liquifaction}$: Energy required for liquefaction - 10 kWh / kg H_2 [5]
- $E_{transport}$: Distance traveled and energy consumed per kg H_2 - 32.5 g CO2 / t nm (for LNG carriers) [6]
- $E_{distribution}$: Energy required for local distribution - 0.45 kg CO_{2eq} / kg H_2 [7]
- $EF_{electricity}$: Emission factor of electricity source - 0.033 kg CO_{2eq} / kWh (for solar photovoltaics) [8]

4. RESULTS AND DISCUSSION

The total power requirement of the vessel is calculated as 1,343 kW with the addition of generator load during navigation. Considering the characteristics of the PEMFC in Fig. 2, 14 PEMFCs were selected for the vessel, each delivering 165.4 A and 580 V with ~50% efficiency and 60 g/kWh specific hydrogen fuel consumption when cruising. The specific fuel consumption is reduced to 51.5 g/kWh on maneuvering and 53 g/kWh during passenger loading/unloading phases. The calculations show that the vessel will consume 315.25 kg of hydrogen fuel per day according to the operation schedule. The comparison of emissions resulting from the use of diesel and hydrogen fuels is represented in Fig. 3.

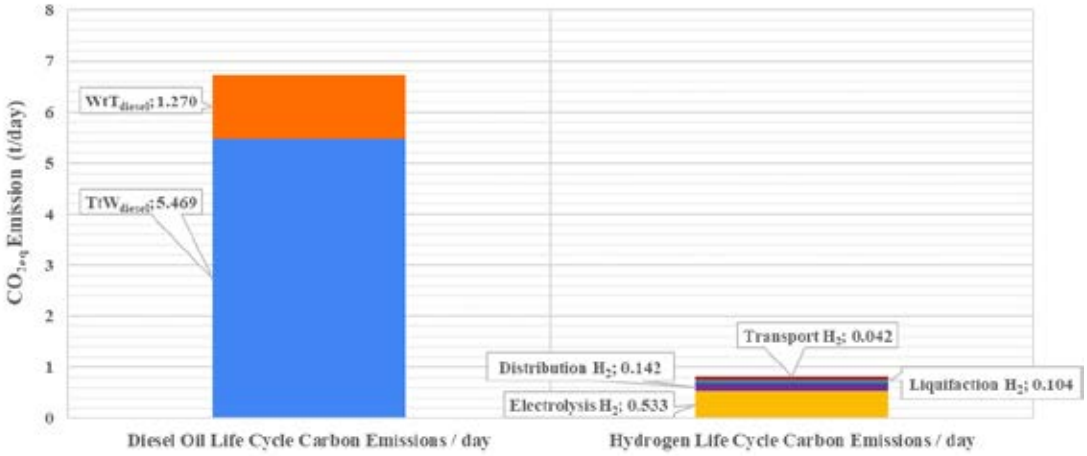

Fig. 3. Comparative life cycle carbon emissions for the diesel oil and hydrogen fuels used by the ferry

The results indicate that the utilization of hydrogen fuel instead of diesel fuel would reduce the life cycle carbon equivalent emissions impact by 87.82%. The share of H_2 production through electrolysis was obtained as the highest stage by 65.88% for the hydrogen utilization in the ferry. It is important because even though renewable electricity is used as the power source for the electrolysis of hydrogen, it is still challenging to obtain net zero emission targets unless all the stages of renewable energy production become carbon-free. Besides, when compared with the transport of H_2 from Australia to Türkiye, the transportation-based carbon equivalent emissions remain at a very low degree cause of emission production (only 5.17% of the hydrogen life cycle carbon emissions) even if the ship used for the H_2 transportation utilizes fossil fuels for navigation.

5. CONCLUSIONS

In this study, the life cycle carbon emissions assessment of diesel and hydrogen fuels were comparatively carried out. This study highlights the significant potential of hydrogen fuel cell propulsion systems in reducing the life cycle carbon emissions of maritime transportation. The comparative analysis between diesel and hydrogen fuel demonstrates an 87.82% reduction in emissions when transitioning to hydrogen-powered ferries. Despite current economic challenges, ongoing advancements in hydrogen production and infrastructure development are expected to enhance its viability as a cleaner alternative to fossil fuels. Future research should focus on optimizing hydrogen storage, distribution, and production methods to achieve net-zero emissions. Ultimately, integrating hydrogen-based solutions into the maritime sector aligns with global sustainability goals and represents a crucial step toward decarbonizing marine transportation.
In this context, hydrogen is considered a natural and clean energy source. However, to achieve the net zero emission goal, there are still gaps and challenges to be fulfilled.

ABSTRACT
Hydrogen is considered a pivotal energy carrier in the transition to a sustainable and carbon-neutral future, with applications in industry, transportation, and power generation. However, the challenge lies in producing hydrogen efficiently and sustainably. This study explores an innovative approach to hydrogen production by utilizing wastewater from domestic heat pump-based tumble dryers. As global energy demand rises and environmental concerns intensify, sustainable hydrogen production methods are gaining increasing attention. The wastewater discharged from heat pump dryers contains thermal energy that can be harnessed for electrolysis or other hydrogen generation techniques. By integrating waste heat recovery and electrochemical processes, this approach offers a novel pathway for improving energy efficiency and reducing water waste in household appliances. The feasibility, efficiency, and potential impact of this method are analyzed, highlighting its role in advancing sustainable energy solutions. The findings of this study reveal that ambient temperature and relative humidity significantly influence the performance of a heat pump-based tumble dryer as well as hydrogen production from waste water. This study highlights the critical role of environmental conditions in optimizing system efficiency and hydrogen yield, providing valuable insights for future design improvements and operational strategies.

Keywords: Hydrogen production, heat pump-based tumble dryer, thermodynamic analysis, innovative approach, sustainability

1. INTRODUCTION

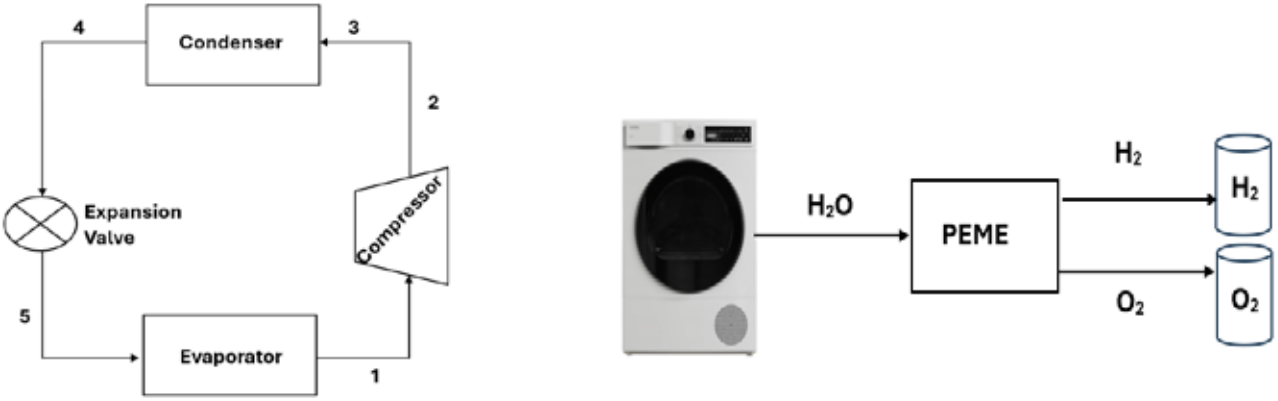
Hydrogen is increasingly recognized as a key energy carrier in the global transition to sustainable energy systems. According to the IEA's 2024 report, global hydrogen production reached 97 million tonnes in 2023, with less than 1% from low-emission sources. Fossil fuel-based methods still dominate, emitting around 900 million tonnes of CO_2 annually. [1]. Green hydrogen production through Proton Exchange Membrane electrolysis (PEME) has gained attention as a clean alternative, particularly when powered by renewable energy sources. However, a major challenge in electrolysis is the dependence on high-purity water, as impurities can reduce efficiency, accelerate component degradation, and increase maintenance requirements [2]. Additionally, electrolyzers face challenges related to energy consumption, system durability, and operational costs. The efficiency of the process is influenced by factors such as electrode degradation, membrane fouling, and heat management, all of which impact long-term performance and sustainability. Nevertheless, significant progress has been made in addressing these challenges through advancements in membrane materials, electrode coatings, and system optimization. Ongoing research continues to improve efficiency, reduce costs, and enhance the viability of electrolysis for widespread hydrogen production.

Heat pump-based tumble dryers have emerged as an energy-efficient alternative to conventional vented and condenser dryers. Unlike traditional dryers, which expel hot, moist air into the surroundings, heat pump dryers recover and reuse heat, reducing energy consumption by up to 50% [3]. These systems operate by circulating refrigerant through a closed-loop system, where it absorbs heat from moist air, condenses the moisture, and reheats the air before reintroducing it into the drum. However, despite their energy efficiency, these dryers generate condensate water as a byproduct, which is typically discarded. The composition and usability of this water for other applications, such as electrolysis, remain largely unexplored.

This study introduces an innovative approach to utilizing condensate water from heat pump-based tumble dryers for decentralized hydrogen production through PEME. Unlike conventional electrolysis systems that rely on tap or purified water, this research investigates the feasibility of repurposing waste condensate, thus integrating household appliances into hydrogen energy systems. Key factors such as ambient temperature, relative humidity, coefficient of performance (COP), total exergy destruction rate, mass flow rate of condensed water and hydrogen production rate are analyzed to assess the practicality of this approach. The findings contribute to the development of sustainable water recovery strategies and open new pathways for resource-efficient hydrogen generation.

2. SYSTEM MODELING

The schematic diagram of heat pump-based tumble dryer integrated with proton exchange membrane electrolyser is given in Fig. 1.



(a) (b)

Fig. 1. (a) The process flow diagram of the heat pump-based tumble dryer, (b) the overall system schematics

The proposed system integrates a heat pump-based tumble dryer with a PEME to utilize the condensed water from the drying process for hydrogen production. In the drying phase, the heat pump cycle efficiently transfers heat within the tumble dryer. The refrigerant circulates through the system, undergoing compression, condensation, expansion, and evaporation. The warm air, heated by the condenser, enters the drum to dry the wet clothes, while the evaporator cools the moist air, causing water vapor to condense into liquid form. This condensed water is collected and directed to the PEM electrolyzer, where it undergoes purification if necessary. The electrolysis process splits water molecules into hydrogen and oxygen using an electric current. Within the PEM electrolyzer, water molecules dissociate at the anode, releasing oxygen and protons. The protons migrate through the membrane to the cathode, where they combine with electrons to form hydrogen gas. The produced hydrogen can be stored or used as an energy carrier, offering a sustainable approach to utilizing waste water from heat pump-based drying systems for clean energy production.
The following assumptions have been considered in the analysis:

- The system operates under steady-state conditions.
- Pressure losses across the inlet and outlet streams, as well as heat transfer from system components to the surroundings, are neglected.
- Kinetic and potential energy effects are assumed to be negligible.
- The drum inlet air is considered to be saturated, implying a relative humidity of 100%.

The modeling approach and equations used are given as follows. These equations are solved using a software namely Engineering Equation Solver (EES). In order to ascertain the unknown properties, it is necessary to apply the open system energy balance equation for steady-state operation, which encompasses the control volume of the system's component. This equation is given in Eq. (1) [4].

$$0 = \dot{Q}_{cv} - \dot{W}_{cv} + \sum_i(\dot{m}_i \cdot h_i) - \sum_e(\dot{m}_e \cdot h_e) \quad (1)$$

Where, $\dot{Q}_{cv}$ and $\dot{W}_{cv}$ are defined as heat transfer from the components to the environment, and power, respectively. $\dot{m}$ and h are depicted as mass flow rate and specific enthalpy, respectively. The subscript i and e are inlet and exit, respectively. The condenser and evaporator capacities are calculated from Eqs. (2), and (3), respectively.

$$\dot{Q}_{cond} = \dot{m} \cdot (h_3 - h_4) \quad (2)$$

$$\dot{Q}_{evap} = \dot{m} \cdot (h_1 - h_5) \quad (3)$$

The mass flow rate of condensed water through the drying process can be calculated using Eq. (4).

$$\dot{m}_{cond,water} = \dot{m}_{air} \cdot \left(\omega_{air,drum,in} - \omega_{air,drum,out}\right) \quad (4)$$

In this equation, $\omega_{air,drum,in}$ and $\omega_{air,drum,out}$ represent the humidity ratios of the air entering and exiting the drum, respectively. The humidity ratio is determined using the Engineering Equation Solver (EES) software.

In order to produce hydrogen, PEME system has been used in the system. The main reactions occur the inside of PEME is given as follows.

Anode: $H_2O \rightarrow \frac{1}{2}O_2 + 2H^+ + 2e^-$ (5)
Cathode: $2H^+ + 2e^- \rightarrow H_2$ (6)
Total: $H_2O \rightarrow H_2 + \frac{1}{2}O_2$ (7)

The produced hydrogen, oxygen and remaining water exiting the PEME can be found using molar balance below.

$$\dot{n}_{H_2,produced} = a \quad (8)$$

$$\dot{n}_{O_2,produced} = a/2 \quad (9)$$

$$\dot{n}_{H_2O,out} = \left(\frac{\dot{m}_{cond,water}}{MW_{water}}\right) - a \quad (10)$$

In these equations, a is expressed as the reaction rate which can be found using Faraday's Law [5], and MW_{water} is defined as the molar weight of the water.

$$a = \frac{I}{n \cdot F} \quad (11)$$

In Faraday's Law equation given in Eq. (11), I is the current, n is the number of electrons and F is the Faraday's constant.

Following the energy and mass analysis, the general exergy balance equation for the open system is applied to determine the irreversibilities associated with each component of the system [4].

$$0 = \dot{Ex}_Q - \dot{Ex}_W + \sum_i(\dot{m}_i \cdot ex_{f,i}) - \sum_e(\dot{m}_e \cdot ex_{f,e}) - \dot{Ex}_D \quad (12)$$

where, $\dot{Ex}_Q$ and $\dot{Ex}_W$ are exergy transfer by heat and power, respectively. $ex_{f,i}$ is defined as specific flow exergy. This parameter can be defined using Eq. (13).

$$ex_f = (h - h_0) - T_0 \cdot (s - s_0) \quad (13)$$

Here, h_0 and s_0 are specific enthalpy and entropy at the dead state conditions (T_0=298 K, p_0=100 kPa) .

3. RESULTS AND DISCUSSIONS

The results obtained from the analysis provide valuable insights into the performance of the integrated heat pump-based tumble dryer and PEM electrolyzer system. This section discusses the key findings, including COP, exergy destruction rate of the system, and hydrogen production rates. In addition, the effect of operating conditions on system performance is evaluated. The thermodynamic properties of the system studied at the steady-state conditions and lnP-h and T-s diagrams are presented in Table 1 and Fig. 2, respectively. It is important to note that the following data were obtained from experimental studies conducted in the R&D laboratory of the tumble dryer factory at Vestel Home Appliances.

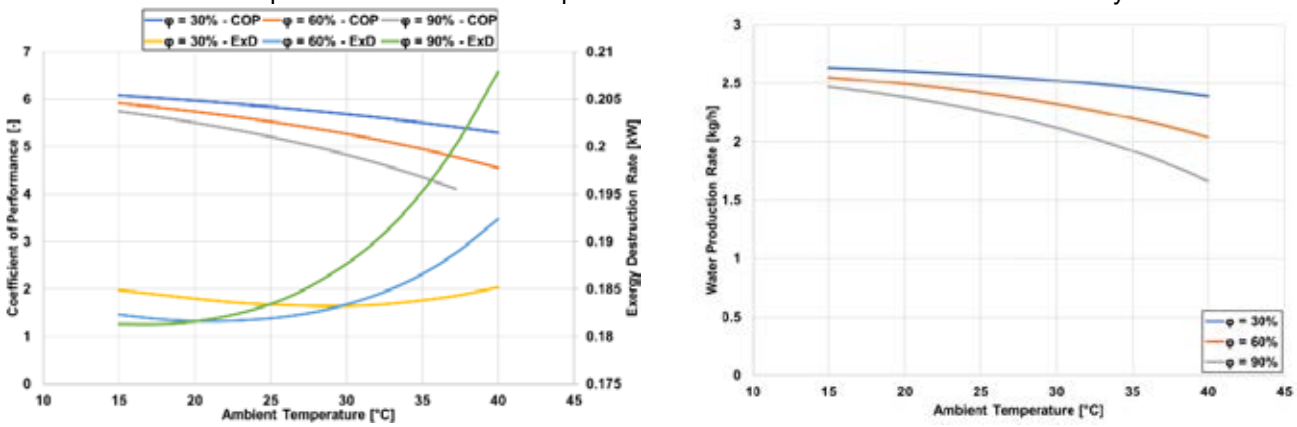
Table 1. State Properties of the System

State Number	Pressure (kPa)	Temperature (°C)	Specific Enthalpy (kJ/kg)	Specific Entropy (kJ/kg·K)	Flow Exergy (W)
1	1000	38.84	627.2	2.429	739.3
2	2200	82.47	683	2.478	991.6
3	2200	77.52	670.6	2.443	979.9
4	2200	56.07	356	1.506	764.7
5	1000	26.94	356	1.527	725.8

(a) (b)

Fig. 2. The property diagram of the system (a) lnP – h diagram, (b) T – s diagram

Fig. 3(a) illustrates the impact of ambient temperature on the coefficient of performance (COP) (left) and the total exergy destruction rate (right) under varying relative humidity conditions. As observed in the figure, the COP decreases as the ambient temperature rises from 15°C to 40°C. This trend can be attributed to several factors. An increase in ambient temperature leads to higher operating pressures in the compressor, thereby increasing its electricity consumption. Additionally, higher ambient temperatures reduce the amount of condensation, which in turn lowers the dehumidification capacity of the dryer. Conversely, as the ambient temperature increases, the total exergy destruction rate increases due to enhanced irreversibilities in both the evaporator and the condenser. On the other hand, Fig. 3(b) shows the effect of ambient temperature on the water production rate according to the different relative humidity values. The results show that as the ambient temperature increases water production rate decreases for all relative humidity values.



(a) (b)

Fig. 3. The effect of ambient temperature on the (a) COP and the exergy destruction rate, (b) the water production rate.

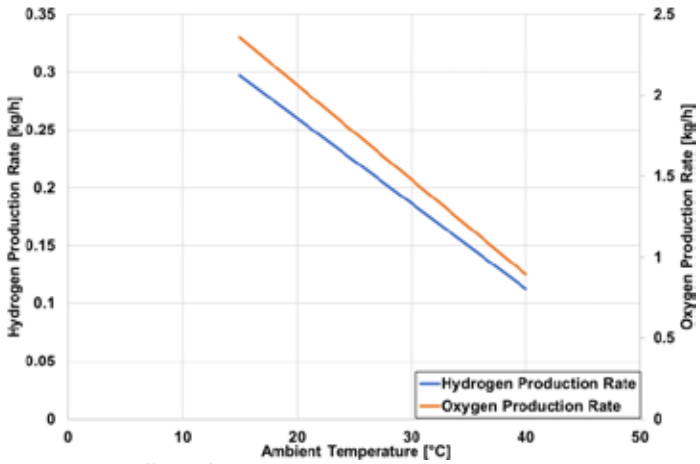


Fig. 4. The effect of ambient temperature on the production rates

Fig. 4 illustrates the effect of ambient temperature on Hydrogen (left) and oxygen (right) production rates. As the ambient temperature increases, the production rates of both gases decrease due to the reduced condensation in the tumble dryer. Moreover, the findings indicate that higher ambient temperatures have an overall negative effect on hydrogen and oxygen production rates.

4. CONCLUSIONS

In this study, a comprehensive thermodynamic analysis is performed to evaluate the feasibility of integrating a heat pump-based tumble dryer with a proton exchange membrane electrolyzer for hydrogen production. To this end, mass, energy, and exergy balance equations are applied, followed by a parametric analysis to examine the effects of ambient temperature and relative humidity on the COP, total exergy destruction, and hydrogen and oxygen production rates. The key findings derived from this study are summarized as follows.

- Increasing ambient temperature reduces the COP and hydrogen production due to decreased condensation.
- Higher relative humidity leads to lower COP and increased exergy destruction.
- At a constant ambient temperature (e.g., 25°C), an increase in relative humidity from 30% to 90% leads to a 24.07% reduction in COP, while the total exergy destruction rate increases by 8.6%.

Future research can focus on optimizing system design to enhance hydrogen production efficiency under varying

environmental conditions. Additionally, exploring alternative working fluids with lower sensitivity to temperature variations could improve energy efficiency. Lastly, experimental validation with long-term performance analysis can provide deeper insights into system reliability and operational feasibility.

ABSTRACT

With the depletion of fossil fuels and the validity of the Paris Climate Agreement, there is growing interest in hydrogen production and storage. Chemical storage method is an effective solution for hydrogen storage, and ammonia borane hydrogen can be stored chemically and safely. In this field, ammonia borane (AB, NH_3BH_3) stands out as a storage material due to its high hydrogen content and recoverability. The importance of the catalysts used in the dehydrogenation process to utilize the hydrogen in ammonia borane is increasing day by day. In this article, after the introduction of the subject, the synthesis of Ni-Co-B (Nickel- Cobalt- Boron) catalyst in 4 different rations (%50, %60, %70, %80 Co/Ni+Co ratio), the characterization devices used for the analysis of the synthesized catalysts and the dehydrogenation system for hydrogen production are included in the materials and methods section. The results and discussion section includes the analysis comments of the synthesized Ni-Co-B catalyst. As a result of the analysis, it was proven that the synthesized catalysts were successfully formed. In the BET analysis, it was determined that the catalyst with the highest specific surface area was found in the 80% Co/Ni+Co ratio and it was determined that the catalyst with the 80% Co/Ni+Co ratio showed the best catalyst properties in the dehydrogenation process.
Keywords: Chemical hydrogen storage, hydrogen storage, hydrogen, ammonia borane

1. INTRODUCTION

One of the most prevalent elements in the universe, hydrogen holds enormous promise for the creation of sustainable energy sources and clean energy. Hydrogen, which can be used in a wide range of applications, also plays an important role in energy storage systems. The technique of storing hydrogen in different chemical compounds so that it can be used as an energy carrier is known as chemical hydrogen storage, and it is one of the energy storage technologies. There is a lot of promise for a safer, more effective, and portable usage of hydrogen via chemical hydrogen storage. Furthermore, this storage method allows hydrogen to be easily released when needed for reuse in energy production, a critical component for sustainable energy solutions. Ammonia borane is an important type of chemical hydrogen storage system. Various catalysts can be synthesized to utilize the high hydrogen content (19.6%) of ammonia borane [1-3].
The synthesis of trimetallic catalysts enables the dehydrogenation of ammonia borane to occur more efficiently, rapidly and stably. This can be an important development, especially in hydrogen storage and transportation technologies. There are ternary catalysts synthesized for the dehydrogenation of ammonia borane in the literature. Fernandes et al. (2012) synthesized Co-Mo-B catalyst by chemical reduction method and carried out the ammonia borane dehydration process as hydrolysis and determined the maximum hydrogen production rate as 2460 ml H_2 min^{-1} (g of catalyst)$^{-1}$ [4]. Lim (2020) synthesized Ni-B-Zr catalyst by co-precipitation method and carried out the ammonia borane dehydrogenation process as hydrolysis at 45°C and the efficiency was 86.91% [5]. Fernandes et al. (2008) synthesized Co-Ni-B catalyst with Co/(Co+Ni) ratio of 0.85 by chemical reduction method and carried out the dehydration of sodium borohydride ($NaBH_4$) by hydrolysis and determined the maximum hydrogen production rate of 1175 ml/(min g) catalyst) [6].
As the originality of this study, ammonia borane compounds were subjected to dehydrogenation in the presence of different ratios of Ni-Co-B catalyst synthesized using the hydrolysis method. Dehydrogenation, i.e. the removal of hydrogen from the compound, was carried out. The ultimate goal of the study is to utilize ammonia borane as a sustainable hydrogen storage material.

2. MATERIALS AND METHODS

Cobalt (II) nitrate hexahydrate ($Co(NO_3)_2.6H_2O$), nickel (II) chloride hexahydrate ($NiCl_2.6H_2O$), sodium borohydride ($NaBH_4$), deionized water, ethanol products were used. In the drying stage, a vacuum oven with nitrogen gas and a tube oven with argon gas were used.
A brief description of the synthesis of the synthesized Ni-Co-B catalysts in different ratios, the characterization devices used for the analysis and the dehydrogenation system for hydrogen production are given below.

2.1. Synthesis of Co-Ni-B Catalysis

Cobalt (II) nitrate hexahydrate ($Co(NO_3)_2.6H_2O$) was weighed in such a way that Co/Co+Ni ratio was 50,60,70,80 % and

Nickel (II) chloride hexahydrate ($NiCl_2.6H_2O$) was weighed according to the calculations. DI water was added in the beaker. $NiCl_2.6H_2O$ was added to the beaker and allowed to dissolve completely. Then, $Co(NO_3)_2.6H_2O$ was added to the beaker and stirred. Sodium borohydride ($NaBH_4$) was added to the solution to carry out reduction and then left to stir. After a certain time, the solution was filtered by vacuum filtration. The washing with deionized water and ethanol was done to remove the impurities in the catalyst and this process was repeated 4 times.
After the filtration process was completed, the drying stage was started. It was kept in a vacuum environment under nitrogen gas. Then, the size reduction process was carried out by crushing in a mortar and pestle. Finally, the sample was dried in a tube oven under argon environment. After the final treatment, Co-Ni-B catalyst was obtained. Fig. 1 shows the experimental process schematically.

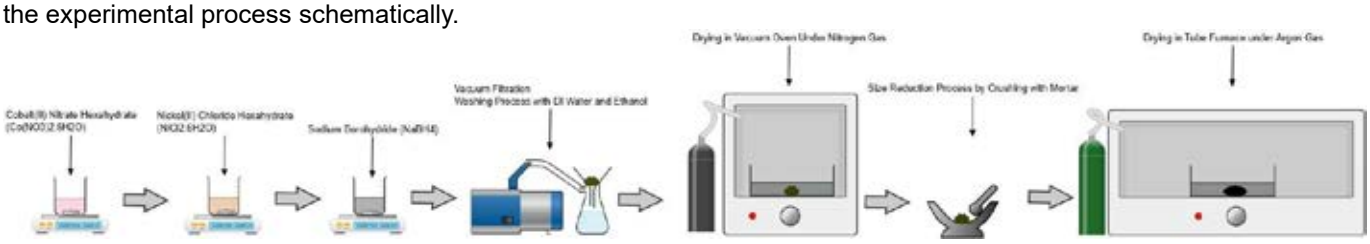

Fig. 1. Schematic illustration of the Ni-Co-B catalyst experimental process

2.2. The System of Dehydrogenation

Dehydrogenation is a type of chemical reaction in which a compound loses hydrogen atoms and hydrogen is obtained. The dehydrogenation reaction of ammonia borane is the conversion of ammonia borane (NH_3-BH_3) to hydrogen (H_2) using high temperature, low temperature, or a catalyst. In this process, ammonia borane is converted into boron (B) and hydrogen (H_2) molecules. In general, the reaction is expressed in Eq. (1) During this reaction, hydrogen is released in the form of gas and it is possible to use this hydrogen as an energy source. In this study, dehydrogenation experiments were carried out to investigate the catalytic performance of the synthesized catalysts. First, the catalyst was weighed in the calculated ratios and added to a 50 mL reactor. The temperature was set to 30°C. Then, AB was dissolved in 30 mL DI water and fed into the reactor with a syringe. The hydrogen evolution was observed as a function of time by utilizing the displacement of water.

$$NH_3BH_3 + 2H_2O = 3H_2 + NH_4BO_2 \quad (1)$$

3. RESULTS AND DISCUSSION

The synthesized catalysts were analyzed by X-ray diffraction (XRD) for structural analysis, Fourier transform infrared spectroscopy (FTIR) for bond structure, X-ray photoelectron spectroscopy (XPS) for elemental analysis, Brunauer-Emett-Teller (BET) for surface analysis and porosity.

3.1 XRD and FTIR Analyses:

The successful formation of the synthesized Co-Ni-B catalyst at different ratios was observed by XRD and FTIR analysis. XRD analysis showed that the successful doping of cobalt with nickel and the presence of boron in the structure without bonding are compatible with the literature and all four syntheses were successfully formed. In addition to the XRD analysis, FTIR analysis also showed that the peaks of the expected bond structures were found to be consistent with the literature. Related XRD and FTIR analyses are shown in Fig. 3.

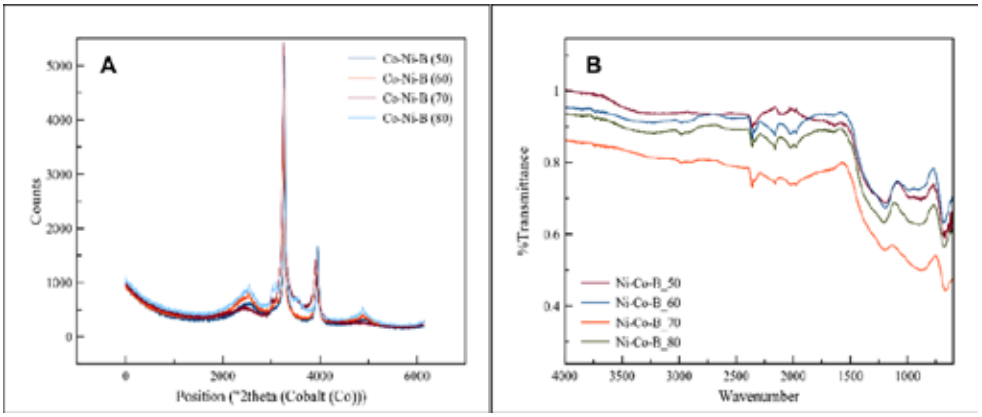

Fig. 3. XRD (A) and FTIR (B) analysis of synthesized Ni-Co-B catalysts in different ratios

3.2 XPS Analysis:

XPS analyses were performed to determine whether the synthesized Co-Ni-B catalysts at different ratios were successfully synthesized. XPS analysis is shown in Fig. 4. In the XPS analysis, it was seen that nickel, cobalt and boron were successfully formed in the structure as atomic percentages and peaks.

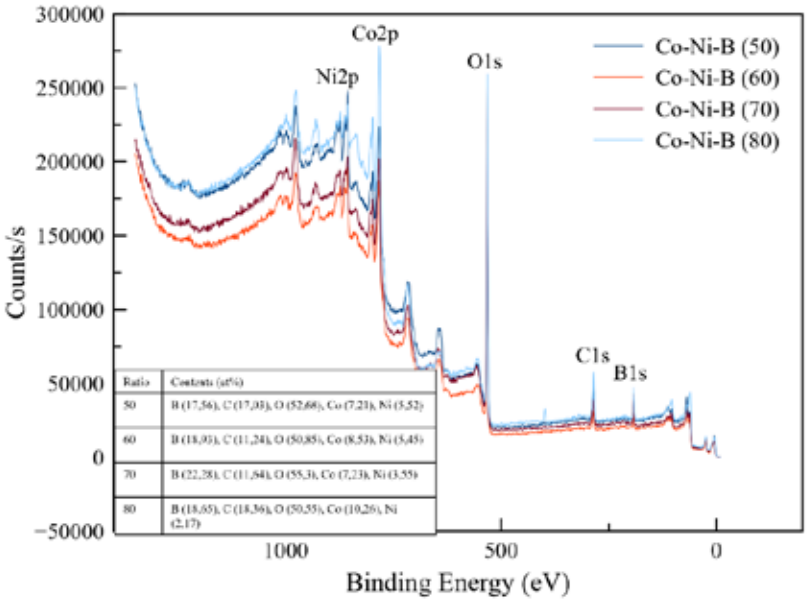

Fig. 4. XPS analysis of Ni-Co-B catalysts

3.2 BET Analysis:

Nitrogen adsorption-desorption experiment was used to characterize the surface areas of the synthesized Ni-Co-B catalysts at different ratios. BET analyses of the related catalysts are shown in Table 1. In Brunauer-Emett-Teller (BET) analysis, the specific surface areas of Ni-Co-B (50%, 60%, 70%, 80%) catalysts were measured as 81.530, 95.909, 105.998, 126.515 m^2/g, respectively. In the analysis, it was observed that Ni-Co-B (80%) had the highest specific surface area and the importance of the specific surface area in the dehydrogenation process was proven.

Table 1. BET analysis of Ni-Co-B catalysts

Catalysts	Total Surface Area (m^2)	Specific Surface Area (m^2/g)
Ni-Co-B (50%)	15.262	81.530
Ni-Co-B (60%)	19.364	95.909
Ni-Co-B (70%)	21.622	105.998
Ni-Co-B (80%)	24.304	126.515

3.2 Dehydrogenation Analysis:

As a result of the dehydrogenation experiments, the time dependence of hydrogen in mL of different ratios of Ni-Co-B catalysts was observed. It was observed that Ni-Co-B catalysts successfully catalyzed the ammonia borane dehydrogenation reaction. It was observed that the fastest hydrogen was obtained when Ni-Co-B (80%) catalyst was used in the experiment. The dehydrogenation experiment results of these catalysts are shown in Fig. 5.

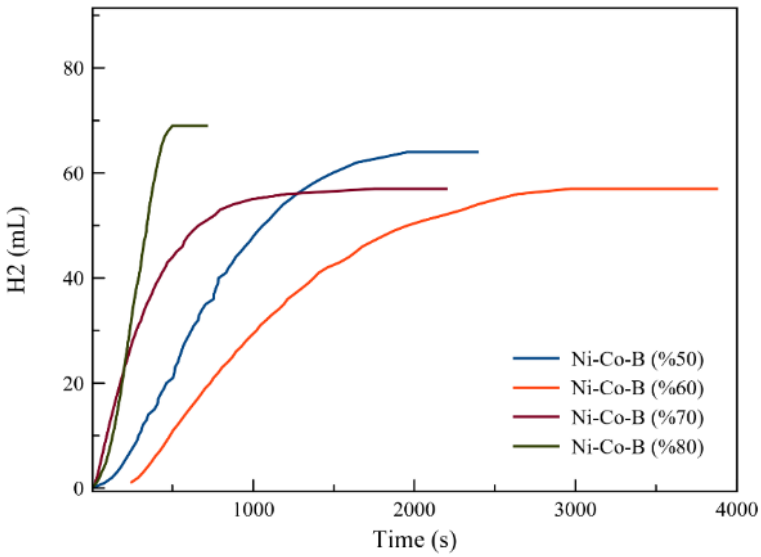

Fig. 5. Results of dehydrogenation experiment of different ratios of Ni-Co-B catalysts

4. CONCLUSIONS

Hydrogen produced with renewable energy sources offers an environmentally friendly option as a zero-emission fuel. Storage technologies are very important for the effective use of hydrogen. The successful synthesis of Ni-Co-B catalysts with different ratios synthesized for chemical hydrogen storage has been proven by characterization tests. It has been determined that the best value in the dehydrogenation process for hydrogen production is the Ni-Co-B catalyst with a Co/Ni+Co ratio of 80%. This study has proven that the catalytic properties of cobalt in the ternary catalyst system are higher than nickel. In the next process, it is aimed to complete the SEM-EDS analysis and support the XPS analysis results with SEM-EDS. At the same time, dehydrogenation experiments will be repeated and the results will be interpreted with the average of the values, and changes in the performance of the catalysts will be observed by increasing the number of cycles.

ACKNOWLEDGEMENT

This study supports chemical hydrogen storage activities carried out at the Clean Energy Research Institute (TEMEN) affiliated with the Turkish Energy, Nuclear and Mining Research Council (TENMAK).

ABSTRACT

The use of alternative energy sources is one of the priority areas of research today. In particular, the use and storage of clean energy sources such as hydrogen, which is considered as a potential energy source, is important in line with sustainable development goals and environmentally friendly technologies. In this context, ammonia borane (NH_3BH_3), which is one of the prominent compounds in terms of chemical storage of hydrogen with its high hydrogen content, attracts attention due to its compatibility with portable systems, its highly stable structure at room temperature and its ability to produce high purity hydrogen by dehydrogenation process. This study investigates the innovative synthesis and catalytic evaluation of rhodium (Rh) catalysts supported on hexagonal boron nitride (h-BN), graphene oxide (GO) and aluminium oxide (Al_2O_3) for the dehydrogenation of ammonia borane. The performances of the synthesised catalysts were systematically compared based on the dehydrogenation results and it was observed that Rh@GO showed the highest hydrogen release activity, with high surface area and strong interactions between Rh active species and support material contributing to this success, followed by Rh@h-BN and Rh@Al_2O_3. The structural and surface properties of the catalysts were investigated in detail by XRD, FTIR, XPS, SEM-EDS and BET analyses and the stability of the catalysts was confirmed. These investigations highlight the catalytic behaviour of Rh-based systems, emphasise the critical role of support material selection in optimising catalytic efficiency, and offer a new future-oriented approach for sustainable hydrogen production and storage systems.

Keywords: Hydrogen storage, Ammonia borane, Dehydrogenation, Supported catalysts, Rhodium catalyst

1. INTRODUCTION

Ammonia borane is used for hydrogen storage because of its high hydrogen content and chemical stability. Dehydrogenation of ammonia borane releases hydrogen gas (H_2), which can be used as a clean energy carrier. However, this process requires the use of suitable catalysts to overcome energy barriers and to be effective at low temperatures.
Chandra et al. investigated the potential of using highly active noble metal nanoparticles in the hydrolysis reaction of ammonia borane. In this study, the catalytic activities of ruthenium (Ru), rhodium (Rh), palladium (Pd), platinum (Pt) and gold (Au) nanoparticles supported on γ-Al_2O_3, carbon (C) and SiO_2 were evaluated. According to the results, Ru, Rh and Pt catalysts produced hydrogen with fast kinetics at stoichiometric ratios and showed high activity, while Pd and Au catalysts showed lower activity [1]. Dai and co-workers investigated fine Pd nanoparticles fixed and homogeneously dispersed in MIL-101 scaffold for the catalytic hydrolysis of ammonia borane. It was reported that the Pd@MIL-101 catalyst synthesised in the study exhibited the highest catalytic activity among the Pd-based nanocatalysts reported so far, with a TOF value of 45 mol H_2 min^{-1}(mol Pd)$^{-1}$ for the hydrolysis of ammonia borane [2]. Wu et al. investigated the use of hexagonal boron nitride (h-BN) supported nickel (Ni) catalyst systems in the hydrolysis of ammonia borane. Kinetic studies showed that hydrogen production depends on the amount of catalyst and the reaction temperature. The results showed that Ni@h-BN composites are promising for applications such as fuel cells [3]. Basu et al. studied the hydrolysis of dilute aqueous ammonia-borane solution over a carbon supported ruthenium catalyst. They showed that carbon supported ruthenium catalysts produced hydrogen about 13 times faster than alumina supported cobalt catalysts at 25°C [4].
Catalytic dehydrogenation of ammonia borane presents challenges such as high temperature requirements and the formation of undesired by-products. Rhodium (Rh) based catalysts are known to be suitable candidates for this reaction due to their superior activity and selectivity. However, the support material used can significantly affect the performance of the catalyst. Support materials such as hexagonal boron nitride (h-BN), graphene oxide (GO) and aluminium oxide (Al_2O_3) have physical and chemical properties that can improve catalyst stability, dispersion and activity.

This study investigates the synthesis and characterisation of Rh@h-BN, Rh@GO and Rh@Al_2O_3 catalysts for ammonia borane dehydrogenation. The synthetic method employed allows for the rapid and controlled reduction of Rh precursors and their efficient incorporation into the support material. The structural and functional properties of the catalysts have been extensively evaluated using advanced characterisation techniques such as XRD, FTIR, XPS, SEM-EDS and BET.

2. MATERIALS AND METHODS

The supported catalyst synthesis process was carried out with the use of support materials to achieve active catalytic performance and long-term stability. Hexagonal bornitride (h-BN), graphene oxide (GO) and aluminium oxide (Al_2O_3) were preferred as support materials. These materials play a critical role in increasing the surface area of the catalysts, ensuring their stability and supporting the homogeneous distribution of the active components.

2.1. Synthesis of supported catalysts:

For the synthesis process, Rhodium (III) chloride hydrate equivalent to 2% of the total catalyst weight was weighed, then deionised (DI) water was added and the solution was dissolved by stirring for 10-15 minutes. Hydrochloric acid (HCl) was added to adjust the pH of the solution to 2-3. As a support material, h-BN, GO or Al_2O_3 was added to the solution and stirred at 1000 rpm for 5 hours. Sodium hydroxide (NaOH) solution was then added dropwise to adjust the pH to 7. In the final step, Sodium borohydride ($NaBH_4$) dissolved in DI water was slowly added to the prepared mixture to initiate the reduction reaction. This process was completed by stirring the solution at 1000 rpm for 16 hours. At the end of the synthesis process, the catalysts formed were filtered by vacuum filtration and washed with DI water to remove impurities. The residue obtained after filtration was dried by freeze-drying. This process was carried out to preserve the active surface area of the catalyst and to prevent structural degradation. As a result of this process using a lyophilisation apparatus, it was observed that the surface area of the catalysts increased and their catalytic performance improved.

2.2. Characterisation of supported catalysts:

X-ray diffraction (XRD) was used to obtain information on the structures of the catalysts synthesised with the support material at 40 mA and 40 kV between 10 and 90 degrees and using cobalt (Co) as X-ray source. The bond structures of the catalysts synthesised with the support material were determined by Fourier Transform Infrared (FTIR) spectroscopy using a Tensor 37 brand FTIR instrument. Analyses were performed in the 640-4000 cm-1 region. The elemental analysis of the catalysts synthesised with the support material was determined by X-ray photoelectron spectroscopy (XPS) using a Thermo Scientific / K-Alpha brand XPS instrument. SEM-EDS imaging and elemental analysis of the catalysts synthesised with the support material were carried out using HITACHI SU5000 brand FE-SEM and Oxford X-MaxN 80 model EDS detector with 80 mm^2 detector area. Surface analysis and porosity characteristics of the catalysts synthesised using Brunauer-Emett-Teller (BET) instrument and Anton Paar Autosorb v2.01 brand and model by performing multi-point analysis (45 points).

2.3. Dehydrogenation process:

Dehydrogenation is the process of removing or separating hydrogen atoms from a chemical compound. During this process there is a loss of hydrogen in the structure of the compound and usually a double bond is formed or an unsaturated compound is obtained.
Ammonia borane dehydrogenation is the reaction of an ammonia borane (NH_3BH_3) molecule to hydrogen (H_2) by removing hydrogen atoms from its chemical structure using high temperature, low temperature or a catalyst.

In general, a theoretical total of 3 moles of H_2 is produced from 1 mole of ammonia borane in the presence of the catalyst, as shown in equation 1.

$$NH_3BH_3 + 2H_2O \longrightarrow NH_4BO_2 + 3H_2 \quad (1)$$

In this process, hydrogen is released in the gas phase and this hydrogen can be used as an energy source.

In this study, the catalytic performance of the synthesised catalysts was evaluated by performing dehydrogenation experiments. During the experiment, the catalyst was first weighed and added to the reactor. The reaction temperature was set at 30°C. Ammonia borane dissolved in DI water was then injected into the reactor using a syringe. Hydrogen gas was obtained by the water displacement method and observed in terms of hydrogen obtained (mL) versus time (s). The dehydrogenation processes of all the catalysts synthesised were carried out under the same experimental conditions.

3. RESULTS AND DISCUSSION

3.1. XRD and FTIR analysis results:

XRD and FTIR analyses were performed on the synthesised Rh@h-BN, Rh@Al_2O_3 and Rh@GO catalysts. The analyses showed that there was no change or degradation in the crystal structures and bond structures of h-BN (hexagonal boron nitride), Al_2O_3 (aluminium oxide) and GO (graphene oxide), which are the support materials of Rh@h-BN, Rh@Al_2O_3 and Rh@GO catalysts, thus preserving the characteristic properties of the support materials. The results obtained confirmed that Rh@h-BN, Rh@Al_2O_3 and Rh@GO catalysts physically coexist and there is no chemical interaction between them.

3.2. XPS ve SEM-EDS analysis results:

XPS and SEM-EDS analyses were carried out to confirm the successful synthesis of Rh@h-BN, Rh@Al_2O_3 and Rh@GO catalysts. XPS analyses clearly showed the successful binding of rhodium to the catalyst surface through atomic percentages and peaks. SEM-EDS analyses clearly demonstrated the effective adhesion of rhodium to the support materials through microscopic images and elemental mapping.

3.3. BET analysis results:

The nitrogen adsorption-desorption test was used to determine the surface area of rhodium catalysts formed on different support materials. The BET analysis results of the support materials and the synthesised Rh@h-BN, Rh@Al_2O_3 and Rh@GO catalysts are presented in Table 1. According to the results of Brunauer-Emett-Teller (BET) analysis, the specific surface areas of h-BN, Rh@h-BN, Rh@h-BN, Al_2O_3, Rh@Al_2O_3, GO and Rh@GO were measured to be 49.938, 58.883, 152.066, 165.021, 270.415 and 249.212 m²/g, respectively. According to the results of the analyses, it was observed that Rh@h-BN and Rh@Al_2O_3 catalysts showed an increase in surface area compared to the support materials, while Rh@GO catalyst showed a decrease.

Table 1. BET analysis results of h-BN, Al_2O_3 and GO supports and synthesised Rh@h-BN, Rh@Al_2O_3 and Rh@GO catalysts

Sample Name	**Total Surface Area** (m^2)	**Specific Surface Area** (m^2/g)
h-BN	9.194	49.938
Rh@h-BN	11.270	58.883
Al_2O_3	15.039	152.066
Rh@Al_2O_3	61.668	165.021
GO	49.432	270.415
Rh@GO	47.350	249.212

3.4. Dehydrogenation Results:

As a result of dehydrogenation experiments, Rh@h-BN, Rh@Al_2O_3 and Rh@GO catalysts were found to provide time-dependent release of hydrogen (H_2) in mL. Supported rhodium catalysts were found to be effective in catalysing the dehydrogenation reaction of ammonia borane. The fastest hydrogen production was obtained in the experiment using Rh@GO catalyst. The dehydrogenation experiment results of these catalysts are shown in Figure 1.

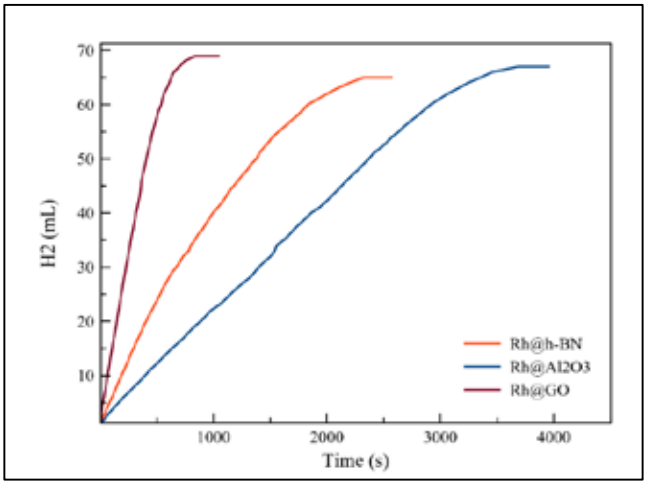

Figure 1. Results of the dehydrogenation experiment on Rh@h-BN, Rh@Al_2O_3 and Rh@GO catalysts.

4. CONCLUSIONS

In this study, the dehydrogenation performances of rhodium (Rh) catalysts supported on hexagonal boron nitride (h-BN), graphene oxide (GO) and aluminium oxide (Al_2O_3) for the dehydrogenation of ammonia borane (NH_3BH_3) were compared. The characterisation analyses and catalytic performances of Rh@Al_2O_3, Rh@GO and Rh@h-BN catalysts, the effect of the structural properties of the support materials and Rh nanoparticles on the loading and catalyst behaviour were investigated. XRD analyses showed that Rh was present in the metallic phase in all catalysts and that the structural integrity of the support materials was preserved. SEM and EDS analyses confirmed that the Rh nanoparticles were homogeneously dispersed in all catalysts and that the active centres were equally accessible. FTIR and XPS results revealed the chemical interactions between the support material and Rh and the formation of active surfaces. BET analysis showed that the Rh loading had different effects on the support materials. In Rh@Al_2O_3 and Rh@h-BN catalysts, Rh loading increased the surface area and contributed to the formation of active centres. In contrast, the initially high surface area of Rh@GO decreased after Rh loading. Rh@GO provided the fastest reaction kinetics and the highest hydrogen production capacity due to its high surface area and layered structure. Rh@h-BN showed efficient performance after Rh@GO catalyst due to its layered structure with thermal and chemical stability and homogeneous distribution of Rh nanoparticles. Rh@Al_2O_3, on the other hand, while providing long-term stability with its porous structure, achieved the lowest hydrogen production capacity due to its lower surface area and slower initial kinetics. In terms of catalytic performance, Rh@GO stood out with its fast kinetics, high hydrogen production and large surface area, while Rh@h-BN stood out as an effective alternative with its stable structure, fast reaction kinetics and high production capacity. Rh@Al_2O_3 had a lower reaction rate and the catalyst did not show sufficient effect. The results provide innovative approaches for the development of sustainable technologies for hydrogen production and storage and shed light on future applications.

ACKNOWLEDGEMENTS

This study supports the chemical hydrogen storage activities of the Clean Energy Research Institute (TEMEN), which is part of the Turkish Energy, Nuclear and Mining Research Council (TENMAK).

ABSTRACT
Geothermal-solar hybrid systems show significant potential due to their reliance on renewable energy sources. To accurately and economically predict the performance of these systems, it is essential to develop thermal models before the construction and experimentation stages. In this study, the thermodynamic performance assessment including mass, energy, and exergy analyses of the geothermal-solar-based organic Rankine cycle system producing hydrogen and electricity is studied. This system includes geothermal-powered supercritical ORC, parabolic trough solar collector (PTSC), and proton exchange membrane electrolyzer (PEME) systems. The effects of some critical parameters (production well temperature, direct irradiation intensity, ORC fluid, PTSC fluid) on the performance of the system (electrical and energetic efficiencies), net electrical energy output, exergy destructions of components productivity lack, fuel depletion ratio, and hydrogen production rate are investigated as parametrically.

Keywords: Geotermal-solar based power system, ORC, energy, exergy, hydrogen production

1. INTRODUCTION

The transition from conventional energy systems to advanced multigenerational solutions has accelerated the exploration of sustainable energy carriers. Among these, hydrogen is gaining significant attention as a promising medium for energy storage, particularly in renewable-based power systems. Unlike conventional hydrogen production methods that heavily rely on fossil fuels, green hydrogen—produced via water electrolysis powered by renewable energy sources—offers a carbon-free alternative with substantial potential for decarbonization [1]. Solar energy, particularly through Parabolic Trough Solar Collectors (PTSC), has been widely investigated as a primary power source for Proton Exchange Membrane Water Electrolyzers (PEMWE) due to its abundant availability and capability to provide clean electricity [2]. Additionally, geothermal energy has emerged as another viable renewable source to drive PEMWE systems. Innovative approaches, such as flash-binary cycles and geothermal-driven dual-fluid Organic Rankine Cycles (ORC), have been explored to harness geothermal energy for hydrogen production [3].

In this study, the mathematical modeling of the integrated system including ORC, PTSC, geothermal, and electrolyzer systems are developed. The effects of some critical parameters on the performance of the system (electrical and energetic efficiencies), net electrical energy output, exergy destructions of components productivity lack, fuel depletion ratio, and hydrogen production rate are investigated as parametrically.

2. MATHEMATICAL MODELING

Figure 1 shows the integrated system including ORC, PTSC, and PEMEC systems. Solar heat used to raise the working fluid's temperature before it enters the turbine. Geothermal fluid heats the ORC working fluid in the heat exchanger, while solar energy heats PTSC fluid. The heated fluid enters the turbine to generate power, and part of the power is directed to a PEMWE for hydrogen production. After the turbine, the fluid enters the regenerator to increase its temperature, then moves to the air-cooled condenser, where it condenses before being pumped back into the regenerator. The cycle concludes with the working fluid entering the heat exchanger, and the geothermal fluid is returned to the injection wells. The detailed energy and exergy balance equations for all components in the integrated system, and these equations are solved using EES program. The main assumptions are the heat loss from components except for PTSC are ignored; Steady-state operation conditions are applied; pressure drops in the heat exchangers and all pipes are ignored; and kinetic and potential energy changes are ignored in the system. The main equations are given as follows:

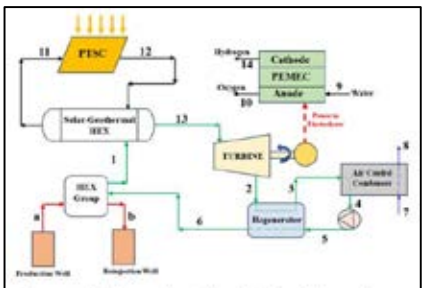

Figure 1. The schematic of integrated system including ORC, PTSC, and PEMEC systems

- A single collector's useful heat gain rate can be calculated as: $\dot{Q}_{useful} = F_R(G_b\eta_r A_a - A_r U_L(T_{11} - T_0))$ (1)

- The temperature of PTSC fluid exiting from the PTSC is found as: $T_{12} = T_{11} + \frac{\dot{Q}_{useful}}{(\dot{m}c_p)_{htf}}$ (2)

- The heat exhangers in the system are modelled using the ε-NTU (effectiveness-Number of transfer units) method. The used equations for heat exchanger are given as follows:

$$\dot{Q}_{HEX,group} = \dot{m}_{geo,fluid}(h_a - h_b) \quad (3)$$
$$\dot{Q}_{sol-geo,hex} = \varepsilon \cdot C_{min} \cdot \Delta T_{max} \quad (4)$$
$$NTU = \frac{\pi d_o L \eta_{pass} N_T U}{C_{min}} \quad (5)$$

- General mass, energy, and exergy balance equations at steady-state conditions are given for all component as follows:

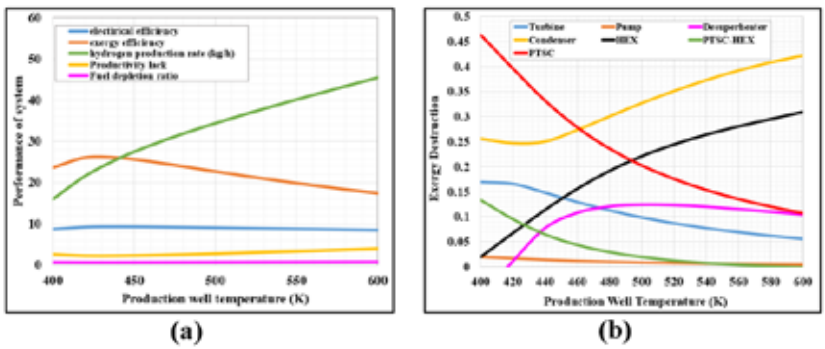
$$0 = \sum_i \dot{m}_i - \sum_e \dot{m}_e \quad (6)$$
$$0 = \sum_i \dot{m}_i \left(h_i + \frac{1}{2}V_i^2 + gz_i\right) - \sum_e \dot{m}_e \left(h_e + \frac{1}{2}V_e^2 + gz_e\right) + \dot{Q}_{cv} - \dot{W}_{cv} \quad (7)$$
$$0 = \sum_j \left(1 - \frac{T_0}{T_j}\right)\dot{Q}_j - \dot{W}_{cv} + \sum_i \dot{m}_i e_{fi} - \sum_e \dot{m}_e e_{fe} - \dot{E}_d \quad (8)$$
$$\dot{W}_{net,sytem} = \dot{W}_{turbine} - \dot{W}_{pump} - \dot{W}_{fan} - \dot{W}_{electrolyzer} \quad (9)$$

- Performance assessment parameters equations are given as follows:

$$\eta_{el} = \frac{\dot{W}_{net,sytem}}{\dot{Q}_{solar} + \dot{Q}_{HEX,group}} \quad (10)$$
$$\dot{Q}_{solar} = A_a F_R S N_{PTSC} \quad (11)$$
$$\eta_{ex} = \frac{\dot{W}_{net,sytem}}{\dot{E}_{solar} + \dot{E}_{HEX,group}} \quad (12)$$
$$\delta = \frac{\dot{E}_{d,,total}}{\dot{E}_{solar} + \dot{E}_{HEX,group}} \quad (13)$$
$$P = \frac{\dot{E}_{d,,total}}{\dot{W}_{net,sytem}} \quad (14)$$

3. RESULTS AND DISCUSSION

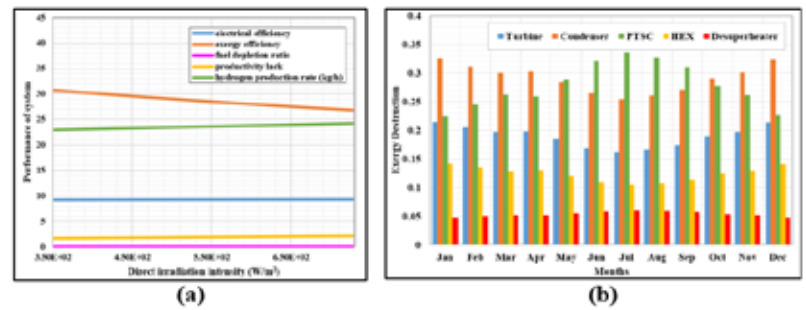
In this study, the mathematical model of an integrated solar-geothermal-based ORC cycle system including hydrogen production from a PEM electrolyzer was developed, and the energy and exergy analyses were applied to all components. The electrolyzer data used in this model were found from a reference study [4] in the literature. The effects of the production well temperature, direct irradiation intensity, ORC fluid, and PTSC fluid on the performance of the system. Figure 2-(a) shows the effect of production well temperature on system performance. As the temperature increases, the hydrogen production rate rises significantly, while electrical efficiency remains stable, and exergy efficiency first increases and then slightly decreases. Figure 2-(b) examines exergy destruction in different components, showing that turbine exergy destruction decreases with temperature, whereas heat exchanger (HEX) exergy destruction increases significantly. Overall, higher temperatures enhance hydrogen production but also affect energy losses in various components.



(a) (b)

Figure 2. The effects of production well temperature on (a) the system performance and (b) exergy destruction of components

Figure 3-(a) illustrates the effect of direct irradiation intensity on system performance. While electrical efficiency and hydrogen production rate remain largely stable, exergy efficiency decreases as irradiation intensity increases. Additionally, parameters such as fuel depletion ratio and productivity lack remain at low levels. Figure 3-(b) presents the monthly variation of exergy destruction in different components. The energy losses in the turbine, condenser, PTSC, heat exchanger (HEX), and desuperheater remain relatively stable throughout the year, with PTSC and HEX showing higher exergy destruction compared to other components. Overall, system performance is moderately affected by irradiation intensity, while energy losses remain consistent over time. In Table 1, the effects of different ORC and PTSC fluids on system performance are compared. Among ORC fluids, R134a shows the highest electrical efficiency (9.27%) and hydrogen production rate (29.02 kg/h), while R245fa has the lowest efficiency and production rate. For PTSC fluids, all options exhibit similar electrical efficiency (~9.42%)



(a) (b)

Figure 3. (a) The effects of direct irradiation intensity on the system performance and (b) exergy destruction distribution of components in annual

and exergy efficiency (~26.48%), with minor variations in hydrogen production rate (~24.74-24.8 kg/h), indicating stable performance across different PTSC fluids.

Table 1. The effects of ORC and PTSC fluid on the electrical and exergetic efficiencies, fuel depletion ratio, productivity lack, and hydrogen production rate

ORC Fluid type	η_{el}**(%), electrical efficiency**	η_{ex} **(%), exergetic efficiency**	δ **(Fuel depletion ratio)**	P **(Productivity lack)**	**H_2 production rate (kg/h)**
R134a	9.27	25.13	0.59	2.376	29.02
R124	7.44	18.78	0.68	3.634	19.9
R245fa	5.56	14.87	0.72	4.849	16.93
Isobutane	6.43	18.55	0.66	3.578	22.76
PTSC Fluid	η_{el} **(%), electrical efficiency**	η_{ex} **(%), exergetic efficiency**	δ **(Fuel depletion ratio)**	P **(Productivity lack)**	**H_2 production rate (kg/h)**
Therminol VP1	9.42	26.48	0.59	2.243	24.8
Syltherm800	9.42	26.46	0.59	2.247	24.78
Dowtherm A	9.42	26.42	0.60	2.256	24.74
Xceltherm	9.42	26.48	0.59	2.244	24.8

4. CONCLUSIONS

The main findings are given as:

- The best performance is observed at 600 K, where the hydrogen production rate reaches approximately 55 kg/h, while the exergy efficiency decreases to around 18%. The worst performance occurs at 400 K, where the hydrogen production rate is the lowest (~15 kg/h). The highest exergy destruction occurs in the turbine at 400 K (~0.45), whereas the heat exchanger (HEX) has the highest exergy destruction at 600 K (~0.35). The lowest exergy destruction is observed in the desuperheater, remaining below 0.1 throughout the temperature range.
- The highest exergy efficiency is around 32% at the lowest irradiation intensity (~350 W/m²), while the hydrogen production rate remains stable at approximately 25 kg/h. The highest exergy destruction occurs in the HEX and PTSC components, reaching values close to 0.3, while the desuperheater has the lowest exergy destruction, staying below 0.05 throughout the year.
- R134a shows the best ORC performance with 9.27% efficiency and 29.02 kg/h H_2 production, while all PTSC fluids perform similarly with ~9.42% efficiency and ~24.8 kg/h H_2 production.

NOMENCLATURE

A_a	Aperture area (m^2)	$\dot{m}$	Mass flows rate (kg/s)
C_{min}	Minimum specific heat of fluids (W/K)	N_{PTSC}	Number of solar collector
d_o	Outer diameter of the tube (m)	N_T	Number of tube
e_f	The specific flow exergy (kJ/kg)	NTU	Number of transfer units
$\dot{E}_{HEX,group}$	Exergy of the geothermal water between the inlet and exit of the heat exchanger group (kW)	$\dot{Q}$	Heat transfer rate (W)
$\dot{E}_d$	Exergy destruction (kW)	$\dot{Q}_{solar}$	Heat transfer rate input from the sun (kW)
$\dot{E}_{solar}$	Exergy entering to the system by the heat transfer from sun (kW)	S	Heat absorbed by the receiver (W/m^2)
F_R	Heat removal factor	U	Overall heat transfer coefficient (W/m^{2}K)
g	Gravitational acceleration (m/s^2)	V	Velocity (m/s)
h	Enthalpy (kJ/kg)	$\dot{W}$	Power (kW)
L	Tube length per pass (m)	$\dot{W}_{net,sytem}$	Net power output of the system (kW)

ABSTRACT
This paper presents low-cost and facile solutions for photoelectrochemical and photocatalytic hydrogen generation using commercial copper mesh as a photoanode and Nickel Zinc Iron Oxide catalyst (NiZnFeO), respectively. Copper mesh is first cleaned (etched) with hydrochloric acid to remove any residue material and existing oxide formations to expose a workable surface for a more uniform oxidation result, both in bulk and on the surface of the copper mesh. After cleaning the electrode, an annealing step is carried out in open air at 500°C to obtain copper oxide, which has a bandgap sensitive to both ultraviolet and visible light. Carbon paper, an Ag/AgCl reference electrode, and 0.1M Potassium Hydroxide (KOH) electrolyte are used in conjunction with the prepared photoanode for photoelectrochemical hydrogen production. Cyclic voltammetry is used to assess the performance of this photoelectrochemical assembly, and it is observed that a higher photocurrent was achieved at around -0.7V vs Ag/AgCl under light conditions. As for the photocatalytic hydrogen generation part of this study, 20mg of NiZnFeO is dispersed in 200ml of water containing 0.1M KOH and 0.1M Triethanolamine (TEOA) sacrificial agent. A maximum hydrogen concentration of 9ppm is achieved after 30 minutes, after which TEOA radicals' sedimentation hinders further hydrogen production.

1. INTRODUCTION
The energy sector is facing an unprecedented need for diversifying the energy mix and establishing groundwork for reliable and independent energy sources. Renewable energy technologies are looked at as a potential replacement for conventional fossil fuel-based technologies, which have dominated the energy market supply for more than 70 years now. Some examples of these technologies are solar photovoltaics and thermal [1], wind-energy based, biomass, and geothermal energy systems. Energy reliability is considered a gray area for most of these technologies with the exception of a few, and given that an effective energy mix, requires implementing various energy sources and technologies, energy storage solutions become paramount.
Hydrogen is the most abundant element in our universe; however, it only constitutes a small percentage of the earth's atmosphere. Most of earth's hydrogen reserves exist in the form of water (H_2O), which means the in order to effectively obtain hydrogen, one must utilize water splitting techniques in order to separate the hydrogen from the oxygen. Conventionally, this requires ample amounts of energy and the use of precious metal catalysts such as platinum in a process called electrolysis. A Gibbs free energy of 237kJ/mol is required along with a potential difference of 1.23V between the electrolysis electrodes to effectively carry out a water splitting process. More advanced hydrogen production techniques that are aided with absorbed solar energy have risen within the hydrogen scene. These techniques are classified into photoelectrochemical, photocatalytic, and biophotolysis. Photoelectrochemical hydrogen generation uses a conventional electrolysis cell assembly with the difference in the anode or cathode used, which in this case would be photoresponsive. A photoanode is a semiconductor that absorbs incident light and generates an electron-hole pair, with the aid of its bandgap the electrons and holes are separated, and the electrons are transported through an external circuit to the cathode. At the cathode, the electrons are combined with water molecules, in a water reduction reaction, to produce hydrogen [2]. A photocatalytic process on the other hand, solely uses a photoresponsive catalyst, either in powder form suspended into an electrolyte, or stationary on an electrode, which splits water into hydrogen and oxygen gases. These processes allow for a passive generation of hydrogen without the need to extensive external energy input, except for that coming from incident sunlight.
The objective of this work is to test and assess the viability of low-cost solutions for photoelectrochemical hydrogen generation electrodes, as well as transition-metal-based catalysts for photocatalytic hydrogen generation.

2. MATERIALS AND METHODS
Commercial copper mesh is used as the photoanode for photoelectrochemical hydrogen generation. Hydrochloric acid (HCl) is used to initially clean copper mesh to strip the surface of any residue or any oxides that might have formed on the surface of the copper mesh preventing the following oxidation step from reaching the bulk of the copper mesh. To do so, copper mesh is immersed into concentrated HCl and sonicated for 15 minutes. Then, the copper mesh is rinsed and immersed in DI water and sonicated for another 15 minutes to remove any leftover HCl. Copper mesh is then placed on a hot plate in atmospheric air to transform the copper into copper oxide at 500°C for 30 mintues. Carbon paper is used

as a counter electrode, and Ag/AgCl is used as a reference electrode, with 0.1M KOH (Sigma Aldrich) as an electrolyte. For photocatalytic hydrogen generation, Nickel Zinc Iron Oxide (Sigma Aldrich) is used as a photocatalyst, with a loading of 10mg/100ml. Moreover, a solution of 0.1M KOH and 0.1M Triethanolamine (TEOA) are used to make up the electrolyte and the sacrificial agent in the photocatalytic hydrongen generation process. The OAI solar simulator, Gamry Reference 300 potentiostat, and DFRobot electrochemical hydrogen sensor are used for the assessment of photoelectrochemical and photocatalytic hydrogen generation. The methodology used for the preparation of the photoanode and photoelectrochemical and photocatalytic hydrogen generation and assessment is summarized in Fig 1.

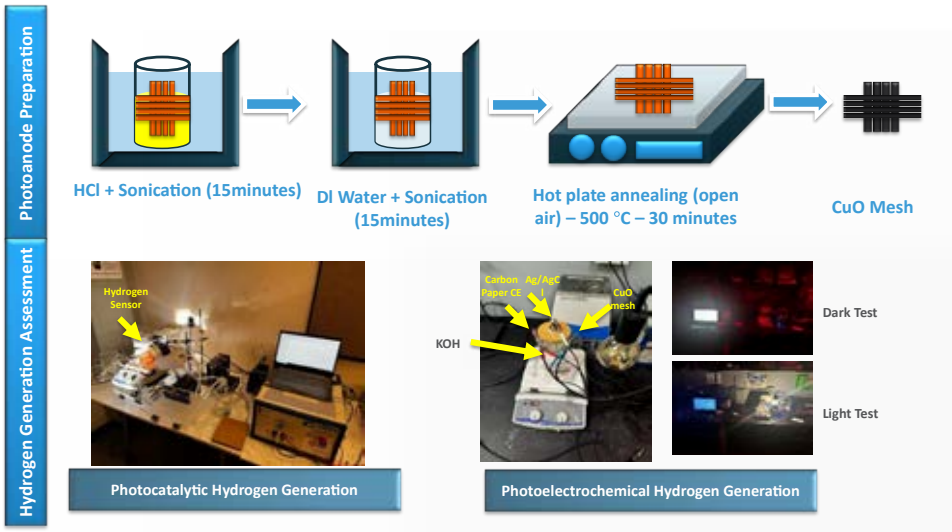

Fig. 1. Photoanode preparation and photohydrogen generation assessment methodology

3. RESULTS AND DISCUSSION

This section showcases results obtained for photoelectrochemical hydrogen generation, using CuO photoanode and carbon paper counter electrode, and photocatalytic hydrogen generation using transition metal-based catalyst.

Figure 2 shows cyclic voltammetry for photoelectrochemical hydrogen production under light and dark conditions. The scan range is chosen from -1.8V to -0.5V vs Ag/AgCl which contains the region for water reduction (hydrogen generation), with a scan rate of 10mV/s. Photoelectrochemical hydrogen generation utilizes complementing effects that increase the overall hydrogen generation in comparison to conventional electrolysis. The photoanode, CuO in this case, absorbs incident light and generates charge-carrier paris (electrons and holes). Electrons are transferred to the counter electrode through an external circuit, which are then used to reduce water into hydrogen. As seen from Fig. 2 the reduction peak at around -0.7V vs Ag/AgCl is relatively greater under light conditions than that of dark conditions, also manifested in a larger current generation which indicates higher hydrogen generation rate.

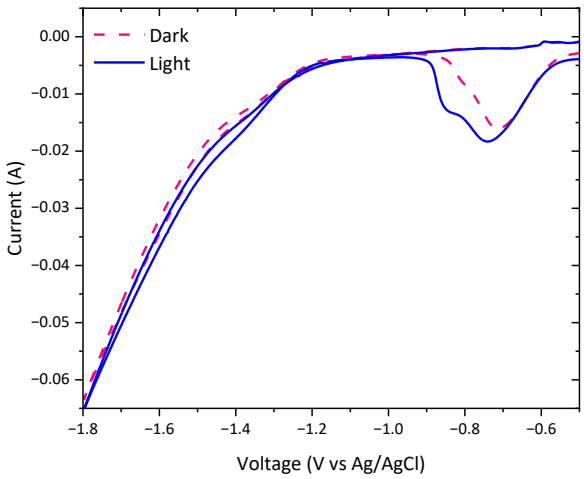

Fig. 2. Cyclic voltammetry results for photoelectorhcemcial hydrogen generation

Photocatalytic hydrogen generation, unlike photoelectrochemical counterparts, is a passive way of producing hydrogen without the need for electricity. A photocatalyst is either dispersed into the targeted solution or deposited into a stationary

electrode. Once the photocatalyst is exposed to light, individual charge carrier excitation and separation events carry out water reduction processes with the aid of a sacrificial agent that takes on the other half reaction for hydrogen generation. Moreover, there are stringent requirements when it comes to choosing a catalyst for photocatalytic hydrogen such as requiring the bottom of the conduction band of the catalyst to be higher than the standard potential for water splitting. Figure 3 showcases results for photocatalytic hydrogen production where a hydrogen concentration of 9ppm is reached after 30mintues, just before radicals from TEOA are formed and sedimented which hinder the intensity of the reactions that occur, degrading the hydrogen concentration in the process after the 30-min mark.

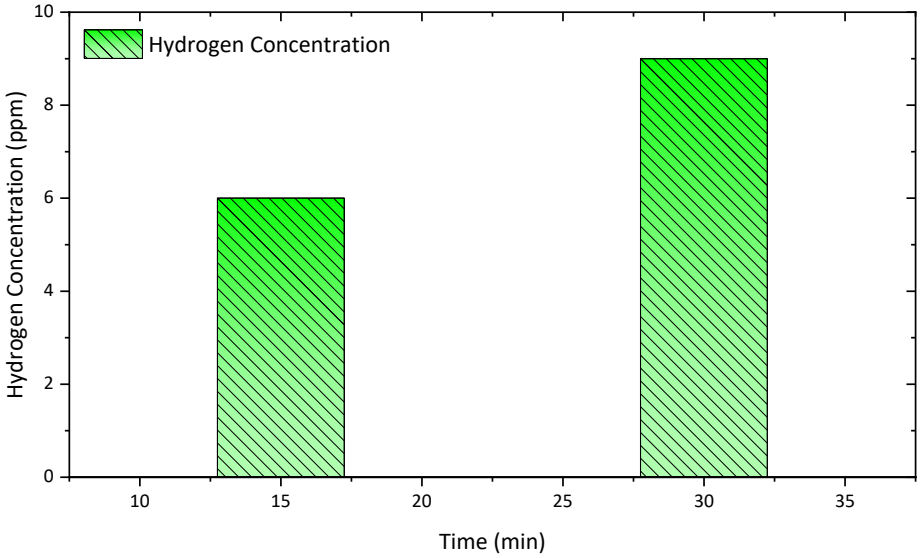

Fig. 3. Hydrogen concentration (ppm) through a 30-minute period for photocatalytic hydrogen generation

4. CONCLUSIONS

In conclusion, low-cost solutions for photoelectrochemical and photocatalytic hydrogen generation using copper mesh and Nickel Zinc Iron Oxide photocatalyst are presented, and their performance assessed. Copper mesh is cleaned with hydrochloric acid, rinsed with DI water, and annealed at 500°C to achieve a uniform formation of copper oxide in both the bulk and on the surface of the copper mesh. The photoelectrochecmial system used for hydrogen generation system comprised of copper oxide mesh photoanode, carbon paper counter electrode, Ag/AgCl reference electrode, and 0.1M KOH electrolyte. Cyclic voltammetry tests conducted under dark and light conditions show that under illumination the water reduction current produced, with a peak at around -0.7V vs Ag/AgCl, is relatively higher than that of dark conditions. Moreover, for photocatalytic hydrogen production, 20mg of NiZnFeO catalyst is dispersed in 200ml of DI water along with 0.1M KOH and 0.1M TEOA sacrificial agent, a solar simulator, and a hydrogen sensor are used to assess the concentration of the hydrogen produced throughout a 30minute period. A maximum concentration of 9ppm is achieved, after which prominent formations of TEOA radicals impede further photocatalytic reactions.

ACRONYMS

Ag/AgCl	Silver/Silver Chloride
CuO	Copper Oxide
HCl	Hydrochloric Acid
KOH	Potassium Hydroxide
NiZnFeO	Nickel Zinc Iron Oxide
ppm	part per million
TEOA	*Triethanolamine*

ABSTRACT
Hydrogen/Bromine (H_2/Br_2) redox flow batteries (RFBs) stand out with their high energy density, efficiency, and low-cost advantages in energy storage systems. Membranes that provide ion conductivity and increase energy conversion efficiency are a critical component in these batteries. Sulfonated polyetheretherketone (SPEEK) membranes have become an increasingly popular material in H_2/Br_2 redox flow batteries. SPEEK membranes have properties such as chemical resistance, thermal stability, and high proton conductivity. SPEEK membranes increase energy conversion efficiency due to their high proton conductivity. As a solution, SPEEK can be supported by composite or blend materials or cross-linking techniques can be used. At this point, polybenzimidazole (PBI) comes to the fore. It is suggested that SPEEK be modified with hybrid structures to increase long-term stability in HBr medium. SPEEK membranes offer an efficient, durable and cost-effective solution in H_2/Br_2 redox flow batteries. However, addressing the swelling and chemical resistance issues is critical for the commercial scale applicability of these membranes. In this study, the use of PBI-SPEEK blend membranes prepared with different weight ratios of PBI in hydrogen bromine redox flow batteries, their characterization, corrosion resistance and the effects of all on performance were investigated parametrically.

Keywords: HBRB, SPEEK, PBI,

1. INTRODUCTION

Redox flow battery (RFB) is one of the emerging large-scale energy storage systems that has attracted great attention in recent years due to its high energy efficiency of about 70–80%, reasonable capital cost and economical life cycle costs without any specific site requirements [1] RFB (Redox Flow Battery) stores energy using two electrolyte solutions, which are kept in separate reservoir tanks. Electron transfer is facilitated by circulating pumps through an electrochemical cell stack made up of a series of cells connected in series or parallel. Typically, each cell consists of an anode, cathode, membrane, and flow channels, similar to fuel cells and electrolyzers [2]. The power of RFBs is determined by the number of cells in the stack and the volume of electrolyte used. This allows the system to be sized independently in terms of power and energy ratio, reducing costs for additional energy storage capacity without increasing the cost of the cell stack. Hydrogen bromide (HBr) redox flow batteries (RFBs) are a type of energy storage system that utilize a reversible electrochemical reaction to store and release electrical energy. They are part of the broader category of flow batteries, which are characterized by the use of liquid electrolytes that flow through electrochemical cells to store energy. Hydrogen bromide redox flow batteries store and release energy through the oxidation and reduction of bromine and hydrogen at two different electrodes, usually made of carbon-based materials. The two main components in these systems are involves the reduction of bromine (Br_2) to bromide ions (Br^-). On the negative side involves the oxidation of hydrogen bromide (HBr) to produce hydrogen gas (H_2) [3]. In 2006, Peled et al. started working on this technology with the aim of using it as a large-scale energy storage system and achieved a power density of more than 1.5 W/cm^2 [4]. Another study has studied HBFB systems based on long-chain perfluorosulfonic acid (LC PFSA) membranes. Cyclic performance analyses showed negligible performance degradation over 600 cycles. The commercialization of HBFB technology depends on achieving both high power density and long lifetime (with a maximum power density of 1 W/cm^2 and 20 years of operational lifetime) [5]. Although critical for the optimization and commercialization of HBFB technology, systematic studies defining fundamental structure-property relationships are still lacking. Furthermore, the availability of commercially viable membranes for HBFB applications is chemically limited, and existing commercial products may not always meet the required specifications (e.g., thickness, ion exchange capacity, water retention). Consequently, laboratory synthesis of these membranes is essential due to their unique chemistry, limitations in material processing routes, labor intensity, and the need for strict safety precautions.

In all electrochemical systems, the membrane is a vital component located in the middle of the cell. It is the electrolyte in an electrochemical cell. Its function is to complete the circuit by passing ions from the anode to the cathode or from the cathode to the anode and to separate the fuel fed to the anode from the oxidant fed to the cathode. The membrane must not have electrical conductivity and must be mechanically, thermally and chemically resistant to operating conditions. The properties of the membrane affect the entire system, especially the selection of the catalyst and the creation of the electrode. Therefore, membrane selection, development and optimization of its properties are comprehensive and important stages that are not easy. The basic properties that a good membrane must have can be summarized as having high ionic conductivity, mechanical, thermal and chemical resistance and not being permeable to the fuel and oxidant used (especially in liquid systems). These necessary properties are directly or indirectly dependent on other directly

measurable properties such as ion exchange capacity, morphology and water retention capacity. For these reasons, there is a group of characterization techniques that must be applied for an ion-conducting polymer membrane that is developed.

Membrane development studies for HBFBs are much more limited compared to Vanadium Redox Flow Batteries (VFRB). Fluorinated Nafion, which is used for VFRBs and is accepted as the industrial standard, has been used in many studies. Nafion, which is in the KDM class, is still used in many studies in HBFBs. Nafion is by far the most studied material in both VRFBs and HBFBs due to its fluorinated backbone similar to Teflon structure, which has high mechanical, thermal and chemical resistance. In this study will examine the performance parameters of SPEEKs with different sulfonation degrees in HBFBs and optimize the membrane that produces the best results.

2. MATERIALS AND METHODS

PEEK that provided by Merck, was dissolved in sulfuric acid. All membranes were prepared with the same procedure as in the study of Ata et al. [8]. The measurements were made by electrochemical impedance spectroscopy with 4-probe through-plane cell. The through-plane ionic conductivity test is commonly used to measure the ionic conductivity of a material in the direction perpendicular to its surface, which is often crucial for evaluating the performance of materials used in electrochemical applications like fuel cells, batteries, and electrolysers. The material being tested (such as a membrane or electrolyte) is cut into a suitable shape and size, typically a thin sheet, to ensure uniformity during testing. It should also be well-prepared to ensure good contact with the electrodes. A small AC signal is applied across the electrodes, and the impedance is measured. The conductivity can be extracted from the impedance spectrum by analyzing the real part of the impedance at low frequencies. The data is typically processed to obtain the ionic conductivity of the material in the through-plane direction. This gives insight into how well ions can move through the material, which is critical for applications like fuel cells, where ions need to travel from one side of the membrane to the other. All impedance measurements were made at room temperature and 100 % relative humidity (RH). Water plays a critical role in the functioning and efficiency of electrochemical cell membranes. However, the water retention capacity of the membrane is also very important, and efficiency can decrease if the correct water balance is not achieved. In a fuel cell, water interacts in a context with the passage of protons (H^+ ions) through the membrane. Water is a carrier for proton conduction in the PEM membrane. In other words, the membrane generates electricity by conducting protons through water. Therefore, it is important to have enough water in the membrane. In order for these systems to work, the membrane must be sufficiently moist. Moisture in the membrane increases the proton conductivity, thus providing more efficient energy production. Dryness of the membrane seriously reduces the proton conductivity and negatively affects the efficiency of the fuel cell. However, too much water accumulation is not desired. Excessive water retention in the membrane can cause the electrode surfaces to become wet, thus reducing the efficiency of the electrochemical reactions. Excessive water accumulation can also compromise the structural integrity of the membrane and lead to permanent damage. Water management is a critical issue in redox flow batteries. There must be sufficient water in the membrane and not too much of it. To achieve this, a water vapor transport system or humidity control mechanisms are usually used. The performance of membranes varies depending on the water content. If the membrane holds enough water, the proton conductivity is high and the battery operates more efficiently. However, excess water can cause side reactions, which reduces efficiency.

The mechanical tests of the prepared membranes were performed using the Instron 3345 desktop tensile device at a speed of 10 mm/min according to the ASTM D882 method (polymeric thin film method). Membrane samples were prepared with a length of 50 mm and a width of 10 mm. During the test, the tensile strength (MPa), Young's modulus (MPa) and tensile amount (% elongation) values were obtained from the device. Tensile test is a test performed to determine the tensile and elongation properties of the material.

Ionic conductivities were measured by electrochemical impedance spectroscopy (EIS). The resistances of the membrane samples at high frequencies were measured and these data were used with parameters such as membrane area and thickness to calculate the ionic conductivity. During the measurements, high conductivity Sigraget 34 BC carbon paper gas diffusion sheets were used to prevent short circuits. Samples and gas diffusion sheets were prepared and placed in 4 cm^2 (2x2 cm) sizes. Measurements were made at 300°C with 100% humidity and at 80°C with the same humidity.

The single cell was adapted from a 10 cm^2 active area. The cell assembly included two stainless steel current collectors and graphite bipolar plates. Carbon paper (SGL Technologies 24) was used at the positive electrode, and Teflon-treated carbon cloth (280 µm) was applied to the negative electrode. For the first experimental setup, the Pt/C anode catalyst loading was used. The Pt/C powder contained 30 wt% Pt on carbon, and the Nafion solution mixture was employed. The flow rate was controlled between 10 mL/min and 50 mL/min. The hydrogen electrode operated in single-pass mode, meaning hydrogen passed through the electrode without being recycled. Hydrogen was humidified using a humidifier bottle heated by a hot plate, with temperature controlled according to experimental conditions. Humidification was provided by the hydrogen supply. Electrochemical measurements were conducted using a potentiostat with an 80A

amplifier and open circuit voltage (OCV).

3. RESULTS AND DISCUSSION

In this section, the results of thermal, mechanical and electrochemical characterization of the produced SPEEK polymers with different sulfonations and PBI-SPEEK blend membranes are given and these data will be compared with the results of previous studies in literature. In this study, the degree of sulfonation was calculated with the help of an equation using the total number of waves of the hydrogen element (at positions A, B, C and D) and the E wave, which is the integration area of the proton, with H-NMR. SPEEK-47 with 47% DS sulfonated for 96 hours, and SPEEK-80 with 80% sulfonated for 168 hours at the same temperature (~25 C) to form SPEEK. DS from the sulfur weight percentage was assumed to be up to 100% in most of the studies. Fourier Transform Infrared Spectroscopy (FT-IR) is used for the determination of organic compounds. Most compounds, except optical isomers, have their own infrared spectrum. These spectra lie between visible light and microwaves in the electromagnetic spectrum and cover the range of 450-4000 cm^{-1}. This method determines the structure of organic samples but does not provide information about purity. The samples were examined using Perkin Elmer Spectrum 100 FT-IR device and diamond crystal. In the SPEEK spectrum, characteristic peaks are observed at 1650 cm^{-1} and 1220 cm^{-1}, while the 1080 cm^{-1} band corresponds to the symmetric stretching vibration of O=S=O. The peak at 1020 cm^{-1} is assigned to the stretching vibration of S=O, and the peak at 710 cm^{-1} is due to the symmetric stretching vibration of S-O. In the blended membranes, specifically in the SPEEK/PBI compositions with 5 wt%, 10 wt%, and 20 wt% PBI, a shift to 1710 cm^{-1} was observed. Additionally, as the PBI content increased, the intensity of the -C=N- peak in the blend membranes strengthened. This change is attributed to the enhanced ionic cross-linking between $-SO_3H$ and -C=N- groups [6,7].

When the ionic conductivity results of the SPEEK membranes with two different sulfonation degrees were examined, SPEEK-47 with a low sulfonation degree was determined as 0.047 mS/cm. SPEEK-80 with a high sulfonation degree was measured as 0.12 S/cm. Pure SPEEK at 100% RH exhibits high conductivity (0.12 S/cm). PBI-SPEEK (5-10%) blend membranes showed conductivities of 0.069 S/cm and 0.057 S/cm, respectively. For the PBI-SPEEK (20 wt%) membrane, the conductivity reached 0.042 S/cm at 80°C (Figure 1).

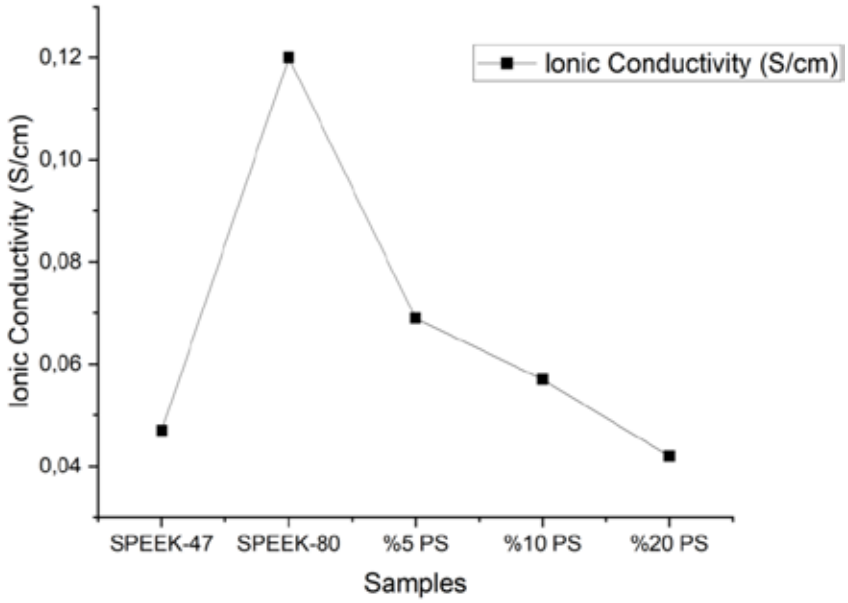

Fig. 1. Ionic Conductivity Results for All Membranes

The water uptake of the SPEEK membrane was 42.5% at 30°C and 50.9% at 60°C. For PBI-SPEEK (10 wt%) and PBI-SPEEK (20 wt%) membranes, the water uptake decreased to 12.8% and 10.7% at 30°C, while it increased to 22.4% and 20.6% at 60°C, respectively. When the PBI content was 5%, the water uptake was 29.4% at 60 C. It was observed that the swelling degree decreased with the increase of PBI content by adding PBI. [7].

In the first stage, tests were conducted using a reference setup to analyze polarization curves. A similar approach was followed here to assess the sources of losses from steady-state polarization curves. Each data point was equilibrated for 30 to 90 seconds. Polarization curves are commonly used to evaluate the performance of hydrogen-bromine redox flow batteries, as they help identify which processes contribute to overpotential at a given current. Initially, a laboratory-prepared electrode with a Nafion®117 membrane and a platinum loading of 0.75 mg/cm² was employed for each

electrode. At the positive electrode, a relatively low concentration of 0.9 M Br_2 in 1 M HBr was used. The polarization curve for this membrane-electrode assembly (MEA) is shown in Figure 2. The linear section of the polarization curve corresponds to the ohmic loss region. The starting portion of the curve indicates that kinetic losses are minimal, with the majority of the curve remaining within the linear ohmic loss region. This suggests that the discharge limiting current density of 400 mA/cm² is primarily influenced by mass transfer. Additional impedance experiments will be conducted to further elucidate this effect.

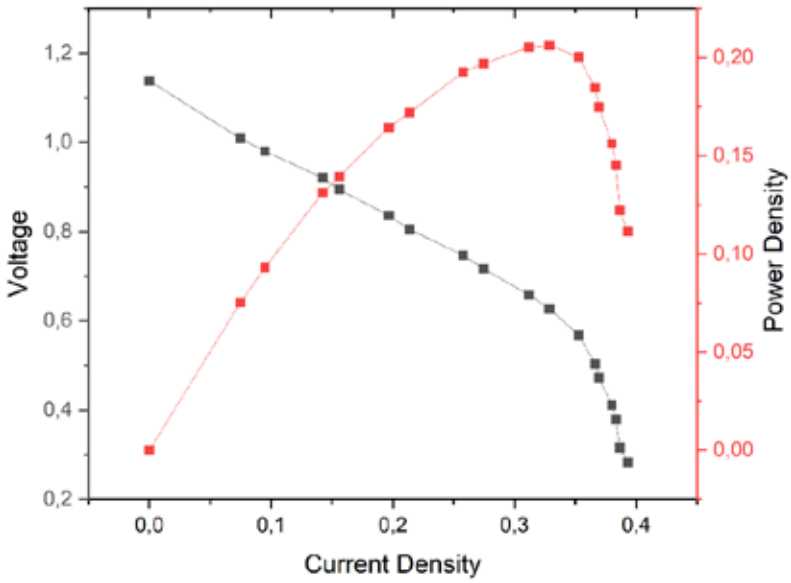

Fig. 2. Single Cell Result of Reference Setup

4. CONCLUSIONS

Hydrogen bromide redox flow battery is a promising technology in the field of energy storage, especially for large-scale applications. It offers advantages over other flow battery chemistries with its high energy density, low-cost materials and long cycle life. However, bromine handling, corrosion and membrane stability are obstacles that need to be solved. The effect of sulfonation time on the degree of sulfonation was investigated and these effects were tried to be minimized by adding PBI polymer. However, bromine handling, corrosion and membrane stability are obstacles that need to be solved. The effect of sulfonation time on the degree of sulfonation was investigated and these effects were tried to be minimized by adding PBI polymer.

ABSTRACT
The goal of this research study is to interpret the activity, stability, and selectivity of designed and developed alkali-promoted Pt-based catalysts via FTIR-DRIFTS-MS analysis. The WGS performances of Pt-Re-Na/CeO2 catalysts with different Na loadings and Pt-Re-Na/TiO_2 catalysts were examined under various reaction conditions previously. The freshly reduced and spent catalyst samples were characterized using SEM, XPS, XRD, and Raman spectroscopy. A combined analysis of the Na1s and Ce3d spectra of the highly active catalysts indicates that NaOx species likely play a more significant role than CeO_x species in the WGS reaction mechanism. *Operando* FTIR-DRIFTS-MS tests were conducted to examine surface formate and carbonate species under reaction conditions on Pt-Re-Na/CeO_2 catalysts. Metal dispersions of these catalysts were also evaluated via CO pulse experiments and were found to be consistent with the activity results.
Keywords: *Operando*, *in-situ*, FTIR-DRIFTS-MS, Characterization, WGS.

1. INTRODUCTION

Hydrogen is recognized as a vital clean and environmentally friendly energy carrier, offering significant advantages over traditional hydrocarbon fuels, including reduced greenhouse gas emissions, higher energy content, and enhanced economic viability.. *On-site* hydrogen production through Fuel Processors (FP) is considered the most promising and feasible alternative, addressing the challenges associated with hydrogenstorage. Conventional WGS catalysts do not meet the necessary performance criteria for fuel processor (FP) operation. These include maintaining high activity after repeated start-up and shut-down cycles, stable operation with oxygen and excess water in the feed, thermal stability, and low methanation activity—requirements that industrial WGS catalysts often fail to fulfill. Additionally, the two-step (HTS and LTS) WGS reactor configuration is unsuitable for small-scale hydrogen production due to its bulky nature, making up the largest portion of the fuel processor. Consequently, substantial research has been devoted to designing and developing active, non-pyrophoric, and durable platinum-group metal (PGM)-based catalysts supported by metal oxides with high activity at HTS-LTS transition temperatures, enabling the use of a single WGS reactor [1,2]. In this context, a detailed *in-situ* and *operando* FTIR-DRIFTS-MS study was performed in order to interpret the WGS reaction mechanism, and structure-mechanism-performance relation.

2. EXPERIMENTAL

FTIR-DRIFTS-MS analysis of the WGS reaction over sequentially impregnated 1%Pt-1%Re-1%Na/CeO_2 and 1%Pt-1%Re-3%Na/CeO_2 was conducted using a Bruker Vertex 70V equipped with a Mercury-Cadmium-Telluride (MCT) detector, combined with a Hiden Mass Spectrometer. The FTIR-DRIFTS setup included a Pike Technologies DRIFTS cell with a ZnSe window, a PIKE Technologies temperature controller, and Brooks mass flow controllers for the feed section, allowing thermal treatments in controlled atmospheres and spectral scans at temperatures between 20°C and 300°C. FTIR spectra were recorded with a resolution of 4 cm^{-1}, 128 scans, and a wavenumber range of 4000-800 cm^{-1}. For activity screening via MS, precise catalyst sample weight was essential, and it was ensured that each sample weighed 25±2 mg for every analysis. Catalyst samples were reduced *in-situ* under 15% H_2 containing inert (He) flow at 375°C for 2 hours before each FTIR-DRIFTS-MS analysis. In all tests, the total feed flow was maintained at 50 ml/min. Prior to analysis, a background spectrum was recorded under He flow at the analysis temperature (300°C). Spectra were collected every ten minutes over a 30-minute period, with the feed mixture sequence introduced over the catalyst surface as follows: (i) He flow for 30 minutes, (ii) 1% CO in He for 30 minutes, (iii) He flush following 1% CO adsorption for 30 minutes, (iv) 1.36% CO and 2.72% H_2Oin He as the WGS ideal feed, and (v) He flush after the WGS ideal feed for 30 minutes. Thirty-minute spectra were used for comparisons, as the surface did not reach equilibrium during the first 10 minutes but equilibrated after 20 minutes. SEM analysis was used to interpret the microstructure and morphology of freshly reduces and spent catalysts, along with their performance data under various realistic conditions. Crystalline phases were determined using a Rigaku X-ray diffractometer having an X-ray generator with Cu target and scan speed of 2°/min. Electronic interactions and oxidation states in the samples were examined with Thermo Scientific K-Alpha XPS. Raman spectroscopy was employed to observe coke formation on spent catalysts. Furthermore, Pt dispersion was quantified by CO chemisorption with Hiden Analytical CATLAB, utilizing 0.1 ml pulses of 5% CO to measure the metal available for reaction.

3. RESULTS AND DISCUSSION

In *operando* reaction tests, FTIR-DRIFTS spectra were employed to identify the reaction steps occurring on the surface, while MS data were used to evaluate catalytic activity and selectivity. A structure-mechanism-performance relationship for the WGS reaction over the Pt-Re-Na/CeO_2 system was tried to be established via comparative analysis of FTIR-DRIFTS and MS data obtained under *operando* conditions.

During CO adsorption over 1%Pt-1%Re-1%Na/CeO_2 at 300°C, a reduction in the wave number of 3643 cm^{-1} was observed in Fig. 1, but the significant reduction in the hydroxyl band around the 3540 cm^{-1} wave number, like in the case of CeO_2 support, attributed to the type III OH group was not observed, indicating other OH groups were used in product formation [3-5]. The absence of formate groups in C-H band suggest either the formate species do not form over Na containing catalysts or that they are generated, but consumed rapidly. The gas-phase CO_2 peak at 2350 cm^{-1} was observed under both CO adsorption and reaction conditions, with a more pronounced intensity under ideal WGS reaction conditions, consistent with the MS data for CO_2 and H_2 shown in Fig.2. Based on the literature, the 2026 cm^{-1} peak, observed alongside gas-phase CO peaks during CO adsorption, corresponds to linearly bonded CO on Pt, while the 2006 cm^{-1} peak at its crest is attributed to linearly bonded CO on Re [6,7]. The 1924 cm^{-1} peak is assigned to CO bridged to Pt, whereas the 1787 cm^{-1} peak corresponds to trifold-bonded CO. Linear and bridge bonded CO molecules were swept via He flush following CO adsorption, but the trifold bonded CO molecules remained on the surface indicating their stronger adsorption on the catalyst. An increase in peaks at 1787, 1613, 1267, 1076, 1038, and 855 cm^{-1}, attributed to carbonates, was observed. Additionally, the reduction in the hydrogen carbonate peak around 1420 cm^{-1} is believed to be specific to Na-containing catalysts and may result from interaction with Na [4,5,8,9]. The notable decrease in the hydrogen carbonate peak intensity in anhydrous conditions during CO adsorption suggests its active participation in the WGS reaction.

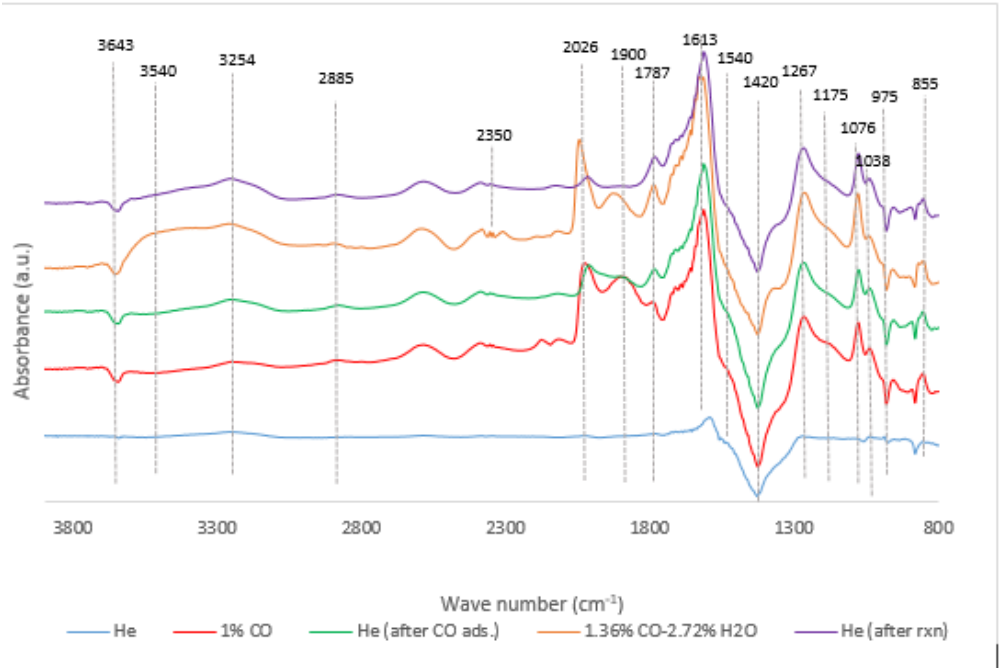

Fig. 1. FTIR-DRIFT spectra obtained over 1%Pt-1%Re-1%Na/CeO_2 at 300°C under various feed flows

After analyzing Pt-Re-Na/CeO_2 system having high WGS performance, the formulation that have shown the poorest performance, 1%Pt-1%Re-3%Na/CeO_2, was also examined under identical conditions aiming to form a comparison basis. Regarding Fig.1. and Fig. 3, while the only formate-related peak in the C-H band for 1%Pt-1%Re-1%Na/CeO_2 appeared at 2885 cm^{-1}, additional formate peaks at 2950 and 2835 cm^{-1} were detected for 1%Pt-1%Re-3%Na/CeO_2 [4,5,10]. These peaks remained unchanged throughout CO adsorption, reaction, and He flush stages. Additionally, the gas-phase CO_2 peak at 2350 cm^{-1}, which was distinctly observed for 1%Pt-1%Re-1%Na/CeO_2, was not observed in the spectrum of 1%Pt-1%Re-3%Na/CeO_2. Consistent with the WGS performance test results indicating the very low activity of 1%Pt-1%Re-3%Na/CeO_2, FTIR-DRIFTS analysis showed that the surface remained unchanged under reaction conditions. Additionally, MS data of CO_2 and H_2 signals (Fig.2.) suggest that the reaction is highly limited on the catalyst surface. The reduction of the 1420 cm^{-1} peak during the reaction over 1%Pt-1%Re-1%Na/CeO_2, in contrast to the unchanged peak under the same conditions for the essentially inactive 1%Pt-1%Re-3%Na/CeO_2, strongly suggests that these groups participate in the reaction.

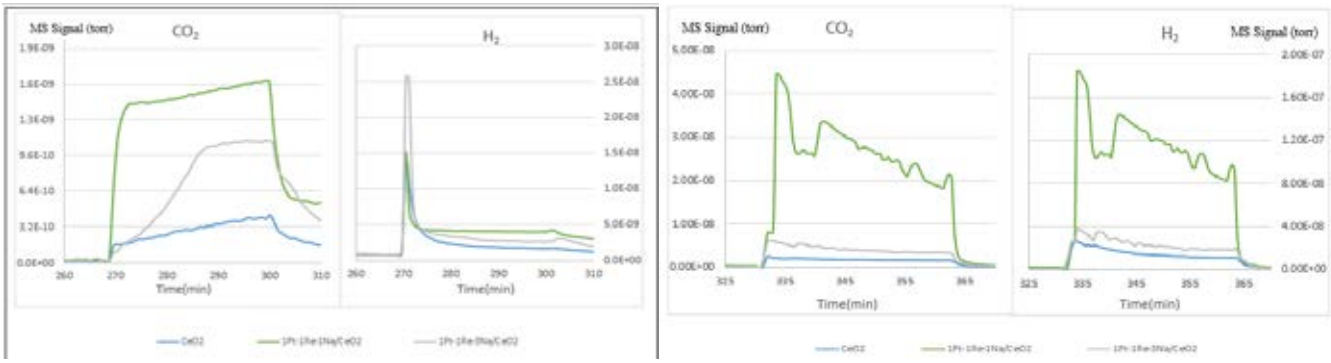

Fig. 2. MS signals of CO_2 and H_2 molecules in the exit stream of FTIR-DRIFTS system (a)during 1% CO adsorption (b) under 1.36%CO-2.72%H_2O feed flow at 300°C over in-situ reduced support and catalyst

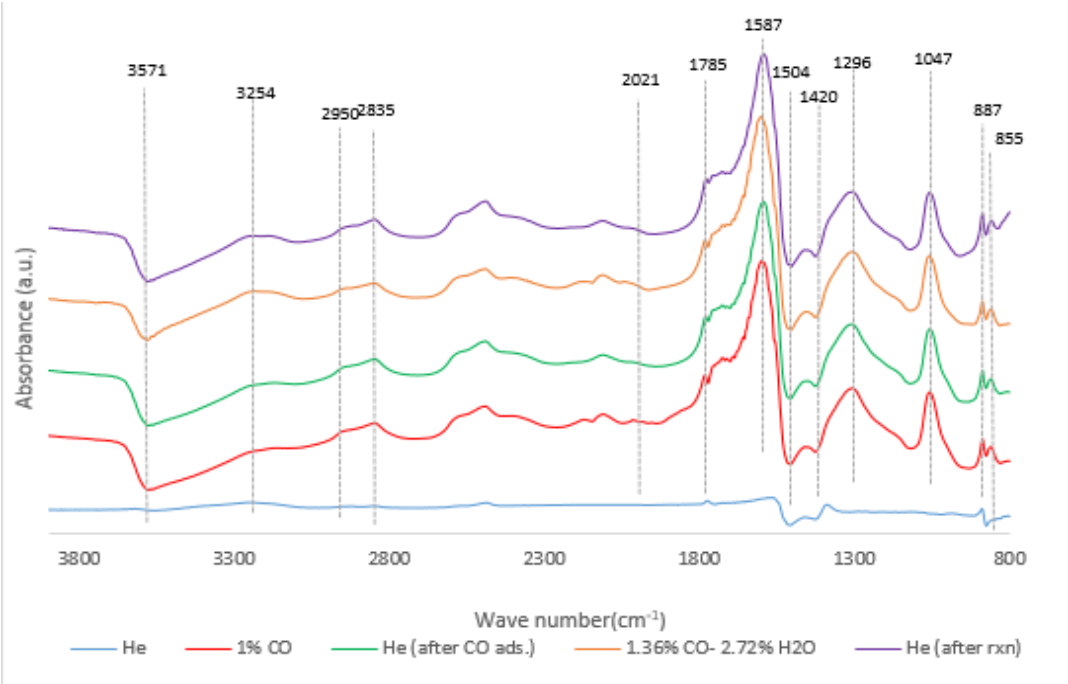

Fig. 3. FTIR-DRIFT spectra obtained over 1%Pt-1%Re-3%Na/CeO_2 at 300°C under various feed flows.

Upon examining the characterizations performed on each catalyst, homogeneous distribution of the metals were supported for Pt-1%Re-1%Na/CeO_2 sample, whereas peaks corresponding to sodium carbonate species were observed in the diftractogram of 1%Pt-1%Re-3%Na/CeO_2 catalyst. Pt4f XP spectra of the 1%Pt-1%Re-1%Na/CeO_2 and 1%Pt-1%Re-3%Na/CeO_2 confirms high WGS activity achieved over sequentially impregnated 1%Pt-1%Re-1%Na/CeO_2 and, blockage of Pt sites at higher Na loadings as in the case of 1%Pt-1%Re-3%Na/CeO_2 resulted as limited Pt^{2+} and Pt^{4+} presence and limited activity accordingly. Metal dispersion results were also correlated with the activity outcomes; specifically, the 1%Pt-1%Re-3%Na/CeO_2 sample, which showed minimal activity, exhibited nearly zero dispersion, while the sequentially impregnated 1%Pt-1%Re-1%Na/CeO_2 sample displayed quite high metal dispersion. Carbonate formation was confirmed via Raman spectroscopy analysis of spent samples.

4. CONCLUSIONS

The CeO_2 support exhibited limited WGS activity, as indicated by the barely detectable gas-phase CO_2 peak and MS data. Formate groups observed in the C-H band on CeO_2 were not present on Na-containing catalysts, which may indicate that either these groups do not form or, if formed, are consumed quickly on these catalysts. Trifold-bonded CO molecules showed stronger adsorption than linear and bridge-bonded CO, as evidenced by their persistence on the surface after a He flush. The formation of bidentate formate groups was found to be more pronounced with the addition of Na. A significant reduction in the hydrogen carbonate peak intensity during CO adsorption in anhydrous conditions suggests that these groups are actively involved in the WGS reaction. In the spectra of 1%Pt-1%Re-3%Na/CeO_2, formate

and carbonate peaks observed after CO adsorption remained unchanged during the He flush and ideal feed conditions. This result, combined with the minimal WGS activity detected via MS, suggests that formate and carbonate groups likely to play a role in the WGS reaction mechanism on Pt-Re-Na/CeO_2 catalysts.

ABSTRACT
The importance of green energy and energy efficiency has increased significantly. Hydrogen, as a green energy source, plays a crucial role in clean energy production. Due to its environmental benefits, hydrolysis of $NaBH_4$ is considered a useful production method.
The study's objective is to enhance the hydrogen generation from $NaBH_4$ with high-surface-area alumina pellets coated with various metal oxides, including Co, Cu, V, and Ru elements. The relevant metal oxides were deposited on pristine alumina pellets via the wash coating method, and hydrogen production was evaluated in an integrated continuous reactor. The results indicate that the $Co/CuV_2O_6/Al_2O_3$ catalyst exhibits promising catalytic activity, with Co significantly enhancing the catalytic performance of the CuV_2O_6 catalyst.
Keywords: hydrogen, sodium borohydride, catalyst, alumina

1. INTRODUCTION

In recent years, there has been a growing interest in replacing fossil fuels with renewable energy sources, primarly due to the non-renewable nature of fossil fuels and their harmful environmental emissions [1, 2]. Among renewable energy sources, hydrogen attracts significant attention. It is known for its high efficiency and status as a clean energy source [1-3].
Among various hydrogen production methods, hydrolysis of $NaBH_4$ is highly preferred. $NaBH_4$ has a very high hydrogen storage capacity (10.8 wt%), and its side product is sodium borate ($NaBO_2$), which is non-toxic to the environment [1, 2, 4]. However, the spontaneous hydrolysis of $NaBH_4$ is very slow and therefore needs to be supported by a catalyst [1, 2, 4]. Generally, catalysts used in hydrogen production from $NaBH_4$ include noble metals such as Pt, Pd, Ru, or Rh [1, 4, 5]. They show enhanced catalytic activity but have high costs [1, 5]. Therefore, using transition metals such as Co, Fe, Zn, Ni, Zr, Bi, Mo, Cu or V is essential in achieving high H_2 generation rates at a low cost [1, 3, 5-11]. Cu-based catalysts exhibit good catalytic activity alongside metals such as Fe, Co, and Zn [5, 6, 9, 12]. Recent research suggests that doping Cu element into a catalyst creates a synergistic effect, enhancing the catalytic activity [5, 7].
Shojaei et al. investigated the catalytic activity of Cu-Fe-B catalysts in the hydrolysis of $NaBH_4$ [6]. Their findings indicate that the presence of copper significantly enhances catalytic activity, provided the optimum amount is indicated into the catalyst.
Another study conducted by Deonikar et al. examined the effects of Cu and Mo elements on the catalytic activity of Co-based catalysts [5]. Among the tested catalysts, $Co_{0.9}Cu_{0.1}MoO_4$ catalyst exhibits the highest H_2 generation performance, demonstrating a synergistic effect between Cu and Co. Additionally, studies also show that the V element has a promising positive impact on the performance of catalysts [11, 13]. A study by Akkus examining the catalytic activity of NiV thin films revealed that V plays an effective role in enhancing the H_2 generation rate of the Ni element [13].
In this study, high-surface-area alumina pellets were coated with various metal oxides containing Cu, V, Co, and Ru-elements via the wash-coating method. The performance of all synthesized catalysts were evaluated in the hydrolysis reaction of an alkaline $NaBH_4$ solution at room temperature.

2. MATERIALS AND METHODS

2.1. Catalyst preparation

In the preparation process of the catalysts, the following metal salts were utilized to prepare each precursor solution: $Cu(NO_3)_2{\cdot}3H_2O$ (Carlo Erba), NH_4VO_3 (Alfa Aesar), and $RuCl_3{\cdot}xH_2O$ (Merck). Citric acid ($C_6H_8O_7{\cdot}H_2O$, Carlo Erba) was used as the chelating agent, and each precursor solution was prepared at a concentration of 1 M. The pH value of the solutions was adjusted to 7 using ammonia solution (NH_4OH, Carlo Erba). However, the pH of vanadium salts containing precursor solutions was adjusted to 1 by adding the citric acid. After the pH adjustment, alumina pellets maintained at a temperature of 50°C for 1 h, however, the Al_2O_3 pellets were wash-coated in vanadium-containing (Al_2O_3) were subjected to a wash coating process in the as-prepared precursor solutions within an ultrasonic bath precursor solution at ambient

temperature. After the coating process, the samples were oven-dried at 230°C. After oven drying, all catalysts were calcined in the air atmosphere for 2 h. Vanadium-containing catalysts were calcined at a lower temperature due to the lower evaporation temperature of vanadium. The nominal chemical structure of the synthesized catalysts, their respective sample codes, and calcination temperatures are listed in Table 1.

Table 1. The sample codes, nominal structure and calcination temperature for prepared catalysts

Sample codes	Nominal chemical structure	Calcination temperature (°C)	Maximum hydrogen generation rate ($mmols^{-1}g^{-1}$)
C-1	**V_2O_5/Al_2O_3**	500	-
C-2	**CuO/Al_2O_3**	700	0.001
C-3	**CuV_2O_6/Al_2O_3**	500	0.0008
C-4	**$RuO/CuV_2O_6/Al_2O_3$**	500	0.0009
C-5	**$Co_3O_4/CuV_2O_6/Al_2O_3$**	500	0.0019

2.2. Catalytic hydrolysis of $NaBH_4$

In this study, the hydrogen generation tests in the presence of all prepared catalysts were carried out in an integrated continuous system. An alkaline solution of $NaBH_4$ was fed to a reactor (filled with 1.7 g coated Al_2O_3-catalysts) by a peristaltic pump with a flow rate of 3 ml/min. Firstly, all catalysts were reduced in 0.075 M $NaBH_4$-solution and then tested at the ambient temperature by water displacement method to determine the hydrogen generation rate.

3. RESULTS AND DISCUSSION

In this study, a 0.5 M $NaBH_4$ solution was continuously fed into the reactor. Hydrogen generation was measured using the water displacement method. The hydrogen generation via $NaBH_4$ hydrolysis is represented by the following reaction (Equation (1)) [14]:

$$NaBH_4(aq)+2H_2O \rightarrow NaBO_2(aq)+4H_2(g) \quad (1)$$

The synthesized catalysts were tested under identical reaction conditions using a continuous flow pump, and their maximum H_2 generation rates are listed in Table 1. Among the tested catalysts, the catalyst C-1 shows no hydrogen production, indicating that the monometallic V coating does not improve the catalytic activity of alumina. Fig. 1a shows the H_2 generation rates over time for the catalysts C-2, C-3, C-4, and C-5, and Figure 1b shows the change in the H_2 generation rate over time of the C-5 catalyst. As shown in Figure 1a, the monometallic C-2 catalyst exhibited the highest initial rate of 0.001 $mmol.s^{-1}g^{-1}$, however, after about 8 minutes, its catalytic activity decreases significantly. Similarly, the catalysts C-3 and C-4 exhibit the same catalytic behavior, starting with a high initial hydrogen generation rate, which gradually declines over time. This suggests that Ru and V elements do not enhance the catalytic activity of the Cu element.

In contrast, the Co-doped C-5 catalyst demonstrated the most promising catalytic activity. Although C-5 exhibits a decelerating hydrogen generation rate at the beginning of the reaction, its activity increased significantly over time, distinguishing it from the others, as shown in Fig. 1b. The C-5 catalyst demonstrates superior performance to the C-4 catalyst, suggesting that the Co element enhances the catalytic activity of Cu and V elements higher than the Ru element. Based on these observations, it can be concluded that the C-5 catalyst shows considerable promise as a catalyst for H_2 generation from $NaBH_4$.

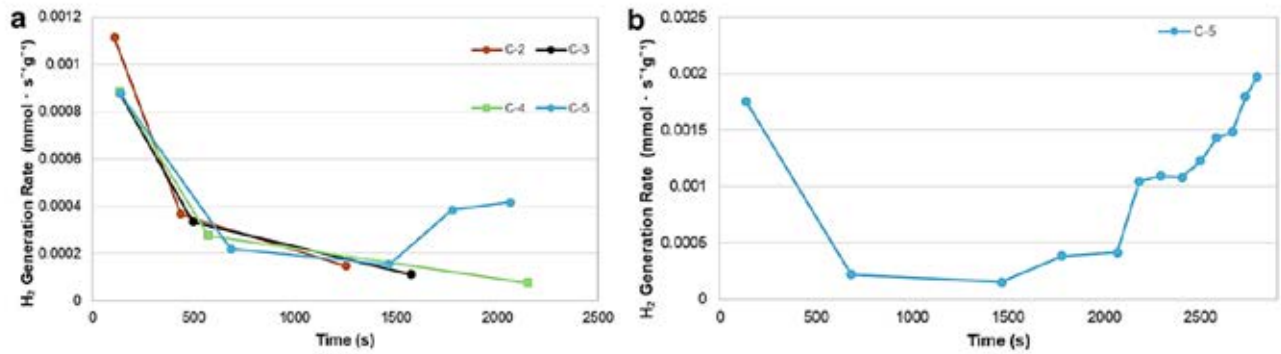

Fig. 1. (a) H_2 generation rates of the synthesized catalysts, (b) H_2 generation rate of the C-5 catalyst over time.

4. CONCLUSIONS

Alumina pellets with a high surface area are shown as effective support materials for catalysts in the hydrolysis reaction of $NaBH_4$. In this study, alumina pellets were coated with various metal oxides via the wash-coating method, and the coated pellets were tested in the hydrolysis reaction of $NaBH_4$ using the water displacement method. Among the synthesized catalysts, the vanadium oxide on the alumina sample exhibits no catalytic activity. A comparison of the initial rates of the synthesized catalysts reveals that the CuO-coated alumina catalyst (C-2) demonstrates the highest initial hydrogen generation rate among all catalysts. However, its' activity declines over time. A similar behavior is observed in CuV_2O_6 (C-3) and $RuO/CuV_2O_6/Al_2O_3$ (C-4) coated alumina catalysts. The Co-doped CuV_2O_6 (C-5) coated alumina catalyst also demonstrates a decelerating catalytic behavior. However, in the later stage of the reaction, the catalyst exhibited a significant acceleration in the hydrogen generation rate, indicating superior catalytic activity compared to the Ru-containing (C-4) catalyst. This observation suggests that the Co-doped CuV_2O_6/Al_2O_3 catalyst exhibits an enhanced catalytic activity when compared to the Ru element containing catalyst, which, despite being a noble metal, is also costly. In light of these findings, the $Co/CuV_2O_6/Al_2O_3$ catalyst emerges as a promising candidate for future studies exploring H_2 generation from $NaBH_4$, a promising option for sustainable energy research, due to its performance and cost-effectiveness.

ABSTRACT

This study investigates the integration of carbon dioxide obtained from a carbon capture facility in an oil refinery and hydrogen produced by electrolysis for methanol synthesis. The use of carbon dioxide and hydrogen in methanol production not only reduces environmental emissions but also optimizes the production cycle by recovering energy. The hydrogen production process by electrolysis includes the recovery of waste heat using a reheat Rankine cycle. This system maximizes both economic and environmental benefits by increasing energy efficiency. This study aims to provide an innovative solution by optimizing the energy and material flows in the hydrogen production, carbon capture and methanol synthesis cycle. In line with environmental sustainability goals, a thermodynamic analysis of this integrated system was performed, and a new perspective was presented in terms of renewable energy management and resource efficiency.

Keywords: Hydrogen production, carbon capture, rankine cycle, methanol production

1. INTRODUCTION

Our world needs sustainable energy solutions due to the increasing energy demand and environmental impacts of greenhouse gas emissions. One of the important goals of the Paris Climate Agreement is to limit the current global warming to just 2 ◦C [1], this limit was proposed to be reduced to 1.5 ◦C at the global meeting COP-26 to keep climate change much lower [2]. Therefore, there is a growing interest in carbon capture, utilization and sequestration to decarbonize the energy and industrial sectors as a measure to mitigate the ever-increasing greenhouse effect that causes climate change [3], [4]. Redirecting industrial plants, oil refinery wastes and emissions into convertible products not only increases environmental sustainability but also offers economic benefits [5].

Traditional fuels such as oil, wood, coal and natural gases are important non-renewable energy sources that have carbon and greenhouse gas emissions and are a major concern to be solved today [6]. Considering such a problem, we should look for a better alternative to fossil fuels that have the potential to change the rules of the game in the energy storage sector. Hydrogen has many unique properties that make it the best alternative to fossil fuels such as oil and natural gas [7]. Hydrogen is a clean, economical and extremely safe renewable energy source that would be ideal to replace fossil fuels because it is light, abundant and produces water as a by-product that does not harm the environment. The hydrogen economy has emerged as a promising alternative to the current hydrocarbon economy [8]. Hydrogen has been proven to be an alternative fuel that can replace fossil fuels due to its many features such as increased energy density, abundance, easy transportability and a variety of different processes from clean renewable energy fuels with zero or negligible emissions [9].

This study focuses on how carbon dioxide obtained from a carbon capture facility in an oil refinery and hydrogen produced by electrolysis are combined to produce methanol. The use of carbon dioxide and hydrogen in methanol production allows not only the reduction of environmental emissions but also the optimization of the production cycle by energy recovery. The electrolysis process used in hydrogen production involves the recovery of waste heat generated in the carbon capture and methanol production cycle by a reheated Rankine cycle. This integrated approach increases energy efficiency, allows its reuse in hydrogen production, and maximizes economic and environmental gains. Our study focuses on the thermodynamic analysis of this integrated process. In line with environmental sustainability goals, it aims to offer an innovative solution by optimizing the energy and material flows in the hydrogen production, carbon capture, and methanol production cycle.

2. MATERIALS AND METHODS

In this study, carbon capture, hydrogen production and methanol synthesis processes are discussed in detail using an integrated systems approach. Each stage of the processes is optimized to increase both environmental sustainability and energy efficiency. Figure 1 shows the flow chart of the optimization processes carried out in the facilities.

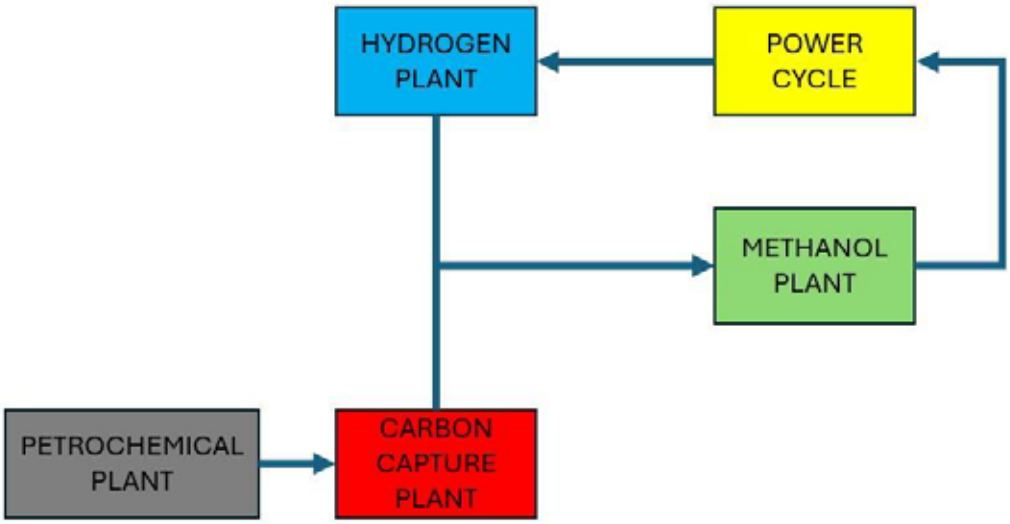

Figure 1: Flow chart of the proposed plant

The carbon capture process carried out in the Carbon Capture Facility is based on capturing carbon dioxide emissions from an oil refinery. Hydrogen production is carried out in the hydrogen facility. Electrolysis method is applied in hydrogen production. The captured carbon dioxide and the hydrogen produced by the electrolysis method are directed to the methanol facility. Methanol synthesis is carried out in this facility as a result of the chemical reaction of carbon dioxide and hydrogen. The process is optimized to provide low carbon footprint and high energy efficiency. The energy released in the methanol production process is recovered by the Rankine cycle with reheating during the power cycle phase. This energy is integrated into the system to be reused in the electrolysis process. This approach increases the total efficiency of the system by minimizing energy losses.

Thermodynamic analyses are performed to evaluate the overall performance of the system. Energy and material flows used in processes are calculated in detail and optimized. Analyses aim to increase the efficiency of the system in line with sustainable energy management goals.

3. RESULTS AND DISCUSSION

In this study, it was investigated how carbon dioxide obtained from carbon capture plants and hydrogen produced by electrolysis could be combined to produce methanol. Optimizing the energy and material flows between carbon capture, hydrogen production and methanol synthesis stages throughout the process both increased energy efficiency and contributed to the reduction of environmental emissions. The electrolysis process used for hydrogen production was supported by the energy recovered through the reheat rankine cycle. This method both recovered energy and made it possible to reuse part of the energy used in methanol production. The reuse of waste heat increased the overall energy efficiency of the system and allowed for cost reductions. This integrated approach not only saved energy but also contributed to a more sustainable design of the methanol production cycle. The use of carbon dioxide and hydrogen in methanol production has provided an effective solution for reducing environmental emissions. The use of carbon dioxide as a carbon source in this process has allowed the recycling of waste gases in energy-intensive industries. The results have shown that methanol production efficiency can be increased through the integration of energy recovery and production processes.

This study is based on the thermodynamic analysis of integrated processes between hydrogen production, carbon capture and methanol synthesis. Simulation results reveal that both economic and environmental gains can be increased by optimizing energy and material flows. In this context, this integrated approach developed in line with environmental sustainability goals stands out as an innovative solution.

4. CONCLUSIONS

Our study presents an integrated energy management model by combining carbon capture, hydrogen production and methanol synthesis processes. The results of this model show that significant gains can be achieved in terms of both energy saving and environmental sustainability. In terms of energy efficiency, the recovery of waste heat generated in the electrolysis process with the reheat Rankine cycle has significantly reduced total energy consumption. In terms of

environmental contribution, the use of carbon dioxide obtained from carbon capture facilities in methanol production has contributed to the carbon cycle and reduced emissions. In terms of economic advantages, energy recovery and integrated processes have allowed the reduction of costs and the optimization of the production cycle. This study presents an innovative production model by optimizing energy and material flows. The results show that renewable technologies such as hydrogen production and carbon capture will find a larger place in the future energy portfolio.

ABSTRACT

This study presents a comprehensive thermodynamic analysis of a synthetic energy plant designed to utilize waste heat from the blast furnace hot stoves of an iron and steel factory. The waste heat, ranging from 300-350°C, is harnessed to improve overall energy efficiency and reduce environmental impact. Initially, a carbon capture process is employed to capture CO2 emissions. The captured thermal energy is stored in a heat storage system comprising two distinct storage units operated sequentially. This stored energy is then converted into electricity, and water is electrolyzed to produce hydrogen (H2). In the methanol plant, the captured carbon and produced hydrogen are combined to synthesize methanol, a synthetic fuel. The analysis includes the evaluation of energy recovery potential, system efficiency, and the integration of advanced heat exchange technologies. Results indicate significant improvements in energy utilization and a reduction in greenhouse gas emissions, demonstrating the viability of waste heat recovery in industrial applications. This study provides a framework for optimizing energy use in heavy industries, contributing to sustainable industrial practices.

1. INTRODUCTION

In today's world, due to advancing technology and increasing population, the global demand for energy is continuously rising. Fossil fuels are being depleted rapidly, and countries are compelled to take necessary measures for energy independence. Consequently, research has been conducted to find new, renewable, environmentally friendly, and cost-effective energy sources and/or carriers. Hydrogen, the most abundant element in the universe, has emerged as the answer to these quests. Hydrogen is one of the cleanest energy carriers and the cleanest energy source that can potentially replace existing energy sources [1]. However, there are numerous challenges that need to be overcome for hydrogen to be used in daily life. Research continues on cost, efficiency, portability, transportation, and storage safety for daily applications. Despite being the fuel that provides the most chemical energy per unit mass, hydrogen poses significant storage challenges, especially in vehicles, due to its lightest and smallest molecular structure [2].

The global steel industry, responsible for approximately 8% of worldwide CO2 emissions, stands at a critical junction where environmental sustainability meets industrial efficiency. As nations worldwide strive to meet ambitious carbon reduction targets, the optimization of industrial waste heat presents a promising pathway toward greener steel production. Blast furnace operations, particularly their hot stoves, generate substantial thermal energy that traditionally dissipates into the atmosphere, representing both an environmental burden and a missed opportunity for energy recovery. At temperatures ranging from 300°C to 350°C, this waste heat carries significant potential for recovery and conversion into valuable products through innovative thermodynamic processes [3].

Previous studies have demonstrated the feasibility and benefits of waste heat recovery in industrial applications. For instance, researchers have explored the use of Organic Rankine Cycles (ORC) to convert low- to medium-grade waste heat into electricity, achieving notable improvements in energy efficiency. Other studies have focused on integrating waste heat recovery with carbon capture technologies, highlighting the dual benefits of reducing greenhouse gas emissions and enhancing energy utilization. In the context of steel manufacturing, investigations into advanced heat exchange systems have shown promise in capturing and repurposing waste heat for various applications, including electricity generation, district heating, and hydrogen production. Furthermore, the synthesis of methanol from captured carbon dioxide and hydrogen has been identified as a viable pathway for producing sustainable fuels, with studies emphasizing its potential to close the carbon loop in industrial processes [4].

Building on these advancements, this study presents a comprehensive thermodynamic analysis of a synthetic energy plant designed to utilize waste heat from the blast furnace hot stoves of an iron and steel factory. The proposed system integrates carbon capture, heat storage, electricity generation, hydrogen production, and methanol synthesis into a cohesive framework. By evaluating energy recovery potential, system efficiency, and the integration of advanced heat exchange technologies, this research aims to demonstrate the viability of waste heat recovery in industrial applications while contributing to the broader goals of energy sustainability and greenhouse gas reduction.

This study proposes the utilization of waste gas storage followed by power generation through a power cycle for the production of synthetic methanol. In the hydrogen plant, hydrogen produced via the Rankine cycle is combined with carbon dioxide removed from flue gas in the carbon capture facility to create synthetic methanol fuel. Additionally, the capture of carbon dioxide aims to reduce CO_2 emission levels.

2. MATERIALS AND METHODS

The recovery of waste heat generated from industrial activities holds significant potential. Despite this potential, industrial waste heat is currently underutilized. This study aims to store waste heat using the Thermal Energy Storage (TES) method for later use. Thermal energy storage systems are technologies developed to store energy derived from temperature differences and to utilize this energy when needed [5]. These systems typically store energy by utilizing heat exchanges occurring in liquid or solid media. Liquid storage systems store energy by heating or cooling liquids and recover the stored energy in this manner. Solid storage systems, on the other hand, store energy through the heating or cooling of materials under the influence of heat. Figure illustrates the stages of synthetic fuel production through the storage of waste heat from stoves in a blast furnace-operated iron factory, carbon capture, and H2 production, as depicted in the flow diagram [6,7].

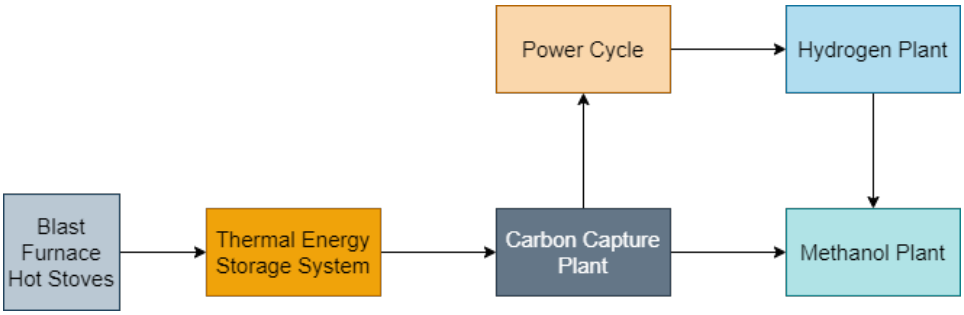

Fig. 1. General layout of the proposed plant.

The diagram represents an integrated energy system designed to enhance sustainability and efficiency by interconnecting various components. At its core, the system begins with the Blast Furnace Hot Stoves, which serve as a primary source of thermal energy. This energy is stored in a Thermal Energy Storage System, ensuring that excess heat can be utilized later to optimize energy use. The stored energy is then directed to a Power Cycle, which likely generates electricity or mechanical power, forming the central energy production hub of the system. A Carbon Capture Plant is integrated into the system to capture carbon dioxide emissions from the Power Cycle, reducing greenhouse gas emissions and promoting environmental sustainability. The captured carbon dioxide is then utilized by two downstream processes: a Hydrogen Plant and a Methanol Plant. The Hydrogen Plant likely uses carbon dioxide, along with other inputs, to produce hydrogen, a clean and versatile energy carrier. Simultaneously, the Methanol Plant synthesizes methanol, potentially using the captured carbon dioxide as a feedstock, contributing to the production of alternative fuels. This interconnected system demonstrates a closed-loop approach to energy production, carbon management, and fuel synthesis, aiming to minimize waste, reduce emissions, and promote the use of clean energy sources. By integrating thermal energy storage, carbon capture, and fuel production, the system exemplifies a forward-thinking approach to sustainable energy management [8].

3. RESULTS AND DISCUSSION

The operation of the integrated energy system depicted in the diagram yields several significant outcomes that highlight its efficiency and sustainability. By incorporating a Thermal Energy Storage System, the system effectively recovers waste heat from the Blast Furnace Hot Stoves, reducing energy losses and enhancing overall efficiency, potentially achieving energy savings of 20-30%. This stored thermal energy supports the Power Cycle, enabling stable and efficient electricity generation, with potential efficiencies reaching 50-60%, comparable to advanced combined cycle power plants. The integration of a Carbon Capture Plant further enhances the system's environmental performance by capturing 85-95% of CO_2 emissions, transforming a major pollutant into a valuable feedstock. This captured carbon dioxide is utilized downstream in the Hydrogen Plant and Methanol Plant, facilitating the production of clean hydrogen and methanol, which serve as alternative fuels and industrial feedstocks. These processes not only reduce the carbon footprint but also contribute to the circular economy by converting waste emissions into valuable products. Additionally, the system's modular design allows for scalability and integration with renewable energy sources, district heating networks, and other industrial processes, ensuring adaptability to future technological advancements and market demands. Collectively, the system exemplifies a forward-thinking approach to industrial decarbonization, achieving a balance between economic

viability, energy efficiency, and environmental sustainability.

4. CONCLUSIONS

In conclusion, this study demonstrates the significant potential of integrated energy systems in addressing contemporary industrial challenges related to energy efficiency, carbon emissions, and sustainable production. The innovative integration of Blast Furnace Hot Stoves with thermal energy storage, power generation, carbon capture, and chemical synthesis processes represents a paradigm shift in industrial process design. The results indicate that such integration can achieve substantial improvements in energy utilization while simultaneously reducing environmental impact through effective carbon capture and utilization. The system's ability to convert waste heat and captured CO_2 into valuable products, specifically hydrogen and methanol, exemplifies the practical implementation of circular economy principles in heavy industry. Furthermore, the modular nature of the system architecture ensures adaptability to future technological advances and varying industrial needs.

The findings of this study have significant implications for both industrial practitioners and policymakers. For industry, it provides a blueprint for sustainable process integration that can enhance operational efficiency while meeting increasingly stringent environmental regulations. For policymakers, it demonstrates the technical feasibility of industrial decarbonization without compromising economic viability. However, it is important to acknowledge that the successful implementation of such systems requires careful consideration of site-specific conditions, economic factors, and technological readiness levels.

Future research directions should focus on optimizing individual component efficiencies, exploring additional integration possibilities with renewable energy sources, and developing advanced control strategies for managing the complex interactions between system components. Additionally, detailed techno-economic analyses and life cycle assessments would provide valuable insights into the broader implications of implementing such systems at various scales. This study concludes that integrated energy systems represent a promising pathway toward sustainable industrial operations, though continued research and development efforts are essential to fully realize their potential.

ABSTRACT
A sectoral addiction on fossil fuels has resulted in significant energy crisis and causes greenhouse gases. Nowadays, renewable energy sources are a promising replacement for fossil fuels. Despite solar and wind energy, hydrogen is a promising energy carrier since it doesn't have limitations like place or time. In this research, solid state hydrogen storage tested with activated charcoal powder. Under a constant hydrogen flow of 2.0 L/min; 2.5 g, 3.5 g, and 5.5 g of activated charcoal were used in experiments for hydrogen storage in cylindrical cells. Results showed that the hydrogen storage was in the range of 1.95 to 4.05 wt%. Overall, considering the results it can be concluded that activated charcoal is a promising solid state energy storage material with its porous structure, surface area, and low cost.

Keywords: Hydrogen storage; Solid state storage; Activated charcoal; Renewable energy; Energy storage

1. INTRODUCTION
The number of concerns about climate change has increased over time due to energy production. Nowadays, new sustainable and green ways to produce energy have been placed such as hydrogen production. Although Hydrogen seems like a potential energy carrier for future generations, there are couple of things to consider such as storage techniques and applications. Cryogenic liquid storage systems and compressed gas tanks are the main basis for traditional hydrogen storage technologies. Although these techniques are widely used in industry, they provide some difficulties. Compressed gas storage, for example, needs high pressure around 700 bars, which causes safety issues. Liquid hydrogen storage is another way to store hydrogen. Although it's good for high-density storage, cryogenic storage requires extremely low temperatures (-253°C), hence increasing energy usage and equipment expenses [1]. Solid State hydrogen storage, on the other hand, is a promising way to store hydrogen safely [2].
In recent years, there has been an increase in the popularity of hydrogen storage in porous materials. Solid state hydrogen storage needs porous structure and extensive surface area materials, such as metal hydrides, complex hydrides, and carbon materials. These materials are a great choice for their capacity to storage physical hydrogen at reduced pressures and ambient temperatures. Carbon-based materials, including activated carbon, graphene, and carbon nanotubes, are promising materials for hydrogen storage applications due to their high surface area, tunable porosity, and chemical stability [3]. The substantial internal surface area of activated charcoal improved adsorption of hydrogen molecules, rendering it a suitable option for hydrogen storage applications.
In this regard, this study aims to hydrogen storage using activated charcoal as a sustainable and green storage material. The hydrogen storage capacity of activated charcoal is evaluated for different activated charcoal dosages (2.5, 3.5, and 5.5) by the analysis of mass differences in ambient conditions. Consequently, this study revaled that the utilization of carbon-based waste resources can be a promising option for hydrogen storage with waste minimization.

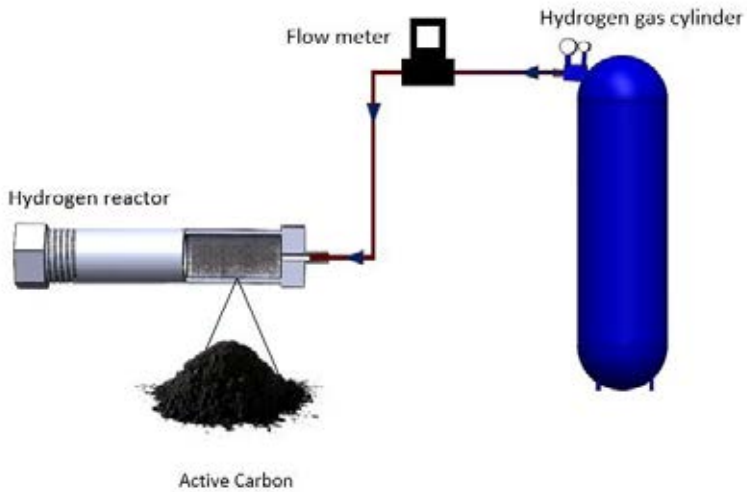

Fig. 1. Experimental setup for solid-state hydrogen storage using activated charcoal.

2. MATERIALS AND METHODS

In this paper, hydrogen storage capabilities of activated charcoal have been studied by changing the mass of the powder amount. The experimental set-up of the hydrogen storage system with its subsystems (hydrogen gas cylinder, flow meter and activated charcoal) is presented in Fig 1. Hydrogen gas has been fed into the reactor with the specified flow rate of 2.0 L/min and pressure of 400 kPa. The activated charcoal samples (2.5 g, 3.5 g, and 5.5 g) were placed into the reactor, and hydrogen gas was fed 3 times for 90 seconds for 1 h. All experiments are repeated for 3 times for each mass. Furthermore, the gravimetric analysis is used to measure the amount of stored hydrogen in activated charcoal with physosorbtion in wt%. Therefore, initial and final masses are recorded for each sample.

3. RESULTS AND DISCUSSION

The effect of activated charcoal dosage on hydrogen storage capacity is evaluated and presented in Fig. 2. As expected, the hydrogen storage capacity is increased with the increasing activated charcoal dosage. For instance, the activated charcoal dosage of 2.5 g had an average hydrogen storage efficiency of 1.95 wt%, while it was 2.85 wt% for 3.5 g and the 4.05 wt% for 5.5 g activated charcoal dosage. These results proved that the 5.5 g had the best storage rate. This indicates that the increase of mass can affect the physical hydrogen storage capacity positively most probably due to expanded surface area and improved gas diffusion.

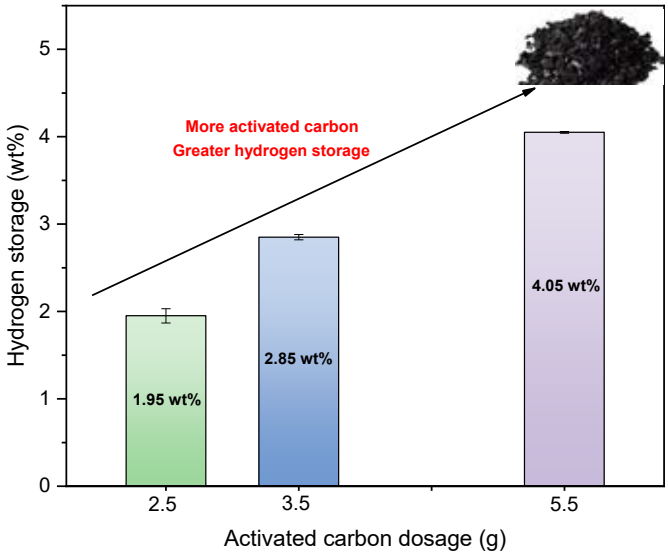

Fig. 2. Hydrogen storage capacity at different activated charcoal dosages.

Overall, these results showed that activated charcoal could be useful as an effective, affordable option for hydrogen storage applications. Future research will investigate the effects of extended exposure periods and metal-loadings on carbon-based materials to enhance storage performance.

4. CONCLUSIONS

This study experimentaly investigated the hydrogen storage performance of the activated charcoal as a sustainable material, considering waste minimization. Our results proved that activated charcoal has potential as a solid-state hydrogen storage material. The 5.5 g sample showed the highest hydrogen storage efficiency with an average of 4.05 wt%, exceeding the 2.5 and 3.5 g samples results. This indicates that the adsorption capacity of activated charcoal increases with increasing mass, likely because of an increased surface area and enhanced gas diffusion. Overall, these findings indicated that activated charcoal can serve as an efficient, economical alternative for hydrogen storage applications.

ABSTRACT

The growing demand for efficient hydrogen storage solutions to reduce the reliance on fossil fuels has sparked considerable interest in nanostructured materials. This study explored the hydrogen storage potential of lithium-decorated porous germanene using first-principles density functional theory (DFT) calculations. Through an analysis of the adsorption sites, binding energies, and charge transfers, the optimal Li-decorated configurations for enhanced hydrogen adsorption were identified. Results show that porous germanene functionalized with six lithium atoms (three above and three below the monolayer) achieves exceptional stability with adsorption energy of 2.39 eV and minimal structural distortion. The maximum hydrogen adsorption capacity of the three H_2 molecules per Li atom was observed with favorable adsorption energies (0.214–0.280 eV) and charge transfer values (0.710–1.113 |*e*|). This study highlights the potential of Li-decorated porous germanene for advanced hydrogen storage applications.

Keywords: Germanene, 2D materials, Hydrogen storage, Energy storage, Porous

1. INTRODUCTION

The emission of greenhouse gases such as carbon dioxide (CO_2) and nitrogen oxides (NO_X) during combustion makes fossil fuels the major contributor to environmental pollution and climate change [1,2]. Therefore, the development and study of cleaner energy sources are critical issues for the scientific community. Thus, hydrogen is a promising alternative as a clean and efficient energy source, and its use in fuel cells produces only water as a by-product [3]. However, its low density and high volatility make its practical use difficult, making its storage and transportation a great challenge.[4].
Nanostructured materials have shown great potential for addressing these challenges and offering efficient and safe hydrogen storage solutions. For instance, porous nanomaterials, carbon nanotubes, and two-dimensional (2D) materials exhibit enhanced interactions with hydrogen, making them ideal candidates for energy-storage applications [5-7]. Among these, porous materials are particularly promising owing to their high specific surface area, which can improve the adsorption and desorption of hydrogen, thereby enhancing the storage capacity and efficiency [8]. Moreover, two-dimensional (2D) materials such as graphene have attracted significant attention for hydrogen storage owing to their exceptional electronic properties, flexibility, and high surface area [9]. Particularly, germanene, a single layer of germanium atoms arranged in a honeycomb lattice, has recently emerged as a promising candidate for energy-storage applications [10]. However, despite its potential, the application of porous germanene in hydrogen storage remains largely unexplored.
In this study, we investigated the hydrogen storage capabilities of Li-decorated porous germanene using theoretical calculations. Specifically, we explored double-sided Li-porous germanene adsorption schemes to evaluate their hydrogen storage performances. Our findings not only provide a deeper understanding of the storage properties of Li-porous germanene but also offer valuable insights for the experimental development of porous 2D nanomaterials for hydrogen storage applications.

2. COMPUTATIONAL METHOD

In this study, all calculations were performed using the spin-polarized first-principles method within the framework of Density Functional Theory (DFT) [11, 12], as implemented in the SIESTA code [13, 14]. For exchange and correlation interactions, the Perdew–Burke–Ernzerhof (PBE) functional in the generalized gradient approximation (GGA) was employed [15]. Additionally, the structures of the studied systems were relaxed until the forces between the atoms reached < 0.01 eV/Å. Furthermore, the Brillouin zone was sampled using 4 × 4 × 1 and 24 × 24 × 1 Monkhorst-Pack k-point meshes [16] for geometry relaxation and electronic property calculations, respectively. To account for van der Waals interactions, long-range Grimme DFT-D2 dispersion corrections [17] were applied with double-ζ polarized basis sets alongside norm-conserving Troullier–Martins pseudopotentials [18, 19]. Subsequently, the Hirshfeld population analysis [20] was used. To ensure accuracy, the basis set superposition error (Δ_{BSSE}) was addressed using the counterpoise method [21]. Finally, the VESTA program [22] was used to visualize the electron densities and optimized geometric structures.
The binding energy (E_B) was calculated using the following equation [7]:

$$E_B = -E_{Li-PGermanene} + E_{Li} + E_{PGermanene} + \Delta_{BSSE} \quad (1)$$

where $E_{Li-PGermanene}$ is the total energy of the Li-decorated porous germanene unit cell, E_{Li} is the total energy of an

isolated Li atom, $E_{\mathrm{PGermanene}}$ is the total energy of the porous germanene, and Δ_{BSSE} is the basis set superposition error. Similarly, the adsorption energy (E_{A}) per hydrogen molecule is given by [7]

$$E_{\mathrm{A}} = \left[-E_{\mathrm{H_2-Li-PGermanene}} + nE_{\mathrm{H_2}} + E_{\mathrm{Li-PGermanene}} + \Delta_{\mathrm{BSSE}} \right] / n \quad (2)$$

where $E_{\mathrm{H_2-Li-PGermanene}}$ is the total system energy including the H_2 molecules adsorbed on the Li-decorated porous germanene, $E_{\mathrm{H_2}}$ is the total energy of an isolated hydrogen molecule, $E_{\mathrm{Li-PGermanene}}$ is the total energy of the Li-decorated porous germanene, and *n* is the total number of adsorbed hydrogen molecules. A positive sign of E_{A} indicates that the system is stable, where a larger value indicates stronger adsorption of H_2 molecules on the Li-decorated porous germanene.

3. RESULTS AND DISCUSSION

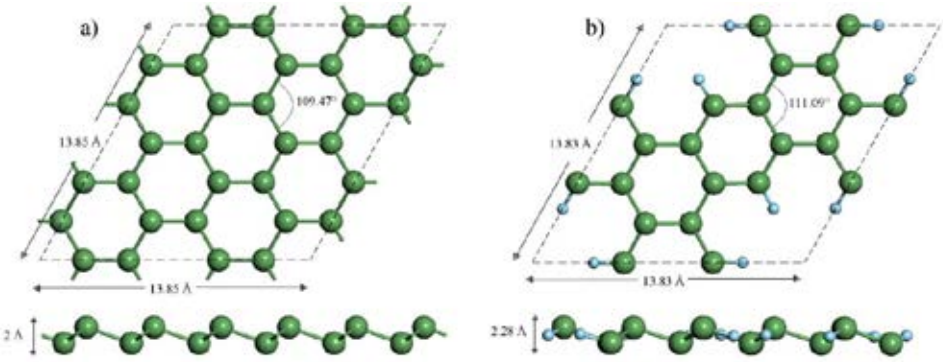

Fig. 1. Top and side view of a) pristine germanene and b) porous germanene.

As shown in the optimized structures of pristine germanene (Fig. 1a) and porous germanene (Fig. 1b), the inclusion of pores reduces the unit cell lattice size from 13.85 Å to 13.83 Å. Specifically, this structural modification introduces minor deformations in the framework of the material. Additionally, the surface roughness increases from 2.0 Å to 2.28 Å, indicating that porosity alters both the geometric and surface properties of germanene.

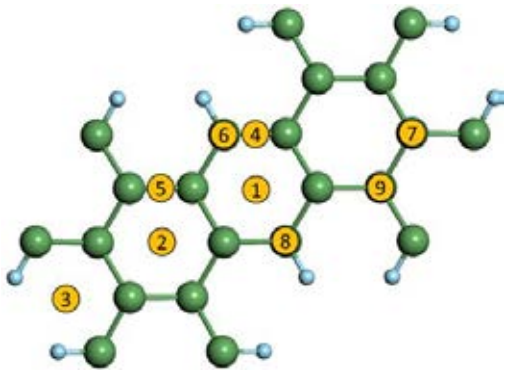

Fig. 2. All possible adsorption sites (1-9) for a Li atom onto porous germanene.

Table 1. Binding energy (E_B) and charger transfer (Q_H) values for nine proposed adsorption sites for one Li atom in porous germanene.

Initial Site	Final Site	E_B (eV)	Q_H (|e|)
1	1	2.1984	0.227
2	2	2.0544	0.219
3	3	2.3303	0.258
4	9	1.9172	0.299
5	9	1.9174	0.302
6	1	2.1978	0.232
7	1	2.1959	0.361
8	3	2.3299	0.248
9	9	2.3302	0.306

Based on the geometric arrangement of the unit cell depicted in Fig. 1b, nine potential adsorption sites (Fig. 2) were identified to determine the optimal locations for monolayer functionalization. Moreover, to analyze the best adsorption site, a Li atom was adsorbed at each site, and E_B and Hirshfeld charge transfer (Q_H) were calculated and are shown in Table 1. The binding energy (E_B) varied across the nine proposed adsorption sites for Li atoms in the porous germanene. Notably, site 3 exhibited the highest E_B value (2.33 eV, accompanied by a charge transfer (Q_H) of 0.258 |*e*|. In comparison, sites 1 and 9 show slightly lower E_B values of 2.20 eV and 2.33 eV, respectively. Based on these results, site 3 (Fig. 2) was selected as the optimal reference for Li incorporation, with Li atoms occupying equivalent positions within the unit cell to maximize stability and adsorption efficiency.

Table 2. Adsorption energy (E_A), average Ge–Li distance (β), and charge transfer (Q_H) for the porous germanene decorated with Li atoms, from 1 up to 6 Li atoms.

Metal adatom	*n*Li	E_A (eV)	β(Å)	Q_H (|e|)
Li	1	2.330	2.764	0.258
	2	2.270	2.791	0.277
	4	2.328	2.813	0.264
	6	2.390	2.788	0.252

Following the selection of the optimal adsorption site, Li atoms were systematically introduced into the identified positions to ensure uniform decoration and maximize the stability of the Li-functionalized porous germanene framework. The configuration of porous germanene functionalized with six Li atoms was selected as optimal because it exhibited the highest E_A (2.39 eV) among the tested systems (Table 2). Notably, this value surpasses those observed for lower Li-loading configurations, indicating enhanced stability of the Li-decorated framework at higher Li coverage. Furthermore, the average Ge–Li bond distance (β=2.78 Å) remains consistent across Li addition, suggesting minimal structural distortion despite increased Li incorporation. Interestingly, the charge transfer (Q_H=0.252 |*e*|) decreased slightly compared with configurations with fewer Li atoms (e.g., Q_H=0.258e for one Li atom), implying a saturation effect in electron donation from Li to the germanene substrate. These results collectively highlight that the 6 Li-atom configuration balances strong binding, structural integrity, and sufficient charge redistribution for its use in energy storage applications.

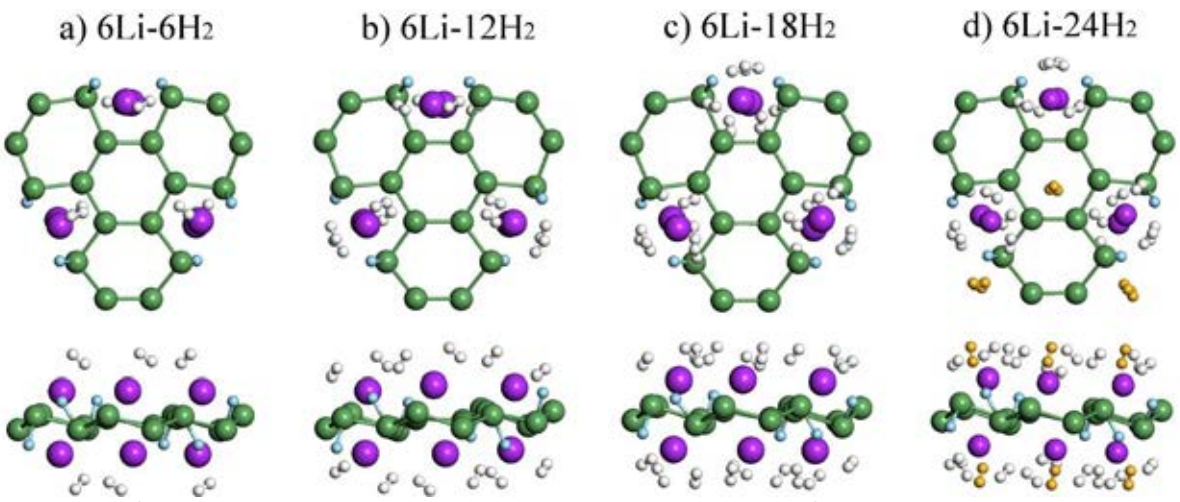

Fig. 3. Top view of the optimized porous germanene with double-sided adsorption of hydrogen molecules per Li atom. The H_2 molecules marked in yellow did not adsorb on Li atom.

Building on Li-decorated porous germanene with six Li atoms (three above and three below the monolayer), hydrogen adsorption was systematically modeled by incrementally adding 1 to 4 H_2 molecules per Li atom (Fig. 3). As shown in Table 3, E_A decreased progressively from 0.280 eV (1 H_2/Li) to 0.196 eV (4 H_2/Li), indicating reduced stability with higher H_2 loading. Notably, at 3 H_2 molecules per Li atom, the system achieved optimal adsorption parameters: E_A=0.214 eV, Q_H = 1.096 |*e*|, and average H_2–Li distance (β) of 2.03 Å. However, when a fourth H_2 molecule is introduced (Fig. 3d, highlighted in yellow), one molecule displaces with a value of β=2.57 Å, leaving only 3 molecules adsorbed per Li atom. This saturation limit aligns with the weak E_A (0.196 eV) observed in Table 3, suggesting that 3 H_2/Li represents the maximum capacity before destabilization occurs.

Table 3. Adsorption energy (E_A), charge transfer (Q_H), and average H_2–Li distance (β) in porous germanene decorated with Li atoms.

nH_2 per Li atom	E_A (eV)	Q_H (|e|)	β(Å)
1	0.280	0.710	1.96
2	0.237	0.964	2.00
3	0.214	1.096	2.03
4	0.196	1.113	2.57

4. CONCLUSIONS

This study examined the hydrogen storage capabilities of Li-decorated porous germanene using DFT calculations. The introduction of pores into the germanene structure reduces the lattice parameters and increases the surface roughness, thereby improving its adsorption properties. The optimal lithium adsorption site, Site 3, demonstrates a binding energy of 2.33 eV, with the configuration of six lithium atoms (three above and three below the monolayer) showing superior stability and consistent Ge–Li bond distances (~2.78 Å). The system can adsorb up to three hydrogen molecules per lithium atom, with stable adsorption energies ranging from 0.214 to 0.280 eV and hydrogen-lithium distances of approximately 2.03 Å. The fourth hydrogen molecule causes displacement, indicating the saturation limit of the system. Progressive charge transfer, ranging from 0.710 to 1.113 e, highlights the role of electron donation in stabilizing the hydrogen interactions. These findings suggest that Li-decorated porous germanene holds significant promise as a high-capacity material for hydrogen storage, offering key insights for future development in this field.

ABSTRACT

Methane, the major component of natural gas, shale gas, and combustible ice, is widely spread throughout nature. Direct conversion and efficient methane usage have emerged as a major research topic. However, two fundamental hurdles remain: activating methane and avoiding overoxidation. Recently, research in this sector has reached a critical point. This paper proposes a novel three-step cycle for direct methane to methanol conversion at comparatively lower temperatures than conventional technologies. Furthermore, based on the proposed cycle, this article reports the thermodynamic assessment of a three-step electro-thermochemical process for methane to methanol conversion. The analysis concluded that the energy and exergy efficiencies of the proposed system are 24.1-24.3% and 29.2-29.4%, respectively.

1. INTRODUCTION

Methane is abundant on earth, serving as a primary energy source and a significant element in a variety of businesses. However, it is the second-largest contributor to greenhouse gas emissions after carbon dioxide and hence plays an important role in global warming [1]. Converting methane into useful products or cleaner energy is critical for a sustainable future. Currently, two large-scale methods- methane-to-gasoline and Fischer-Tropsch synthesis-are used to produce methanol or liquid fuels from methane. However, both require a high-energy step known as steam reforming, which converts methane into synthesis gas (a mixture of carbon monoxide and hydrogen) before converting it into the desired chemicals. Methanol is an essential commodity with numerous applications, including use as a solvent in chemical industries as a fuel in the energy sector. Methanol, sometimes known as clean coal has a high-octane value of 113, making it acceptable as a fuel or gasoline additive. The need for methanol is rising, particularly in the automotive industry. The global methanol market was valued at $30.9 billion in 2023, and it is predicted to increase at a 4.2% annual pace to $38.0 billion by 2028 [2].

At present, about 90% of methanol is manufactured by converting various carbon sources into syngas, which needs extremely high temperatures (800-1000 °C). In the following step, syngas is converted to methanol at a lower temperature. This process requires a lot of energy, rapid temperature fluctuation, several processes, and a lot of carbon waste, stressing the need for a simpler and more efficient solution [3]. Direct methane to methanol conversion (DMTM) is a viable option with numerous benefits. It simplifies the process and lowers the total cost of commercial methanol production. DMTM uses an effective catalyst, which reduces temperature, prevents catalyst damage, and saves energy. Additionally, it reduces carbon waste and CO_2 emissions, making it more environmentally friendly and sustainable. However, directly converting methane to methanol is difficult. Methane is an extremely stable molecule with strong C-H bonds (438.8 kJ/mol), which makes it difficult to break. Furthermore, because methanol is more reactive than methane, controlling its overoxidation into undesirable products such as formaldehyde or formic acid remains a significant issue in DMTM conversion [4]. This study analyses and reports the thermodynamic assessment of a novel three-step cycle for direct methane to methanol production.

2. METHODOLOGY

The reactions involved in the three-step cycle are shown in Table 1. The data, such as enthalpy and change in Gibbs free energy of reactions, is obtained from HSC 10.5.3.0 chemistry software. Based on the values provided by HSC chemistry, the energy and exergy efficiencies of the proposed cycle are evaluated using equations 1 and 2, respectively. The energy and exergy required for the cycle are calculated based on the electricity required for the electrolysis process. It is assumed that the electricity is drawn from solar PV with an efficiency of around 20%.

$$\eta_{STF,\ energy} = \frac{(n_{CH_3OH} \times LHV_{CH_3OH}) + (n_{H_2} \times LHV_{H_2})}{(n_{CH_4} \times LHV_{CH_4}) + Electricity\ required} \quad (1)$$

$$\eta_{STF,\ exergy} = \frac{(n_{CH_3OH} \times ex_{CH_3OH}) + (n_{H_2} \times ex_{H_2})}{(n_{CH_4} \times ex_{CH_4}) + Electricity\ required} \quad (2)$$

Table 1. Reaction involved in the three-step cycle

Step 1 (CH_4 Bromination)	$CH_4(g) + 2H_2O(g) + 4Br_2(g) \xrightarrow{200-250\,°C} 8HBr(g) + CO_2(g)$ ΔH<0
Step 2 (Electrolysis)	$8HBr(g) \xrightarrow{200-250\,°C} 4H_2(g) + 4Br_2(g)$ ΔG>0
Step 3 (CO_2 Hydrogenation)	$CO_2(g) + 3H_2(g) \xrightarrow{200-250\,°C} CH_3OH(g) + H_2(g)$ ΔH<0
Overall	$CH_4(g) + H_2O(g) \rightarrow CH_3OH(g) + H_2(g)$

3. RESULTS AND DISCUSSION

The analysis shows that both energy and exergy efficiencies decrease with an increase in temperature. This is because the electricity required for step 2 is more at higher temperatures. The maximum energy and exergy efficiencies are found to be 24.3% and 29.4%, respectively, at 200 °C. Furthermore, the variation of energy and exergy efficiencies with different operating temperatures has been depicted in Fig. 1. Additionally, some key parameters have been found and shown in Table 2.

Table 2. Key parameters found after the analysis

Parameter	Values
Solar to fuel energy efficiency (%)	24.1-24.3
Solar to fuel exergy efficiency (%)	29.2-29.4
Temperature of the cycle (°C)	200-250
Operating voltage of the electrolyser (V)	0.7

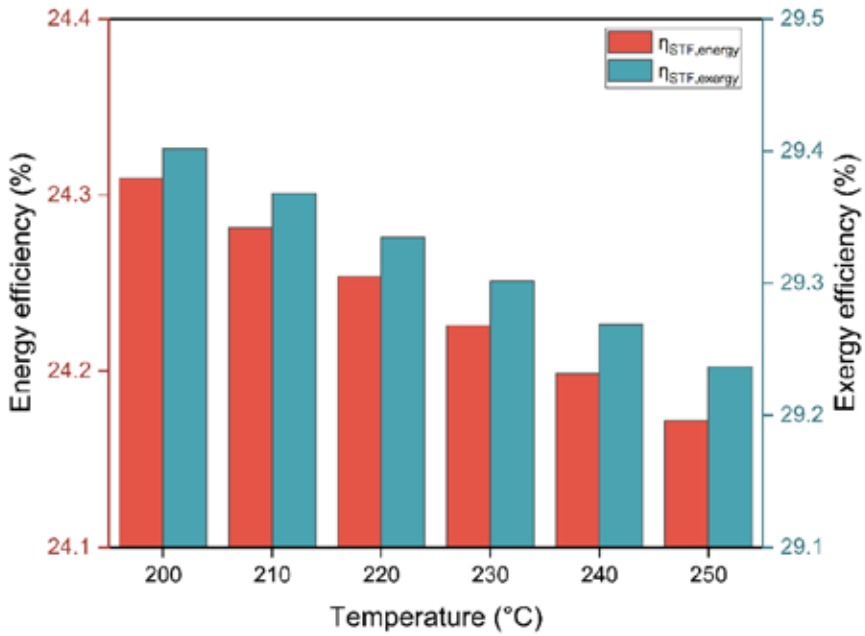

Fig. 1. Variation of energy and exergy efficiencies with different temperatures of cycle.

4. CONCLUSIONS

In this study, a novel method for producing methanol and hydrogen using methane and water as feedstock based on the three-step cycle is proposed and analysed. After doing the thermodynamic analysis, the maximum energy and exergy efficiencies of the mentioned cycle are calculated as 24.3% and 29.4%, respectively. This study can be utilised as an alternative way for producing methanol at lower temperatures and lead to the opening of new avenues for methanol production. The result shows that the proposed cycle can be efficiently integrated with renewable energy sources like concentrated solar power, waste heat, and nuclear reactors.

ABSTRACT

A sustainable future depends on switching from fossil fuels to renewable, carbon-neutral, or decarbonized fuels. Fuels made from biomass are becoming more widely acknowledged for their ability to cut carbon emissions, pollutants, and particulates. There are numerous ways to produce value-added products using biomass through different techniques such as pyrolysis, hydrothermal liquefication, and molten salt electrolysis, etc. This study reports the energy efficiency and exergy efficiency of a novel method for hydrogen (H_2) and methane (CH_4) production using lignin through molten salt electrolysis. The analysis has been done for two different electrolysis parameters, i.e. temperature and current supplied during the electrolysis. The electrolysis temperature varies between 280 to 340°C, and the current supplied during the electrolysis ranges from 0.1 to 0.4 A. After doing the thermodynamic analysis, it has been reported that the total energy efficiency and total exergy efficiency of the mentioned method increases with increases in the current supplied. The highest total energy and exergy efficiencies of 11.2% and 11.3% have been achieved at 0.4 A current supplied.

Keywords: Lignin, Hydrogen, Methane, Molten salt electrolysis, Energy efficiency, Exergy efficiency

1. INTRODUCTION

The world's population grows, and so does the use of fossil fuels, leading to increased anthropogenic greenhouse gas emissions and global warming. Environmental problems, energy crises, and resource depletion arise from scoring 2015 World Energy Statistical Review [1]. These reserves account for around 85% of the total energy demand, and a sustainable solution is a pressing issue [2]. Scientists are researching new environmentally friendly renewable fuel sources to replace fossile fuels. Hydrogen, methane, and biodiesel represent the most potential renewable energy sources [3]. Biomass, a renewable resource, has significant application potential due to its high yields. India has the second-largest agricultural biomass supply, with an estimated 990 million metric tonnes (MMT) available yearly. India creates around 160,038.9 tons of municipal solid trash per day, providing a significant source of biomass [4]. Biomass conversion processes, including hydrothermal liquification, gasification, and pyrolysis, are energy-intensive and have limited selectivity, efficiency, and environmental sustainability [5]. The most popular method for creating hydrogen is based on natural gas or other fossil fuels, which require a lot of energy and a significant amount of carbon dioxide into the environment [6]. Innovative technology, such as biomass to hydrogen conversion, is necessary to accelerate the energy transition. Hydrogen can be produced from biomass using various biological, electrochemical, thermochemical, and hybrid processes. Utilizing biomass energy, which is regarded as a green source with nearly negligible carbon emission, is an alternative to getting hydrogen.
This paper explores an innovative approach that utilizes a thermo-electrochemical process for sustainable value-added products using lignin. H_2 and CH_4 are produced by the molten salt electrolysis of lignin at high temperatures. Furthermore, the analysis of the findings indicates the energy and exergy efficiencies of the proposed method.

2. SYSTEM DESCRIPTION AND ANALYSIS

This work evaluates the thermodynamics of a novel method for producing hydrogen and methane from lignin using molten salt electrolysis, as reported in [7]. They utilise 1 g of lignin with 17 g NaOH and 13 g KOH for performing the experiments. The analysis is done based on the different reaction temperatures and currents supplied during the electrolysis. The electrolysis temperature varies between 280 to 340°C with the step of 20°C while the current ranges between 0.1 and 0.4 A with the step of 0.1 A. Applying an electric current at a specific temperature facilitated the electrochemical reaction, producing hydrogen (H_2) and methane (CH_4), as shown in Figure 1. The heat and electricity required for the electrochemical reaction are calculated using equations 1 and 2, respectively. The energy efficiency and exergy efficiency of the method are evaluated using equations 3 and 4 based on the current supplied. Table 1 shows the amount of H_2 and CH_4 produced during the process, based on the data from [7].

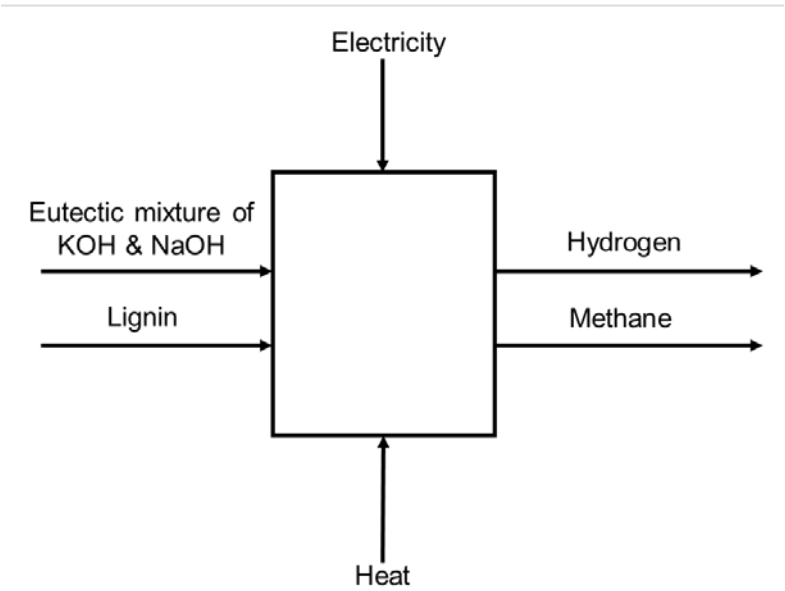

Fig. 1. Schematic diagram of high-temperature electrolysis process for lignin conversion

$$Q_{heat} = m_{Lignin} \times C_p \times \triangle T \quad (1)$$

$$W_{electricity} = I \times V \times t \quad (2)$$

$$\eta_{total\ energy} = \frac{(m_{H_2} \times LHV_{H_2}) + (m_{CH_4} \times LHV_{CH_4})}{(m_{Lignin} \times LHV_{Lignin}) + Q_{heat} + W_{electricity}} \quad (3)$$

$$\eta_{total\ exergy} = \frac{(m_{H_2} \times ex_{H_2}) + (m_{CH_4} \times ex_{CH_4})}{(m_{Lignin} \times ex_{Lignin}) + Q_{heat}\left(1 - \frac{T_0}{T_{reaction}}\right) + W_{electricity}} \quad (4)$$

where m is the mass (kg), C_p is the specific heat capacity of lignin (J/kg.K), $\triangle T$ is the temperature difference, I is the current supplied (A), V is the voltage supplied (V), t is the electrolysis time (sec), LHV is the lower heating value (J/kg), ex is specific exergy (J/kg), T_0 is the ambient temperature, and $T_{reaction}$ is the reaction temperature.

Table 1. Correlation between current (A) Hydrogen and Methane production

Current (A)	Hydrogen (mL)	Methane (mL)
0.1	67.5	13
0.2	145	14
0.3	196	14
0.4	247	14.5

3. RESULTS AND DISCUSSION

According to the investigation results, the total energy and exergy efficiencies of the mentioned method increase with increases in the current. This is because at higher currents, losses are less, resulting in improved energy and exergy efficiencies. The maximum total energy and exergy efficiency of 11.2% and 11.3% have been achieved at 0.4 A of the current supply. The energy efficiency and exergy efficiency of the current system details are illustrated in Figure 2. Furthermore, some key parameters have been calculated and reported in table 2.

Table 2. Key parameters found after the analysis

Parameter	Values
Energy efficiency of the overall process (%)	4.3-11.2
Exergy efficiency of the overall process (%)	4.4-11.3
Temperature of the process (°C)	280-340
Operating voltage of the process (V)	1 V

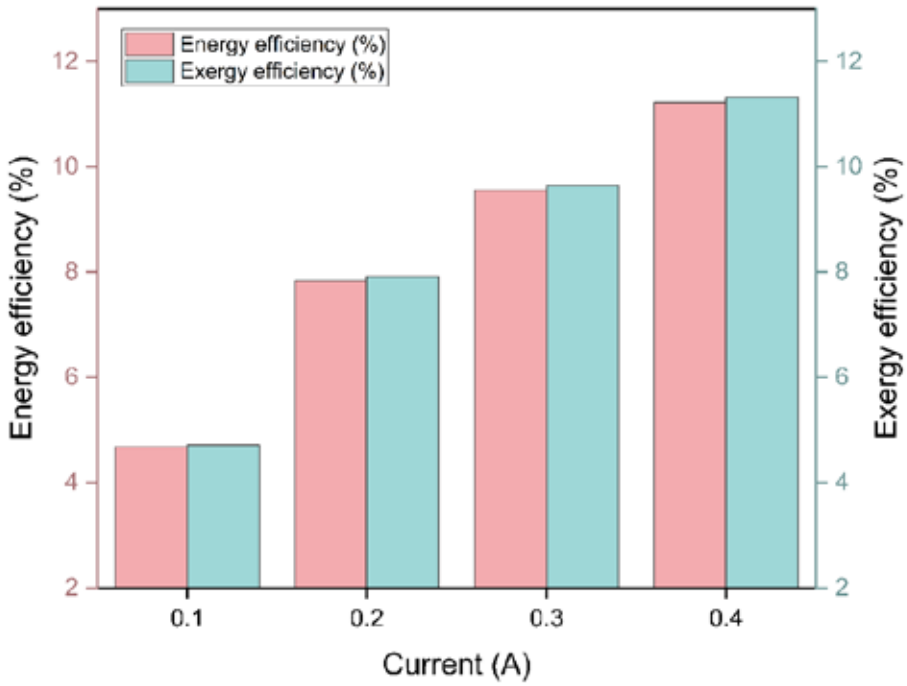

Fig. 2. Energy efficiency and exergy efficiencies variation with current

4. CONCLUSIONS

The need to produce carbon-neutral and renewable resources-based products is increasing. In this regard, biomass, which is cheap and abundant, can be the primary raw material that satisfies these requirements. It is comparatively less expensive in terms of energy. Using lignin and a thermo-electrochemical process, this study offers a novel concept for sustainable hydrogen and methane production. The result shows that the highest total energy and exergy efficiencies of 11.2% and 11.3% were achieved at 0.4 current supplied.

ABSTRACT
The transition to sustainable energy solutions is a key requirement in the fight against climate change, while the transport sector is a major source of global carbon emissions. Fuel Cell Electric Vehicles (FCEVs) offer a promising alternative to reduce dependence on fossil fuels, but one of the technical barriers to their widespread deployment is the low output voltage of Proton Exchange Membrane (PEM) fuel cells. This paper presents the design of a high voltage gain LLC resonant converter to overcome the mismatch between the output voltage of a 160 kW PEM fuel cell and electric vehicle (EV) batteries. The converter is optimised to stabilise the variable output voltage of the fuel cell (between 227 V and 310 V) at 300-400 V DC and is designed to operate with high efficiency at a switching frequency of 100 kHz. Simulations were carried out using PLECS software and the results show that the converter provides high efficiency, stability and safe operation while meeting the isolation requirement. This study provides valuable insights into the integration of PEM fuel cells with EV batteries and lays a solid foundation for the future development of power systems of FCEVs.
Keywords: Fuel cell, electric vehicle, resonant converter, LLC converter.

1. INTRODUCTION

The rapid depletion of traditional fossil fuel resources and the environmental pollution caused by their utilization processes increase the need for sustainable energy solutions on a global scale [1,2]. Within the scope of reducing greenhouse gas emissions and combating climate change, the integration of renewable and clean energy sources is of critical importance. In this context, photovoltaic systems, wind energy, and fuel cell technologies are among the key technologies that stand out in the sustainable energy transition [3,4]. The transport sector also accounts for a significant portion of carbon emissions worldwide, and solutions to reduce fossil fuel dependency in this field are becoming increasingly important. In this regard, zero-emission FCEVs emerge as an environmentally friendly transport alternative, contributing to sustainable mobility [5]. While fuel cell vehicles attract attention with their high energy conversion efficiency and low emission profiles, they also have the potential to offer a longer range compared to EVs. These features make fuel cell vehicles an attractive option, especially for long-distance transportation and commercial vehicle applications. However, despite these advantages, fuel cell technologies face several technical challenges that must be addressed to enable their widespread adoption in electric vehicles [6-8].

One of the main challenges is that PEM fuel cells tend to produce low output voltage and high output current. This characteristic makes it difficult to directly integrate electric vehicles into DC bus systems, which usually operate at 400 V or 800 V [9,10]. Fig. 1 shows the power distribution architecture of a fuel cell vehicle. As observed in the architecture, high voltage gain DC-DC converters are utilized between the fuel cell stacks and the DC bus. Under operating conditions, the cell voltage of fuel cells tends to decrease as the output power increases. Therefore, converters must be capable of operating with high efficiency over a wide voltage gain range [11]. Among the converter topologies that provide high efficiency and a wide voltage gain range, LLC resonant converters stand out. These converters offer advantages such as high efficiency, low electromagnetic interference (EMI), and a wide operating range. Given these advantages, designing an LLC resonant converter specifically for fuel cell vehicles can significantly enhance their energy conversion performance. Their high-frequency operation reduces the size of the magnetic components and increases the overall system efficiency. These features play a critical role in improving energy conversion efficiency and optimizing system performance in fuel cell vehicles.

In this paper, a high voltage gain LLC resonant converter is designed to meet the energy conversion requirements of a 160 kW PEM fuel cell and to charge the battery of an electric vehicle from a fuel cell vehicle. The idle operating voltage of the fuel cell was determined as 310 V and 227 V under full load, and these variable voltages were converted to 400 V DC bus voltage using an isolated LLC converter. The designed LLC converter is optimized to operate with 95% efficiency at a switching frequency of 120 kHz. The design process and performance analyses are carried out in the PLECS simulation environment, verifying that the converter provides high efficiency and stability. These findings contribute to the development of more efficient and reliable power conversion solutions for fuel cell electric vehicles, paving the way for future advancements in sustainable transportation technologies.

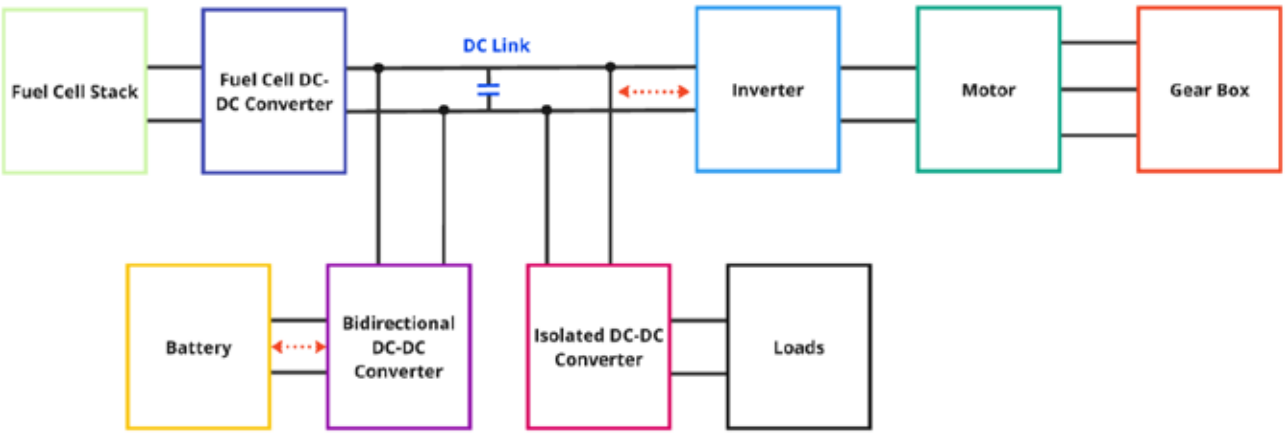

Fig. 1. Fuel cell vehicle power architecture schematic [12]

2. FUEL CELL, BATTERY and CONVERTER DESIGN

The low output voltage of PEM fuel cells is incompatible with electric vehicle (EV) battery voltage levels. To address this, a high-gain, LLC resonant DC-DC converter is designed to transfer energy from the fuel cell to the EV battery. The converter parameters are optimized based on fuel cell output characteristics and EV battery requirements, considering factors like minimum and maximum fuel cell voltages, battery voltage, and current. The design is analyzed using PLECS simulation software to verify efficiency and performance under various operating conditions.

2.1. PEM Fuel Cell and Performance Criteria

PEM fuel cell generates electricity through an electrochemical reaction, where hydrogen splits into protons and electrons at the anode. Protons pass through the membrane, while electrons flow through an external circuit, producing current. At the cathode, they react with oxygen to form water and release heat. In this study, the PEM fuel cell has a 160 kW power output, 705 A current capacity, and 227 V output voltage, with a power density of 4.4 kW/L. It uses hydrogen fuel and air (2.6 bar) as an oxidizer. The system operates between -30°C and +90°C, with a cold start at -30°C and a maximum coolant temperature of +95°C. Weighing 65 kg and measuring 572 mm, it is designed for efficient integration into EV applications [13].

2.2. Battery Specifications

Batteries are a critical component for safety, long life and high performance of EVs. Lithium Iron Phosphate (LFP) batteries are widely preferred in EV applications due to their high thermal stability, low self-discharge rate and wide operating temperature range. In addition, they offer a cycle life of 1500-4000 cycles, ensuring long-term use and minimising the risk of overheating. In this study an LFP battery with a capacity of 2.6 Ah was selected. The nominal voltage of the battery is 3.3V and the energy density varies between 90-160 Wh/kg. The charging temperature range is between 0°C and 45°C and it functions as a reliable power source against instantaneous high current demands.

2.3. LLC Converter Design and Parameters

In the design phase, the aim is to match the output voltage of the fuel cell to the voltage levels of the EV batteries. The LLC resonant converter is selected as a suitable solution based on performance criteria such as high voltage gain, high efficiency and isolation. As the energy is transferred from the FCEV to the EV, the isolation requirement is considered, the battery can not be affected in the event of a malfunction. The LLC resonant converter was selected to meet this safety requirement. The converter is designed taking into account the minimum and maximum fuel cell voltage, the battery voltage and various load conditions. The parameters used in the design are calculated according to the formulas and flowchart in [14]. The obtained results and design parameters are presented in Table 1. The circuit diagram of the design is shown in Fig. 2.

Table 1. LLC converter design parameters

Parameter	Value
Input voltage (V_{fc})	227 V - 310 V
Battery voltage (V_{bat})	300 V - 400 V
Magnetisation inductance (L_m)	81 µH
Resonant inductance (L_r)	6 µH
Resonant capacitance (C_r)	220 nF
Resonant frequency	100 kHz

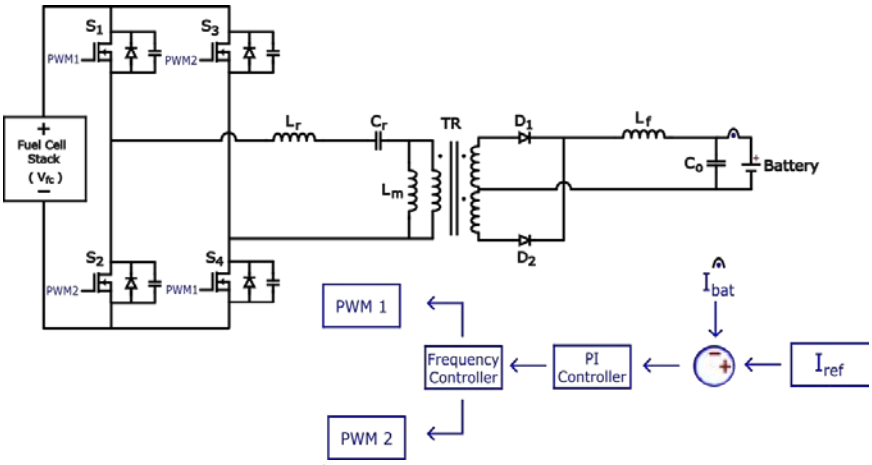

Fig. 2. LLC converter simulation schematic

3. SIMULATION AND RESULTS

Simulation of the proposed system is achieved in PLECS program under real conditions and parasitic effects (eg. capacitors) related to the design parameters. In the simulation, critical system parameters such as voltage-current levels, efficiency and transient response are analysed. Therefore, the accuracy and applicability of the design are assessed. The control signals of the switches in the LLC converter are generated using the frequency control method. The circuit diagram and control method of the converter simulated in PLECS is shown in Fig. 2. Here, the LFP type battery is chosen 2.6 Ah capacity, nominal voltage of 3.3 V. Therefore, battery pack consists of 100 series cells in one module and two modules in parallel. The results of the battery parameters considering the fuel cell at 227 V are shown in Fig. 3. Here, 2C contant current (CC) is considered for charging battery. Analysis of the waveforms shows that when the battery is charged at a constant current of 13 A, the battery voltage increases and the SoC value increases.

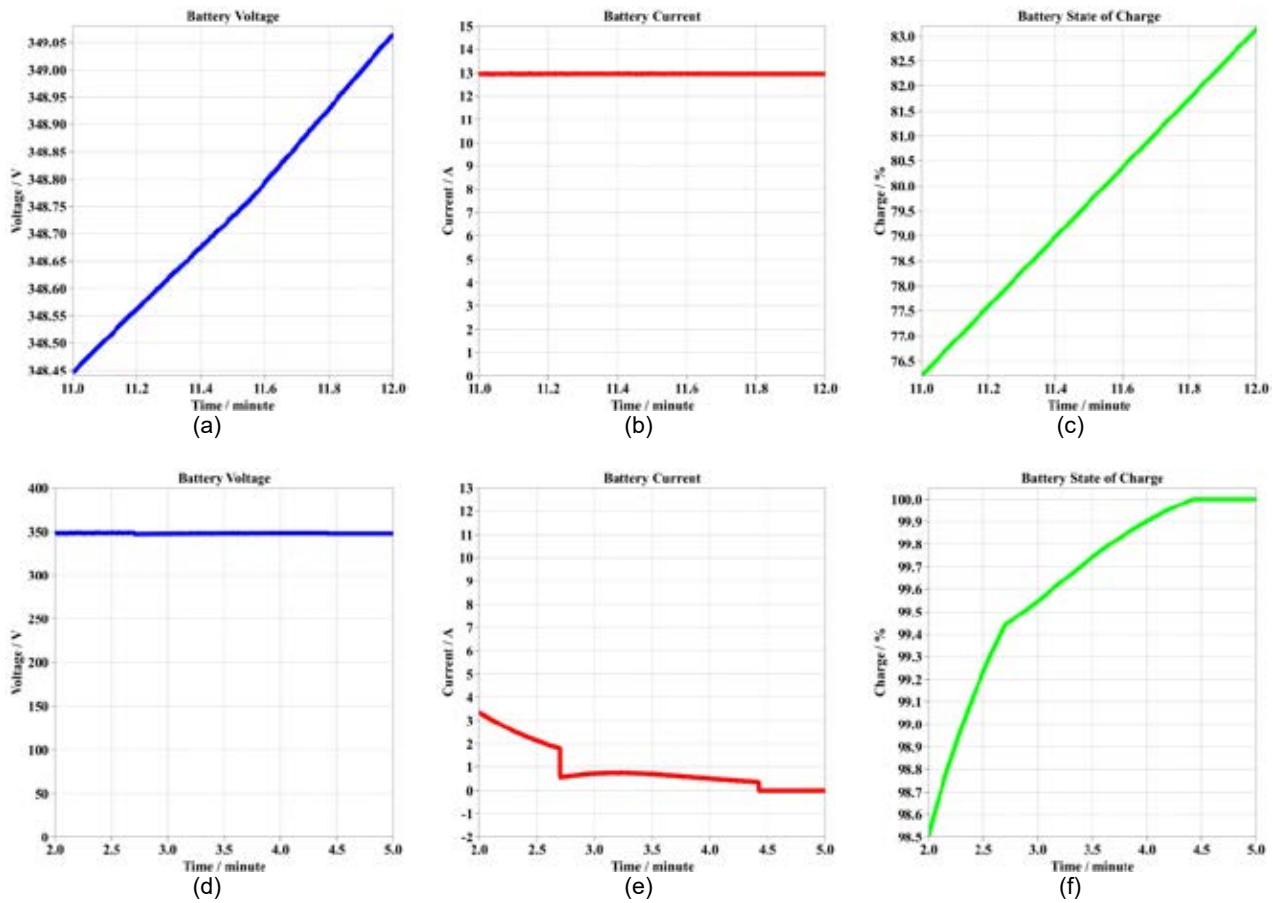

Fig. 3. (a) CC mode battery voltage, (b) CC mode battery current, (c) CC mode battery SoC, (d) CV mode battery voltage, (e) CV mode battery current and (f) CV mode battery So

4. CONCLUSIONS

The high voltage gain LLC resonant converter is designed to transfer energy from the fuel cell to the electric vehicle battery provides an efficient solution to meet the energy conversion requirements of a 160 kW PEM fuel cell. The converter is designed to operate in the fuel cell output voltage range of 227V - 310V and charge the electric vehicle battery in the range of 300V - 400V. In addition, the isolation feature of the LLC resonant converter makes the system more reliable by increasing safety under fault and arc conditions. Simulation results show that the LLC resonant converter operates with high efficiency at a switching frequency of 100 kHz and provides successful energy conversion from fuel cell to battery. The results show that LLC resonant converters provide an efficient, reliable and scalable power conversion solution for fuel cell electric vehicles. This study contributes to the development of more efficient and sustainable fuel cell electric vehicle systems by providing a solid foundation for future designs.

ABSTRACT
Developing energy demands and environmental concerns have increased interest in sustainable and clean energy sources. In this context, the photoelectrochemical (PEC) method for hydrogen production has become crucial in renewable energy technologies, as it directly transforms solar energy into chemical energy. The efficiency, light absorption and electrochemical stability of the electrocatalysts used in PEC systems are of great importance. Perovskite type materials provide significant advantages in this field due to their wide band gap, light absorption capacity, and excellent electrochemical stability. In this study, perovskite type $LaNiO_3$ electrocatalyst was synthesized by a sol-gel method, which provides homogeneous structure and controlled morphology. The structural, morphological and electrochemical properties of the synthesised $LaNiO_3$ perovskite were characterised by XRD, FE-SEM/EDS and electrochemical tests. XRD analyses confirmed that the synthesized catalyst features a rhombohedral hexagonal crystal structure. Additionally, FE-SEM and EDS analyses revealed uniform elemental distribution and a porous morphology. PEC tests indicate that $LaNiO_3$ possesses a capacity for sunlight absorption and shows promising electrochemical performance. These results suggest that $LaNiO_3$ perovskite-based electrocatalysts could serve as a viable alternative for sustainable and low-cost hydrogen production.

Keywords: Photoelectrochemical, Perovskite, Electrocatalyst, Sol-Gel

1. INTRODUCTION

Research on directly utilizing solar energy for hydrogen production from renewable sources has been increasing and photoelectrochemical (PEC) methods based on water splitting play a crucial role in integrating hydrogen into the hydrogen economy, contributing to advancements in production technologies. A photoelectrochemical cell fundamentally comprises a semiconductor-based photoanode (n-type) that enables the oxygen evolution reaction (OER), or a semiconductor-based photocathode (p-type) which drives the hydrogen evolution reaction (HER). Additionally, it encompasses a counter electrode where the complementary reduction and oxidation half-reactions occur [1]. The semiconductor material actively absorbs ultraviolet and visible wavelengths, accounting for 47% of the solar spectrum, and generates electron-hole pairs when excited by photons [2]. When an n-type semiconductor serves as the working electrode, water molecules interact with surface holes to generate oxygen; conversely, using a p-type semiconductor produces hydrogen. The complementary half-reaction occurs at the counter electrode. The development of PEC hydrogen production technologies, aimed at reducing production costs and improving efficiency, is particularly achievable through the synthesis of efficient photocatalysts. In traditional metal-based photocatalysts (such as TiO_2, ZnO, and Fe_2O_3), performance is limited due to the restricted mobility of charge carriers within the atomic structure, solar light absorption resulting from the wide bandgap, and rapid recombination of electron-hole pairs recombination [3]. Perovskite-type catalysts, which are widely used in fuel cells [4], supercapacitors [5], methane combustion reactions [6], and solar cells [7] offer a range of advantages for solar-based hydrogen production technologies due to their strong light absorption properties, adjustable oxide bandgaps, good stability, and low cost [8]. Perovskites consist of complex oxides with an ideal crystal structure formula of ABO_3 [9]. In this structure, the B cation can be transition metals (Cr, Mn, Fe, Co, Cu, Zn) or non-transition metals (Al, Ga, In), which are surrounded by six oxygen anions to form B-O bonds. The A cation can be lanthanides (La, Ce, Pr, Gd) or alkaline earth metals (Ba, Sr), which form A-O bonds with twelve anions. In this study, the $La_xNi_{1-x}O_3$ perovskite-type catalyst will be synthesized via the sol-gel method, which offers the advantage of low-cost synthesis of particles with different chemical compositions. Compared to high-tech hydrogen production methods, the use of direct photonic energy in the PEC process reduces energy losses, allowing for an environmentally friendly, low-operating cost approach to hydrogen production.

2. MATERIALS AND METHODS

2.1. Preparation of $La_xNi_{1-x}O_3$ Electrocatalyst by Sol-Gel Method and Characterization

The $La_xNi_{1-x}O_3$ perovskite was synthesized using the sol-gel method, which ensures homogeneity and controlled production. Lanthanum nitrate hexahydrate $La(NO_3)_3{\cdot}6H_2O$ (ABCR, 99%) and nickel nitrate hexahydrate $Ni(NO_3)_2{\cdot}6H_2O$ (Merck, 99%) were mixed with 125 mL of distilled water. Following the mixing of the precursor solution in a molar ratio of La:Ni=0.5:0.5, citric acid monohydrate ($C_6H_8O_7.H_2O$) (Merck, >99,5%) was added to induce complexation and polymerization, followed by the addition of ethylene glycol ($C_2H_6O_2$) (Merck, +99%). The pH was adjusted to 6 with 25% ammonia solution (NH_4OH) (Merck, 35%). The molar ratio of total metal ions to citric acid was set to 1.2, and the ratio of

citric acid to ethylene glycol was set to 1. The solution was then heated at 70°C until the gel formed, after which the gel was dried at 200°C for 12 hours and calcined at 1000°C for 5 hours to obtain the nano powder (Fig. 1).

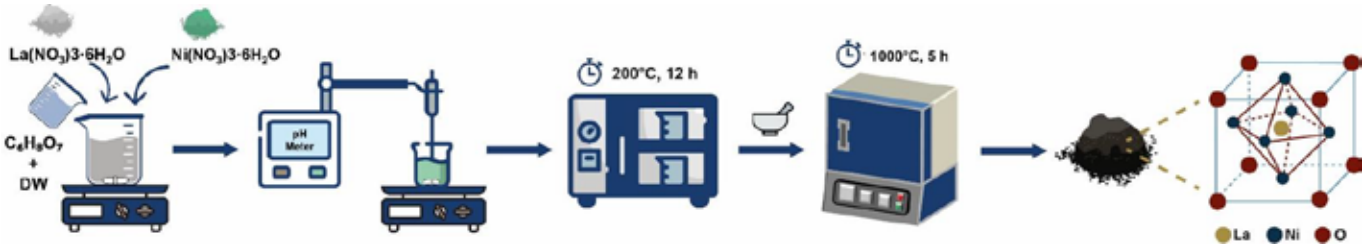

Fig. 1. Synthesis of $LaNiO_3$ Perovskite Type Electrocatalyst

XRD: The crystalline phases of the synthesized catalyst were characterized using a Philips Panalytical X'Pert Pro X-ray diffraction (XRD) instrument equipped with a copper (CuKα) tube, operating at an acceleration voltage of 45 kV and a current of 40 mA. The calcined powder samples were placed on an aluminum holder to ensure a smooth surface and were prepared for analysis. XRD measurements were carried out with a step size of 0.01° (2θ) and a scan time of 1.2 seconds.
FE-SEM: The sample's surface morphology and elemental composition were examined using field-emission scanning electron microscopy and energy-dispersive X-ray spectroscopy (FE-SEM/EDS) (Thermo Scientific Apreo 2S LoVac) images were obtained at different magnification levels under an acceleration voltage of 10 kV. The material was fixed on a sample holder and prepared for analysis by applying an Au coating to ensure conductivity.

2.2. Photoelectrode Preparation
The perovskite gel synthesized for the investigation of photoelectrochemical properties was electrode-coated using the dip-coating method. Stainless steel 306 served as the electrode substrate, and a series of sequential pre-treatment steps were conducted to enhance the catalyst's adhesion to the surface. The process includes three main steps: first, the surface was mechanically smoothed with sandpaper. Second, the electrode was cleaned sequentially with deionized water and ethanol in an ultrasonic bath, then dried under vacuum. The electrode was prepared for coating through an acid immersion process.

2.3 Performance Tests of Photoelectrochemical Systems
Electrochemical tests were carried out under a FYTRONIX solar simulator (400-1000 nm) using a three-electrode configuration in a GAMRY Reference 3000 potentiostat/galvanostat device. A graphite counter electrode, an Ag/AgCl reference electrode, and a 0.5 M KOH solution served as the electrolyte during the tests. Chronoamperometric measurements were performed to determine the photoelectrochemical response of the prepared photoelectrode under chopped light conditions at 0 V (vs. reference electrode) for 300 seconds. The experiments were conducted on a 6 cm² active surface area to investigate the stability of the photocurrent and the potential of light-induced charge carriers.

3. RESULTS AND DISCUSSION
In this study, the synthesized $LaNiO_3$ perovskite sample was initially analyzed by powder X-ray diffraction (PXRD) using a PANalytical X'Pert Pro diffractometer with CuKα radiation (λ = 1.5406 Å). Phase identification confirmed that $LaNiO_3$ has a rhombohedral hexagonal crystal structure with lattice parameters a = 5.4570 Å, b = 5.4570 Å, and c = 6.6030 Å (Fig. 2). The most intense peaks observed at 2θ = 23°, 33°, 41°, 47°, 59°, 69°, and 79° correspond to the crystal planes (101), (012), (021), (202), (122), (220), and (214), which are consistent with the standard reference data (JCPDS: 04-026-8961). These findings confirm the synthesis of $LaNiO_3$ with high crystallinity and purity, providing a foundation for further research into its photoelectrochemical performance.

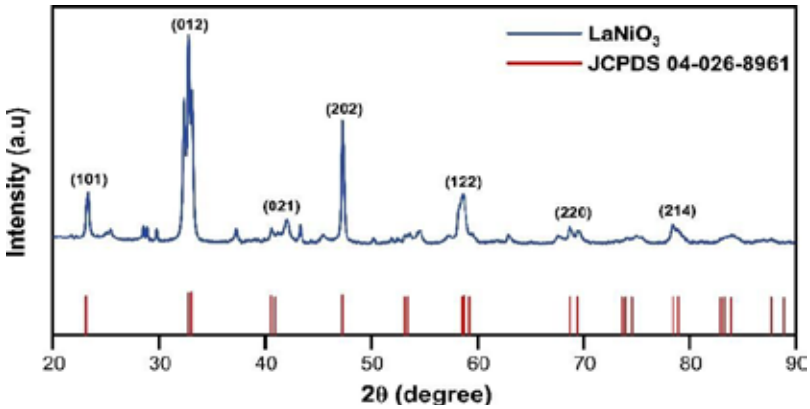

Fig. 2. XRD Pattern of $LaNiO_3$.

FE-SEM and EDS analyses assessed the morphological and chemical structure of the synthesized $LaNiO_3$ perovskite sample. The FE-SEM images indicated that the sample has a cubic, porous structure that tends to agglomerate (Fig. 3). These morphological characteristics imply that the material may have a large surface area, potentially beneficial for catalytic or electrochemical applications. EDS elemental mapping demonstrated a homogeneous distribution of La, Ni, and O elements. The elemental analysis determined the atomic percentages of the sample to be La: 20.6%, Ni: 20.1%, and O: 59.3%, which shows a composition very close to the desired molar ratio (Table 1).

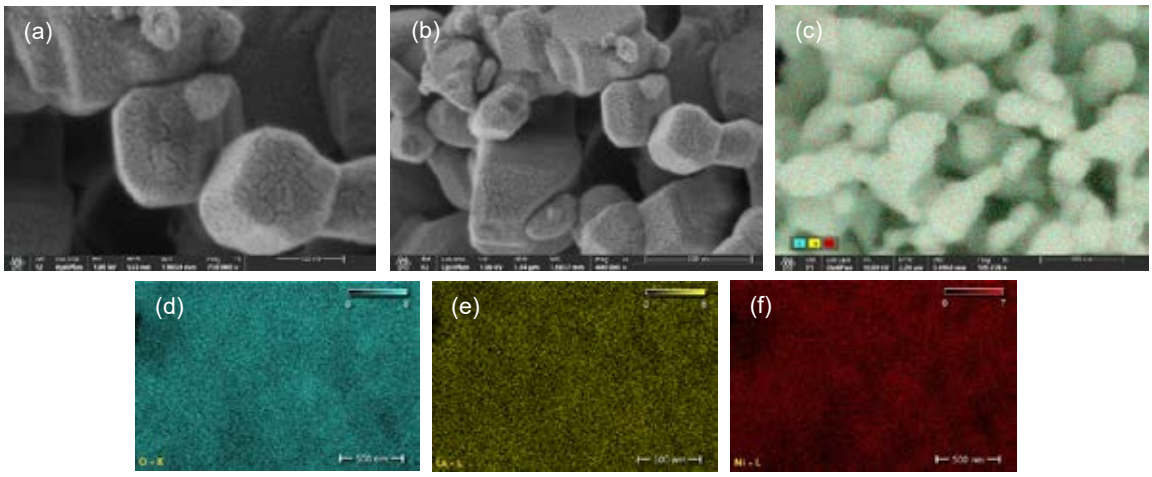

Fig. 3. SEM images of $LaNiO_3$ at a magnification scale of 100 nm (a) and 300 nm (b), along with elemental mapping at 500 nm in (c), (d), (e), and (f).

Table 1. Elemental composition of $LaNiO_3$ determined by EDS analysis.

Element	Atomic %	Atomic % Error	Weight %	Weight % Error	Net Counts
O	59.3	0.3	19.0	0.1	514 760
Ni	20.1	0.1	23.7	0.1	227 320
La	20.6	0.1	57.3	0.3	335 097

Fig. 4 shows the relationship between current density ($\mu A \cdot cm^{-2}$) and time (s) for the chronoamperometric (CA) chopping test performed at 0V for $LaNiO_3$. Periodic light on-off cycles were applied throughout the test, and a significant increase in current density was observed with each light on period. This behavior confirms the photocatalytic activity of $LaNiO_3$ and indicates the photogeneration processes under light irradiation. When the light is on, the current density quickly increases to 0.8–1.0 $\mu A \cdot cm^{-2}$, but when the light is off, it reduces to 0.2–0.4 $\mu A \cdot cm^{-2}$. It is estimated that the photoinduced current is around 0.6 $\mu A \cdot cm^{-2}$. Additionally, the material exhibits photostability over a certain period, as seen by the repeatable current density response in each light on-off cycle.

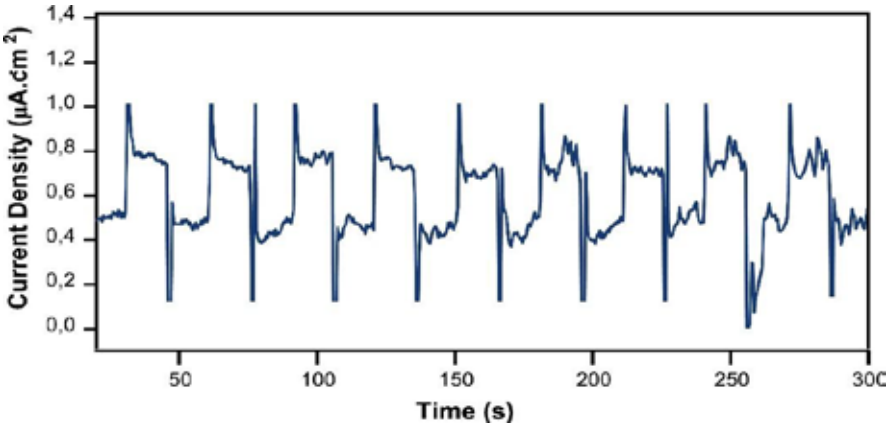

Fig. 4. Chronoamperometric chopping test of $LaNiO_3$ at 0V.

4. CONCLUSIONS

In this study, $LaNiO_3$ perovskite electrocatalyst was successfully synthesized using the sol-gel method, and its applicability for photoelectrochemical hydrogen production was investigated. XRD analysis confirmed that the synthesized catalyst has a rhombohedral hexagonal crystal structure, while FE-SEM and EDS analyses revealed homogeneous elemental distribution and porous morphology. Photoelectrochemical tests indicated that $LaNiO_3$ has sunlight absorption capacity and showed promising results in terms of electrochemical performance. These findings suggest that $LaNiO_3$ perovskite-based electrocatalysts could be a suitable alternative for sustainable and low-cost photoelectrochemical hydrogen production. Future studies will focus on exploring different synthesis conditions to improve the catalyst's efficiency and investigating the hydrogen production activities of the perovskite structure under solar light.

ABSTRACT
The development of cost-effective and sustainable electrocatalysts for hydrogen production is crucial for advancing clean energy technologies. In this study, a boron-doped activated carbon-starch-based (B@AC-S) bioelectrode was synthesized via a green and scalable approach and employed as a metal-free cathode for hydrogen evolution in an electrolysis system. The impact of varying boron doping concentrations (1.5–3.0 g) on electrochemical performance and hydrogen production was systematically investigated. The 2.5 g-boron-doped electrode exhibited the highest current density, demonstrating superior electron transfer capabilities, while the 3.0 g-doped electrode showed a slight decline due to potential conductivity limitations. Hydrogen evolution tests confirmed a substantial increase in H_2 production with increasing boron content, with the 3.0 g-doped electrode achieving the highest cumulative hydrogen yield of 1000 ppm in approximately 6 min. The study highlights the effectiveness of boron doping in enhancing electrochemical activity and hydrogen production efficiency, offering a promising alternative to conventional metal-based electrocatalysts.

Keywords: Hydrogen production, Green synthesis, Boron, Bioelectrode, Activated carbon

1. INTRODUCTION

Hydrogen (H_2) is a promising fuel for energy conversion and storage applications because of its high gravimetric energy density. The water splitting with electrolysis process is a well-established and eco-friendly method of producing H_2 when compared to other methods. However, traditional water electrolysis requires a large amount of external energy (> 1.8 V) and sustainable electrode materials with high electrical conductivity [1].

Mostly, precious noble metals, such as Pt-based materials for the H_2 evolution reaction (HER) at the cathode and IrO_2-based materials for the oxygen evolution reaction at the anode in the electrolysis process, have been employed as electrocatalysts, however, which increases the cost [2]. For H_2 evolution processes, Pt is the typical electrocatalyst; nevertheless, it is costly and scarce. Enhancing the electrocatalytic activity and durability of the electrodes is necessary to reduce the manufacturing cost and make the process economically viable. Therefore, it is urged to look for substitutes for Pt-based electrocatalyst. For the H_2 evolution process, alternative non-Pt-based low-cost electrocatalysts should be required. Recently, different carbons are utilized as support materials that increase the surface area and electrical conductivity to enhance H_2 production performance of the electrode [3]. Namely, high surface area, optimal porosity, high stability in an acidic environment, and strong electrical conductivity are all requirements for support material. A variety of carbons, including graphene, fullerenes, carbon nanomaterials, and carbon black, were recently identified by several studies as support materials for the H_2 evolution reaction in water electrolysis. However, because of their intrinsic properties of having few active sites on the chemically inert sp2 carbon framework for HER reaction, the performance of HER with carbon-based materials is still insufficient to reach the same level as that with Pt-based catalysts. In this regard, another potential method to improve the electrochemical ability is to dope heteroatoms with carbons to increase the number of active sites on the carbon surface and enhance the catalytic activity.

According to reports, adding the various heteroatoms (B, N, P, and S) that result from the electronic structure alteration might enhance the electrochemical performance of the cathode [4]. It has been also demonstrated that the heteroatom doping technique is an effective method to enhance the electrochemical characteristics of carbon-based materials [5]. Non-metallic elements like B, N, P, and S heteroatoms may usually be added to the carbon matrix's lattice structure to increase layer spacing, create mismatched electrons, enhance active sites, and speed up electrochemical kinetics. Overall, the carbon skeleton structure is rearranged when heterogeneous atoms are added, and the surface chemical environment of activated carbon is altered. This results in increased internal disturbance, enhanced structural stability, surface functional groups, and specific surface area. Activated carbon improves ion transit and storage, resulting in superior electrochemical qualities.

Electron-deficient boron (B) is known to be a capable component for promising chemical dopants on carbons, among other heteroatom dopants, because it only has three valence band electrons. This allows the inert sp2 carbon framework to be chemically functionalized, initiates the copious free-flowing π electrons, and functions as an electrocatalyst. Moreover, adding B could significantly increase the carbon conductivity by increasing the density of hole type charge carriers. These virtues boost the electrocatalytic activity of carbons towards the HER, therefore, the B-doped carbons have gained a growing interest in recent years. Despite the growing interest in boron-doped carbon-based electrode materials for H_2 production, several critical gaps remain in the literature. For instance, the synthesis methods for boron-doped carbon electrodes often involve costly and complex procedures, limiting their large-scale feasibility. There is also

a lack of comprehensive studies comparing the performance of boron-doped carbon materials with conventional and emerging electrode materials in terms of cost-effectiveness, sustainability, and efficiency. Moreover, in most studies on boron-doped carbon-based electrodes for H_2 production, transition metals such as nickel, cobalt, and iron have been predominantly used as base materials due to their favorable electrocatalytic properties [6]. However, considering the practical limitations of these metals, incorporating metal-free materials offers several advantages. Traditional metal-based cathodes often suffer from high costs, limited availability of precious metals, and susceptibility to degradation in harsh electrolytic environments. In contrast, metal-free cathodes, typically composed of carbon-based materials or doped polymers, provide a cost-effective and sustainable alternative with enhanced chemical stability and corrosion resistance. Moreover, these cathodes can exhibit high electrocatalytic activity for the HER when engineered with appropriate surface modifications, such as heteroatom doping or structural optimization. The absence of metal components also mitigates metal leaching and contamination concerns, ensuring long-term operational efficiency and environmental compatibility. Therefore, metal-free cathodes represent a promising path for the development of next-generation, sustainable H_2 production technologies.

To the best of our knowledge, limited studies in the literature utilize metal-free material in electrochemical H_2 production, despite its potential advantages. Therefore, this study is focused on the H_2 production performance of the B-loaded carbon/starch-based biocathode in the electrolysis process. Namely, B-loaded carbon/starch-based biocathode with various boron loading percentages have been synthesized and utilized in the electrolysis process for green H_2 production.

2. MATERIALS AND METHODS

The boron-doped activated carbon-starch-based (B@AC-S) bioelectrode is produced with green synthesis (Fig. 1). 20 mL of distilled water, 2 mL of vinegar as an acetic acid source, 10 g of starch, and 2 mL of mineral oil are mixed to synthesize the bioelectrode. Next, different quantities of boric acid (H_3BO_3, Sigma Aldrich) as a boron heteroatom source are added to the synthesized B@AC-S bioelectrode. Then, this mixture is continuously stirred at 60 °C until it becomes more concentrated and uniform. Finally, a thin layer of the B@AC-S bioelectrode mixture is put into the glass, and allowed to solidify and remove moisture for a day.

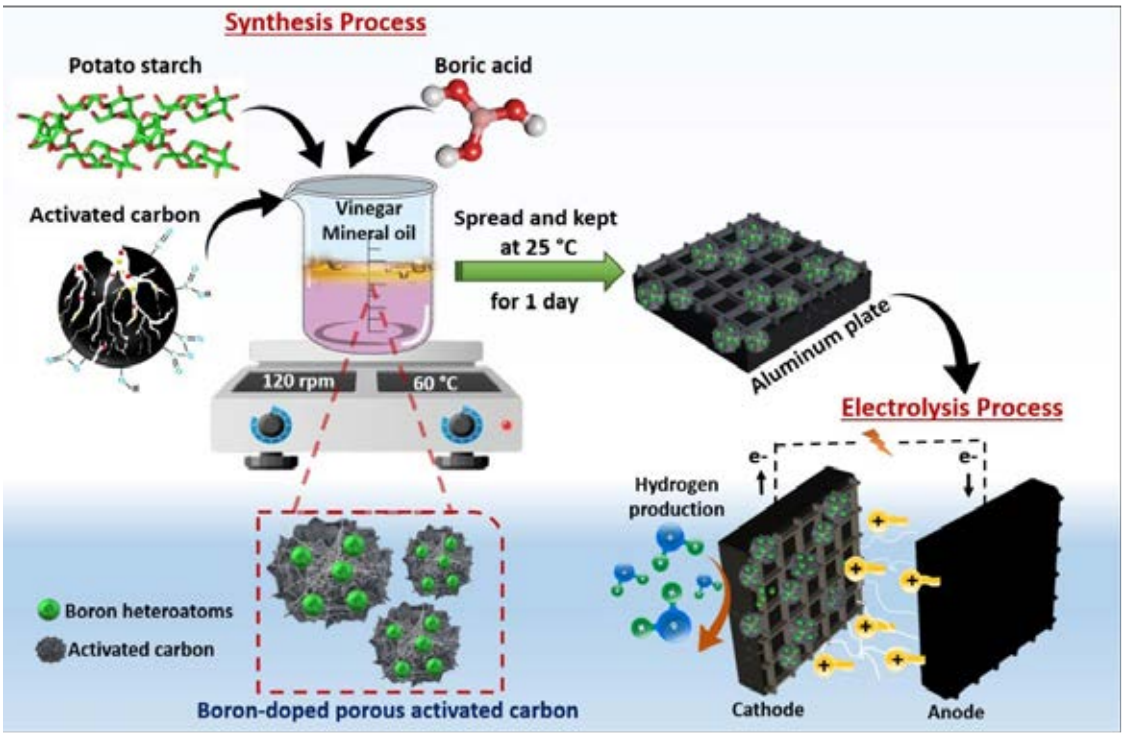

Fig. 1. Page size and margins (9 pt Arial, centered)

A laboratory-scale membraneless cylindrical electrolysis reactor is used for the H_2 production tests. A 1 M potassium hydroxide (KOH) solution is used as the electrolyte solution in the electrolysis reactor. An H_2 sensor, electrodes, electrode connection cables, and a DC power supply were among the tools and components used in the experiment. After the electrodes are first placed into the cell for the testing, the electrolysis process begins at a predetermined electrical voltage. Before and after the testing, the cell voltage and current are measured at specified intervals from the DC power supply. Furthermore, the surface morphologies and elemental content of the produced electrodes are evaluated using the scanning electron microscopy (SEM). Additionally, the electrodes are electrochemically characterized using Gamry-3000

potentiostat/galvanostat. In this analytical device, a saturated Ag/AgCl electrode acts as the reference electrode, a platinum electrode as the counter electrode, and the generated electrodes as the working electrode. Each measurement is conducted in an electrolyte solution with 1 M KOH at 24 °C. Furthermore, cyclic voltammetry measurements of the electrodes were performed in the potential range of -0.1−0.9 V at a scan rate of 50 mV/s.

3. RESULTS AND DISCUSSION

The water electrolysis tests for H_2 production are performed at different boron loadings (Fig. 2a). As expected, H_2 production performance of the B@AC-S bioelectrode is increased with the increasing boron dosage. Initially, raw activated carbon exhibits the lowest hydrogen production rate and cumulative production, indicating its limited catalytic efficiency. The introduction of boron doping significantly enhances performance, with a notable increase in hydrogen output as the doping concentration rises. Among the boron-doped samples, the 1.5 g-doped electrode shows a moderate improvement over raw activated carbon but remains suboptimal compared to higher doping levels, considering the H_2 production time. The 3 g-doped electrode further enhances hydrogen production (1000 ppm), reflecting improved catalytic activity due to increased electron transfer efficiency, and the H_2 production time considerably decreased.
Regarding the time-dependent H_2 production, all boron-doped electrodes accelerate H_2 production compared to raw activated carbon, reducing the time required to reach peak production.

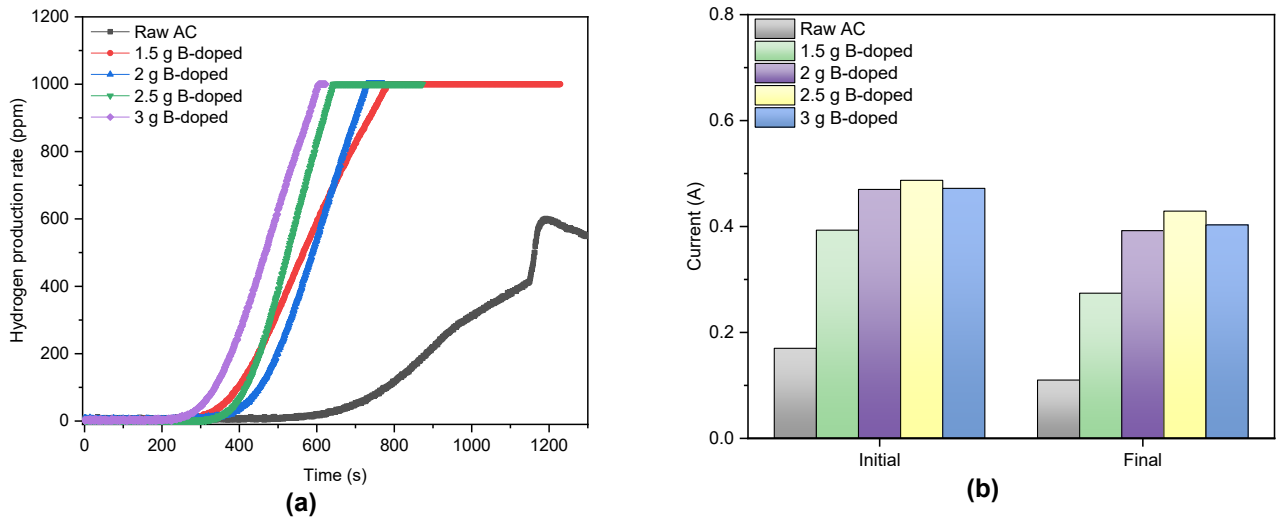

Fig. 2. The hydrogen production rate (a) at different boron loadings and (b) initial and final current values.

Moreover, the initial and final current values during the H_2 production are measured and reported in Fig. 2b. The raw activated carbon exhibits the lowest current, starting at 0.17 A and reaching a final value of 0.11 A, indicating limited conductivity and electron transfer efficiency. In contrast, boron doping significantly enhances the initial current values. The 2.5 g-doped electrode exhibits the highest current, beginning at 0.487 A and stabilizing at 0.429 A, indicating an optimal balance of boron content that maximizes electrical conductivity and minimizes charge transfer resistance.
Overall, boron doping significantly enhances both H_2 production and the electrochemical activity of the electrode by improving electrical conductivity, facilitating electron transfer, and reducing charge transfer resistance, with 2.5 g doping demonstrating the most optimal performance.

4. CONCLUSIONS

Boron-doped activated carbon-starch-based (B@AC-S) bioelectrode was successfully synthesized and utilized for the H_2 production using the electrolysis process. Boron was doped to improve the electrochemical activity of the biocathode and enhance the H_2 production performance of the bioelectrode. The highest H_2 production of 1000 ppm is obtained using 3 g-boron-doped electrodes at the end of the operating time of approximately 6 min.

ABSTRACT
The combustion stability of the small-bore Gasoline Direct Injection (GDI) engine at homogeneous near stoichiometric and lean burn combustion is investigated experimentally. The intake manifold is slightly modified to accommodate the hydrogen induction, wherein mixture of hydrogen enriched methane (30% hydrogen enrichment-hythane30) and air is formed in the intake manifold, attaining the excess air ratio of 1.0 to 1.22. With the increment of hythane30 fraction the fuel leaning (Gasoline) is attained and achieving economical fuel consumption rate. The hydrogen fraction in the methane decreases the coefficient of variance, and it was found to be within the limit of 5%. For the lean limits it was found that the peak pressure of the lean air fuel ratio was reduced consistently. The spark timing was optimized for the lean limit with hythane30 addition to attaining the maximum brake torque and CA 50 location of the mass fraction burn. Hydrogen induction improves the combustion rate and mean effective pressure; shortens the flame propagation, maximizes the heat release rate and peak pressure attainment. On the emission side there is a consistent decrease in CO and HC emission; and an increase of NOx emission since the mean gas temperature has increased. The cycle-to-cycle variation during the lean operating condition at 1.22 shows combustion stability and effective flame propagation.

1. INTRODUCTION
The utilization of small-bore engines for motorcycles and other last-mile connectivity has limited potential due to lower thermal efficiency and performance [1]. Most of these engines operate under part-load conditions due to their low compression ratio. The implications of rigorous CO2 regulations and increasing energy demand per capita highlight the need for carbon-neutral fuel gases. Since natural gases have a high-octane number and a good hydrogen-to-carbon ratio, they have higher knocking resistance [2] and can be used in spark-ignition (SI) engines that burn fuel more slowly. When used as a fuel for mobility solutions, natural gases present special problems because the amount of CO_2 in the fuel gases can change the misfiring of engines in different ways, often depending on the terrain. Using fuel gases to extend lean operation makes it harder to light the fuel-air mixture because the charge density near the spark plug is lower when the equivalence ratio is extended. Among various fuel gases, hydrogen stands out due to its physico-chemical properties, which support SI engine combustion [3-5]. However, as energy progresses toward hydrogen, its storage, and supply have limitations in implementation and continuous production for mobility solutions. Enriching existing fuel gases with hydrogen offers a midway solution to overcome these limitations in the ongoing development to meet increasing energy demand based on hydrogen [6].

The goal of this study is to find out how hythane, which is methane that is enriched with hydrogen, affects the performance of direct-injection spark-ignition engines by making smaller differences in the engine cycles. Employing gaseous fuels in these engines offers a promising solution to challenges such as wall wetting and the complexities of fuel droplet size and evaporation within the cylinder. Direct injection engines can work at higher compression ratios and quickly mix air and gaseous fuel. This makes gaseous work efficiently at a wide range of loads without engine knocking. Moreover, direct-injection engines generally achieve higher thermal efficiency compared to traditional SI engines. This technology also enables leaner engine operation, potentially leading to better fuel efficiency and lower emissions. This study builds on earlier work by looking at how well hythane30-gasoline lean burn combustion works and how much pollution it causes in small-bore GDI engines. Additionally, the study explores how adding hydrogen to methane affects combustion stability and the lean combustion limit.

2. ENGINE TEST RIG AND METHODS
The engine used in this study is a 390 cm³ small-bore single-cylinder air-cooled GDI engine. The experimental setup is illustrated in Figure 1. Initially, the engine was a carbureted model from Honda, but it was modified to a direct-injection gasoline engine. The engine head was changed to make room for a GDI injector, the throttle control was switched to an electronic actuator, and an Electronic Control Unit (ECU) was added to control the spark and injection timing. To create

a closed-loop system, CAM and crankshaft position sensors were added, along with fuel rail pressure control. The specifics of these modifications are not detailed here as they fall outside the article's scope. Engine specifications are provided in Table 1. The spark plug is located on the sides of the engine, which features a hemispherical combustion chamber. The piston head remained unmodified, retaining its original flat design. A spray-guided fuel injector was used, positioned near the spark plug.
A water-cooled eddy current dynamometer was used to load the engine under operating conditions. An HFM-type T-MAF sensor checked the amount of air coming in, and a gravimetric fuel flow system found out how much fuel was being used. A contact-type encoder attached to the crankshaft triggered the data acquisition system to record sensor data. A piezoelectric pressure transducer with a resolution of 0.1 crank angle degrees records in-cylinder pressure data. A Bosch LSU 4.9 wideband Lambda sensor monitored the air-fuel ratio, while exhaust gas temperature was measured using a K-type thermocouple. An AVL Di-gas analyzer 444 was used to record engine-out emissions.

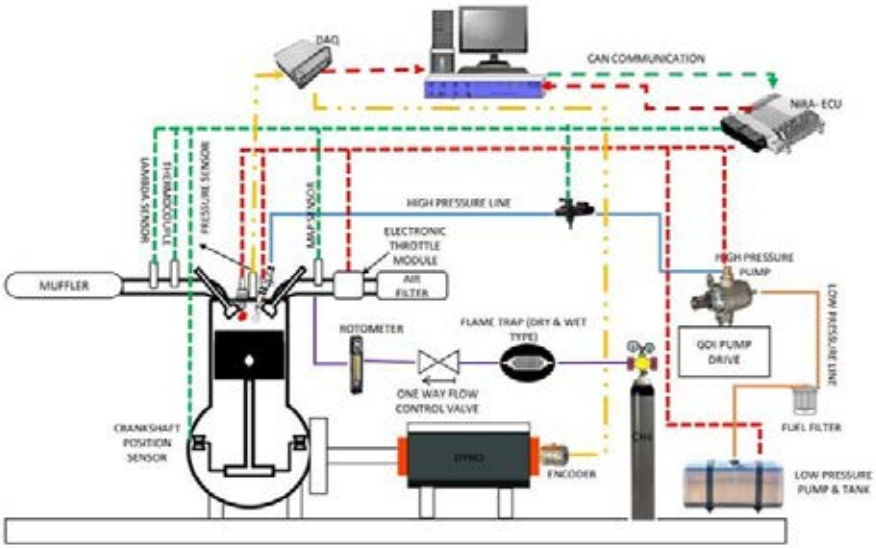

Fig. 1. Experimental Layout

2.1. Methods

The test conditions for this investigation involved operating the engine at 3000 rpm with the throttle fully open, which corresponded to the maximum brake torque achievable with the given spark timing. The specific engine operating conditions are detailed in Table 3. Hythane30 flow rates were determined based on an energy balance, ensuring that hydrogen did not exceed 30% of the total energy input. For an equivalence ratio of 1 to 1.22, the hythane30 addition fraction varied from 4.5% to 19.5%. Similarly, the equivalence ratio was increased to 1.22 wherein the gasoline injection is stratified. To maintain a consistent increase in the equivalence ratio, subsequent tests involved progressively leaning the gasoline mixture.

Table 1. Engine Details

Particulars	Details
Make	M/s. Honda
No. of Cylinders	1
No. of Valves	2
Type of CAM	Single Overhead
Ignition	Spark
Bore*Stroke (mm)	88*64
Displacement (cm^3)	390
Compression Ratio	8.2:1
Induction	Naturally Aspirated
Rated Torque	24 Nm @3000 rpm
Rated Power	8 hp @3600 rpm
Cooling system	Air

3. RESULTS AND DISCUSSION

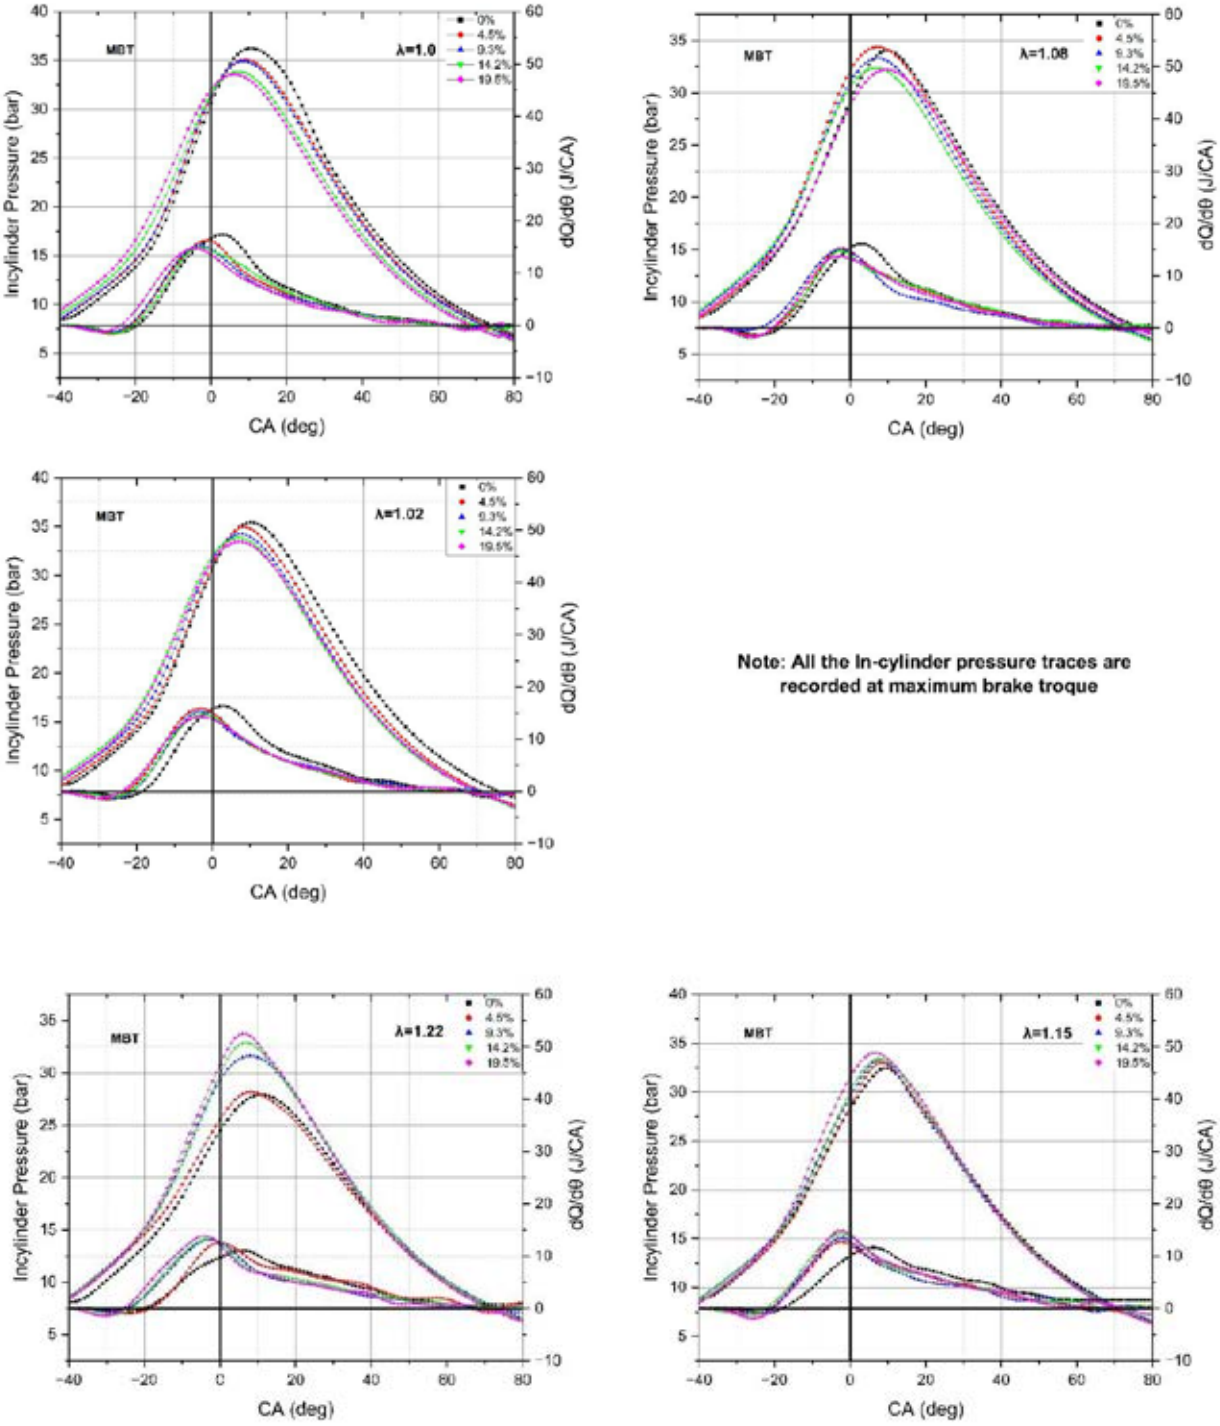

Fig. 2. Pressure Traces and Instantaneous Heat Release Rate of hythane30 for the homogeneous near stiochimetric lean mixture formation for the given equivalence ratio

4. CONCLUSIONS

1. The spark timing for the equivalence ratio for the given equivalence ratio was set as the location of CA50; the peak pressure improved by 12%. Spark advancement beyond 37°CAD causes misfire in the engine.
2. The lean limit was further increased to 1.22 for the spark timing of 30°CAD bTDC as the hydrogen addition favors the combustion stability.
3. Engine operation with 100% wide-open throttle, an equivalence ratio of 1.0, 1.02, 1.08, 1.15 & 1.22, and the varied hythane30 fraction has a significant effect on the engine performance, combustion, and emission characteristics. The thermal efficiency and indicated mean effective pressure both go up a lot as the hydrogen fraction for the equivalence ratio goes up.
4. Engine operation with 100% wide-open throttle, an equivalence ratio of 1.0, 1.02 & 1.08, and with the increase in the hythane 30 fraction, the combustion duration was shortened, leading to peak pressure attained after TDC. Keeping the hydrogen fraction constant and increasing the equivalence ratio improves the heat release rate and consistent reduction in the delay period.
5. Engine operation with 100% wide-open throttle, an equivalence ratio of 1.15 & 1.22, and with the increase in the hythane 30 fraction, CO and HC emissions decrease, and there is an increment in NO_x emissions. If you keep the Hythane30 fraction the same and raise the equivalence ratio, CO emissions go down a lot, and HC emissions go down at first and then up later. The increase in hydrogen fractions adversely affects the NO emission.

ABSTRACT
This study proposes a hybrid multigeneration system that combines biomass and solar energies to overcome the limitations of individual renewable energies. The system utilizes solar energy for hydrogen production through a proton exchange membrane electrolyzer powered by photovoltaic-thermal panels. The generated hydrogen is introduced into the gas turbine cycle's combustor. The system integrates a biomass-fueled gas turbine with a closed Brayton cycle and organic Rankine-vapour compression cycles (ORC-VCR). This arrangement is quite innovative for an energy system. The system's configuration enhances the utilization of heat recovered from the turbine, producing 0.00699 kg/s of hydrogen, 931.8 kW of electricity, 180 kW of cooling, and 122.4 kW of heating. Moreover, the system demonstrates an exergy efficiency of 22.18%, showcasing its effectiveness in converting input energy into useful outputs. This innovative hybrid configuration demonstrates the capability to provide various clean energy outputs.

Keywords: Hybrid system, Multigeneration, Hydrogen production, Solar, Biomass

1. INTRODUCTION
The current era of industrialization heavily relies on the production and distribution of clean energy to facilitate sustainable development [1]. The detrimental air pollution and harmful emissions associated with fossil fuels have created a pressing need to transition towards renewable energy sources. To achieve improved reliability, the limitations of individual renewable energies can be overcome by utilizing hybrid energies [2]. In this context, there has been a growing focus on combining solar and biomass energies in multigeneration systems. Numerous studies have been conducted to explore various configurations of hybridizing biomass and solar energy in power generation systems. These investigations aim to assess the feasibility, performance, and potential benefits of combining these two renewable energy sources [3]. In a study by Khalid [4], a thermodynamic analysis was conducted on a multigeneration hybrid system that combines a biomass energy-driven gas turbine with an ORC activated by solar energy. The researchers found that the system exhibits higher efficiency when both renewable energy sources are integrated compared to relying on a single renewable energy source alone. According to research conducted by Dincer et al [5], multigeneration systems based on renewable energies offer advantages in terms of reduced fuel costs and decreased emissions of harmful pollutants compared to conventional systems. These studies suggest that integrating two renewable energy sources in a multigeneration system can yield significant benefits. In a study by Livshit et al [6], a solar hybrid steam injection gas turbine system was investigated. The researchers found that the combination of solar energy into the solar hybrid steam injection gas turbine (STIG) cycle leads to a significant improvement in system productivity. The efficiency of the combined system was reported to reach over 40-55%, whereas the efficiency of the STIG cycle without solar integration was only about 25-35%.
The literature review emphasizes that combining solar and biomass energy in a hybrid system can improve the system's efficiency. The present study introduces a novel hybrid biomass and solar energy-based combined cycle. This research is distinguished by an innovative energy system design, integrating a Closed Brayton Cycle (CBC), Gas Turbine (GT), and ORC in a novel configuration. Such a system has not been investigated in any previous study. This arrangement aims for synergistic operation, leveraging the strengths of each cycle to achieve enhanced energy recovery. The main objective is to minimize waste energy by effectively capturing and converting exhaust heat from the GT and CBC into useful power via the ORC-VCR, ultimately maximizing overall system efficiency and reducing environmental impact.

2. SYSTEM DESCRIPTION
The proposed system, illustrated in Fig. 1, comprises three cycles: a GT as the main cycle, a CBC as the middle cycle, and an ORC-VCR as the bottoming cycle. The system is operated using a combination of biomass and solar resources. Biomass is the primary fuel, while solar energy is used for hydrogen generation by Proton Exchange Membrane Electrolyzer (PEME). The hydrogen is then burned in a combustor to reheat the flue gas from the turbine. The utilization of hydrogen combustion in the gas turbine results in an elevated flue gas temperature from the turbine. This increased temperature is too high to be directly utilized as a heat source in an ORC-VCR, which would lead to significant exergy destruction in heat exchangers. To address this issue, a CBC is employed. The CBC efficiently recovers the waste heat and prevents excessive exergy destruction. In the CBC, helium is chosen as the operating medium. Helium offers yields a higher efficiency compared to similar gases, such as N_2 [7]. Additionally, the lower working pressure of helium, when

compared to CO_2, provides an additional advantage. To simplify the modeling of the investigated system, certain assumptions have been made [8].

- Thermal losses from the components of the system are disregarded.
- Changes in kinetic and potential energy were considered negligible and therefore excluded from the analysis.
- The system operates under a steady-state condition.

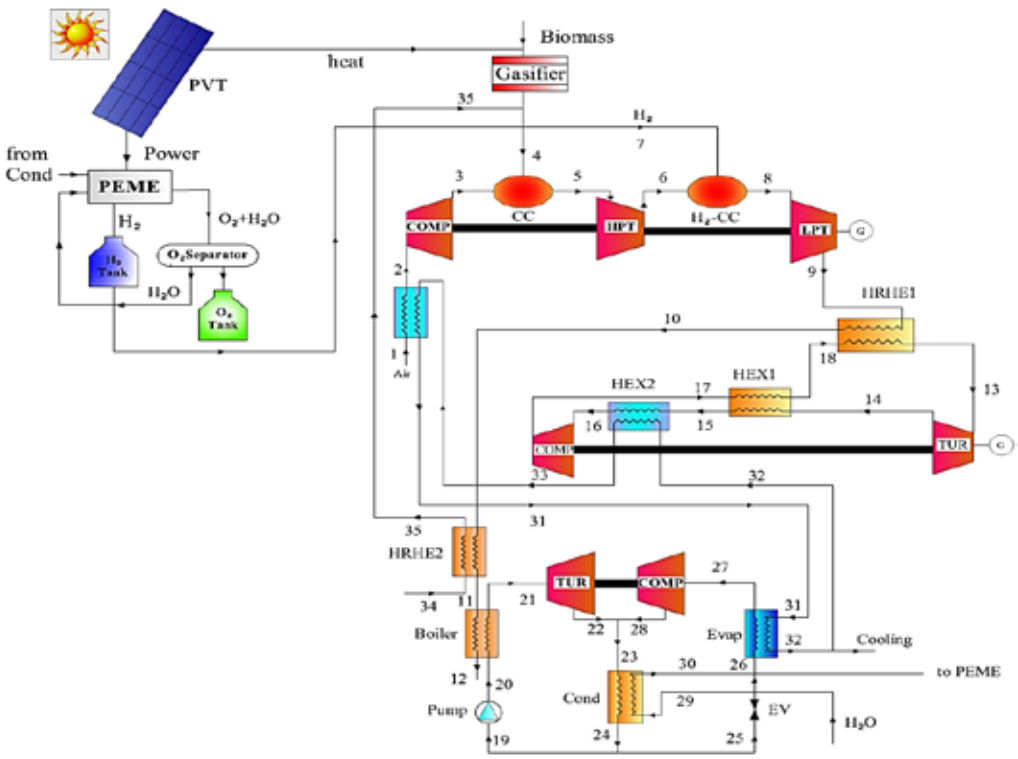

Fig. 1. Schematic of the proposed multigeneration system driven by solar and biomass energy sources

3. THERMODYNAMIC MODELING

To evaluate the feasibility of the system from both energy and exergy perspectives, the system is formulated thermodynamically. These models utilize the principles of energy conservation and exergy analysis to assess the performance of each component within the system. The Engineering Equation Solver (EES) software is used to model the system's behavior and solve the resulting system of equations [9].

$$\sum_{in} \dot{m}_i = \sum_{out} \dot{m}_e \tag{1}$$

$$\dot{Q}_{cv} + \sum_{in} \dot{m}_i h_i = \dot{W}_{cv} + \sum_{out} \dot{m}_e h_e \tag{2}$$

$$\dot{E}x_Q + \sum_{i} \dot{m}_i ex_i = \sum_{e} \dot{m}_e ex_e + \dot{E}x_W + \dot{E}x_D \tag{3}$$

$$ex_{ph} = (h - h_0) - T_0(s - s_0) \tag{4}$$

The exergy efficiency of the studied system is determined from Eq. 5.

$$\eta_{ex} = \frac{\dot{W}_{net} + \dot{m}_{31}(h_{31} - h_{32})}{\dot{E}_{Biomass} + \dot{E}_{solar}} \tag{5}$$

Chemical exergy represents the maximum useful work obtainable when a substance transitions from its initial chemical state to equilibrium with the environment. For the fluids within the investigated system, calculations of chemical exergy were performed using the equations detailed in [2-4]. The biomass properties used as well as the equations used to model the PEME, and PVT are taken from references [8-9].

4. RESULTS AND DISCUSSIONS

Figs 2 and 3 present the validation of models for the GT cycle and PEME, using previous research conducted under identical conditions. The comparisons performed in this study demonstrate a strong agreement with the findings reported in the corresponding references (less than 1.5%), indicating the reliability and consistency of the results.

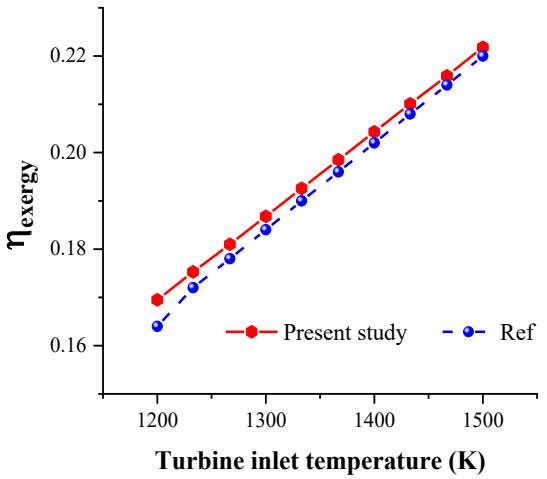

Fig. 2. Comparison of GT modeling with Ref [7]

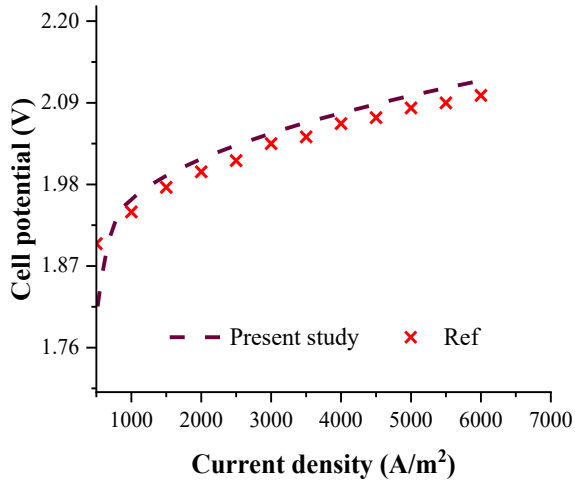

Fig. 3. Comparison of PEME modeling with Ref [10]

Fig. 4 illustrates the variations in exergy efficiency and system production power with the CBC compressor pressure ratio. As depicted in the figure, an initial increase in the compressor pressure ratio leads to a corresponding increase in both the system production power and exergy efficiency. However, beyond a certain point, these values start to decline. This indicates that the optimal values for these two parameters occur at approximately 4 for the compressor pressure ratio. This trend is because, for pressure ratios below 4, the power generated by the system surpasses the power consumed by the compressor, resulting in an overall improvement in system efficiency. Conversely, the situation is reversed for pressure ratios higher than this threshold, leading to a decrease in efficiency.

Fig. 5 illustrates the changes in exergy efficiency and system production power concerning the GT compressor pressure ratio. As clearly evident in the figure, with an increase in the compressor pressure ratio, the efficiency and production power of the system increase continuously. This finding is why, at all pressure ratios, the amount of power produced by the turbines of the GT cycle exceeds the power consumed by the compressor. It should be noted that at high-pressure ratios, the slope of the curve decreases, indicating that the increase in turbine production power compared to compressor power consumption occurs at a lower rate.

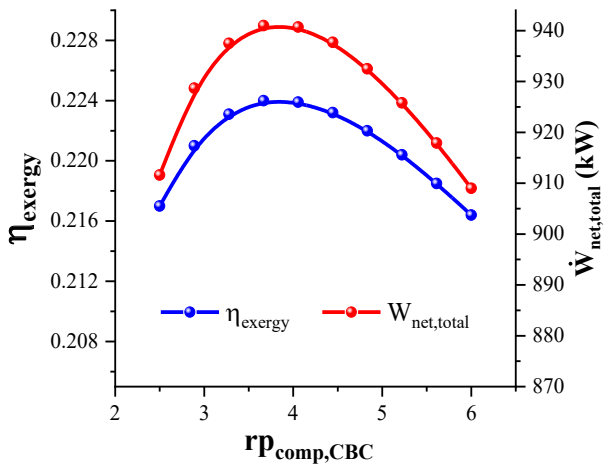

Fig. 4. Changes in $rp_{comp,CBC}$ with system performance

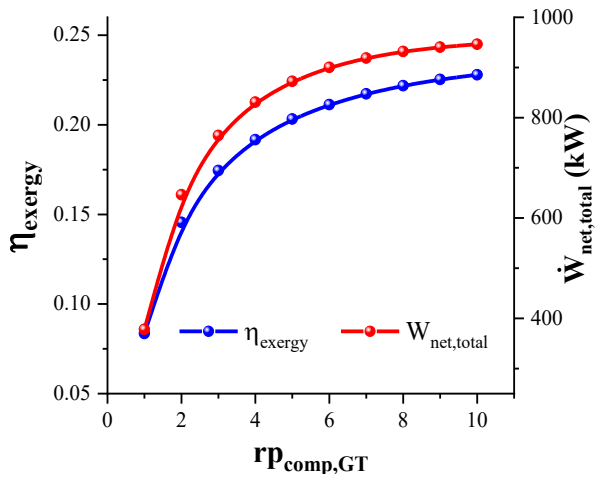

Fig. 5. Changes in $rp_{comp,GT}$ with system performance

Another parameter influencing the performance of the investigated system is the ORC-VCR turbine inlet temperature, which indicates the proportion of heat transferred to the subsystem and the portion assigned to the gasifier for recovery. Changes in T_{21} with two stated parameters are depicted in Fig. 6. According to the figure, with the increase

in T_{21}, the input energy to the subsystem rises, leading to an increase in cycle production cooling. Conversely, the amount of recovery heat to the gasifier decreases. The interaction of these two issues establishes optimal conditions for the system. Additionally, the temperature variations of T_{21} concerning the heat transferred to the subsystem and the quantity of biomass required in the gasifier are illustrated in Fig. 7. With the temperature increase, the heat input to the subsystem rises. Conversely, the amount of heat transferred to the gas turbine cycle decreases. Consequently, consuming more biomass to compensate for this heat loss becomes necessary, ensuring the required heat supply for the system through combustion.

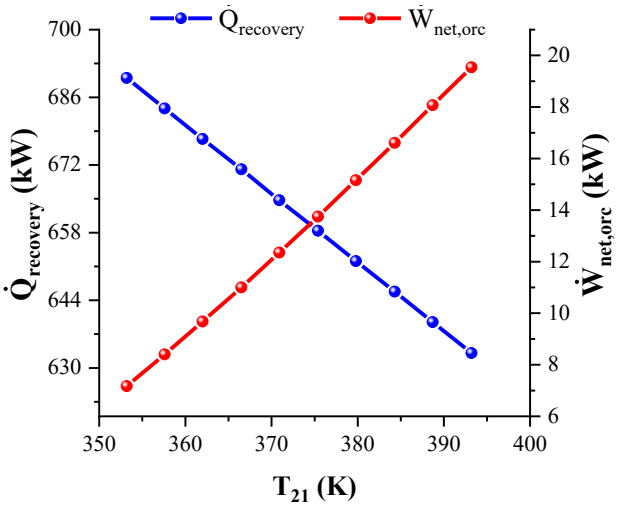

Fig. 6. Changes in T_{21} with system performance

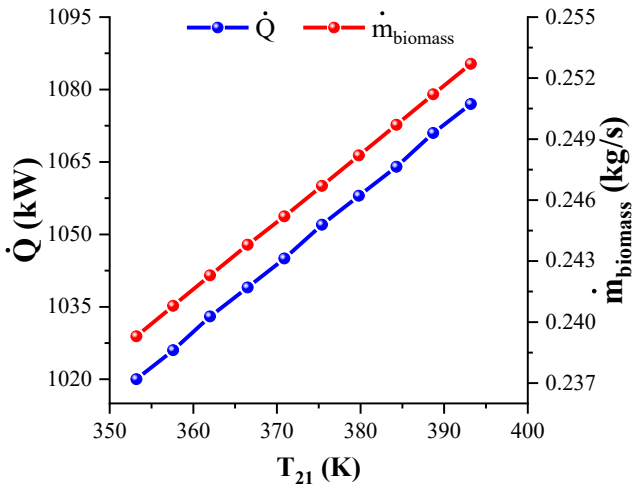

Fig. 7. Changes in T_{21} with heat and required biomass

5. CONCLUSIONS

This study presents a novel multigeneration system that integrates biomass and solar energy. The system utilizes solar energy for hydrogen production to mitigate the intermittency of solar radiation, ensuring a stable and efficient energy supply. Subsequently, the generated hydrogen is transferred to the post-firing combustor to enhance the power generation capability. The system is engineered to optimize the utilization of recycled heat from the turbine, yielding 0.00699 kg/s of hydrogen production, 931.8 kW of electricity generation, 180 kW of cooling output, and 122.4 kW of heating capacity. With these parameters, the system attains an exergy efficiency of 22.18%.

ABSTRACT
This study aims to produce hydrogen using the photoelectrochemical method, which is a sustainable and reliable hydrogen production method. This study used gallium and zinc oxide due to their photocatalytic properties. Stainless steel was selected as the electrode to be coated, and the coating process was carried out using the dip coating method. Light and dark environments were created using a solar simulator, and then measurement analyses were obtained using a GAMRY device in these environments. According to the data, the photocatalytic properties of Ga-doped ZnO coating on stainless steel are highly efficient.

Keywords: Dip-coating, Hydrogen production, Ga-doped ZnO, Photoelectrochemical method, Stainless steel.

1. INTRODUCTION
Hydrogen has been playing a vital role in recent years in terms of environmental impact and sustainability as a clean and reliable energy carrier [1]. It needs to go through various processes to make hydrogen effective as a usable energy carrier. The choice of the production method of hydrogen, which must be produced safely and efficiently, is crucial in terms of the emission effect in the production process. Photoelectrochemical hydrogen production is a reliable and clean method that is very important in sustainability. Studies are being carried out on material coating methods to be used as catalysts to make hydrogen production efficient with this method. Gallium (Ga) and zinc oxide (ZnO) have been investigated recently due to their photocatalyst properties. In a study by Nuñez et al., photocatalytic hydrogen production of Ga-modified ZnO photocatalysts prepared by hydrothermal methods was investigated. Their study used Platinum (Pt) as a cocatalyst and noted that this accelerated hydrogen production as an electron scavenger [2]. Taha et al. produced Ga-doped ZnO material using a spin-coating method to be used as a sensor in a study they conducted [3]. The methods and chemicals used in their research are important for this study. In this study, hydrogen production was realized by coating Ga-doped ZnO photocatalyst on stainless steel using the dip-coating method.

2. MATERIALS AND METHOD
Figure 2 shows a schematic representation of this study. First, the solution to be used in the coating was prepared. The solution contains 2-propanol, ethanolamine, Gallium oxide, and Zinc acetate dihydrate in specific proportions. The electrolyte to be coated was determined to be stainless steel. First, the stainless-steel surface was sanded and then kept in hydrochloric acid. Then, dipping-pulling was carried out in the prepared solution, and the coating was adhered to the surface by applying heat with a heat gun. The coated material was then placed in a drying oven. A solar simulator was used for hydrogen production using the photoelectrochemical method. The necessary measurements were taken using a GAMRY device with the material coated as a photocatalyst.

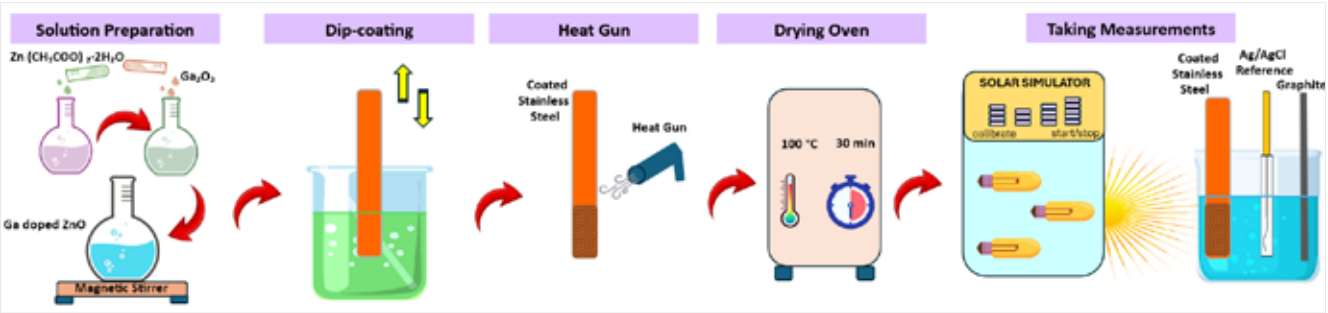

Fig. 1. Schematic representation of this study.

3. RESULTS AND DISCUSSION

Figure 2 shows the photocurrent experimental results of the coated material. The data shows the current changes under light illumination and in a dark environment. The figure shows that the coated material does not produce a photogenerated current when there is no light illumination. The increase in current value when light is applied indicates that electron-hole pairs are formed due to photogeneration; thus, photoelectrochemical reactions take place on the coated electrode. According to the graph, photogeneration of photogenerated current occurs in the coated materials when illuminated by light. This indicates that the coated materials act as photocatalysts. In addition, the fact that the photocurrent levels reached similar values in the light-on-off processes suggests that the electrode under light has a photoelectrochemically stable performance.

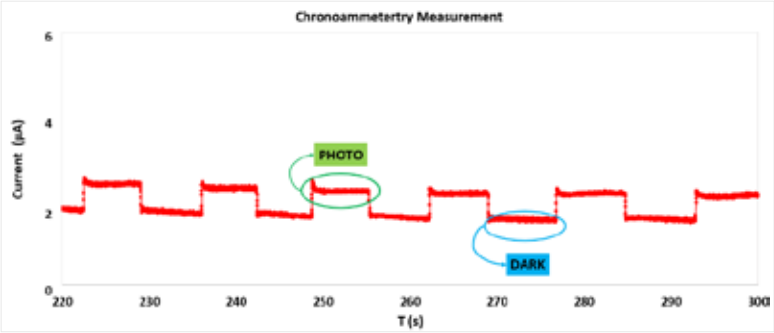

Fig. 2. Photocurrent experimental result graph of the coated material.

4. CONCLUSION

In this study, the photoelectrochemical method applied Ga-doped ZnO coating on stainless steel for hydrogen production. Dip-coating was used as the coating method, and the necessary processes were applied to ensure that the coating adhered to the surface. The GAMRY device was used to measure the photocatalytic properties of the coated material, and measurements were taken both in the dark and under light. According to the study results, the material developed as a photocatalyst shows highly efficient photocatalytic properties under light illumination. This study's innovative aspect is combining the electrode and coating method with Ga and ZnO.

ABSTRACT
The advancement of technology and industrialization has increased environmental pollution, prompting individuals and institutions to seek sustainable solutions. Fuel cells, offering high efficiency, an eco-friendly structure, and long range, stand out as a strong alternative to reduce dependence on fossil fuels. In this study, a T-Class Fuel Cell Hybrid Electric Off-Road Vehicle powered by an electric motor instead of an internal combustion engine was modeled in Matlab/Simulink, and drive cycle simulations were performed. In this study, electric motor power requirements were calculated and power outputs of the fuel cell and battery was compared during the simulation time. Additionally, The SOC of the battery was determined based on the battery power output. The findings highlight the potential of T-Class Fuel Cell Hybrid Electric Off-Road Vehicles for sustainable transportation and demonstrate positive improvements in range and efficiency.

Keywords: fuel cell electric vehicle, battery, Off-Road Vehicle, sustainable transportation

1. INTRODUCTION

The disruption of environmental balance has prompted people to explore alternative energy sources. Research has shown that fuel cells have the potential to solve this problem. Due to their high efficiency and minimal environmental impact, these cells have secured a significant place among the most important alternative energy sources of the future. Fuel cells are devices that produce electricity and heat by allowing a chemical reaction between a fuel, such as hydrogen, and oxygen. In this process, the energy from the fuel is directly converted into electrical energy, with minimal harmful waste released into the environment [1]. This technology offers a significant environmental advantage compared to fossil fuel-based energy production methods, as it generates less carbon emissions and pollution. Furthermore, the abundance of hydrogen makes fuel cells a sustainable energy source in the long term.

The use of fuel cells in vehicles offers important advantages, such as high energy efficiency and the ability to convert fuel directly into electrical energy, without the need for combustion, resulting in very low emission levels [2]. This technology is more environmentally friendly and ensures more efficient energy use compared to vehicles with internal combustion engines. This study aims to examine the performance of fuel cell and battery-based power systems through the design of a T-Class Fuel Cell Hybrid Electric Off-Road Vehicle powered by an electric motor instead of an internal combustion engine. The vehicle, modeled on the Matlab/Simulink platform, will be simulated using the Worldwide Harmonized Light Vehicles Test Cycle (WLTC), and a comparison of the efficiency, range, and overall effectiveness of both power sources will be made. These simulations will evaluate how the T-class fuel cell hybrid electric off-road vehicle performs in real-world conditions and highlight the advantages of both technologies.
The research results are expected to more comprehensively showcase the potential of fuel cell vehicles in contributing to sustainable transportation. Furthermore, this study will provide valuable insights into the development of FCEV technology and energy efficiency improvements, contributing to future transportation solutions. Fuel cells, compared to batteries, are expected to make significant contributions to industry developments as a more efficient and environmentally friendly option. This research aims to accelerate innovations in the sector and contribute to the development of sustainable transportation solutions.

2. MODELING AND SIMULATION

2.1 Vehicle Models

Calculating the vehicle's traction power is essential for determining the energy required by the electric motor during driving. This calculation requires knowledge of the total forces acting on the vehicle during its motion. These forces are fundamental physical factors that influence the vehicle's movement and stability and play a crucial role in optimizing its dynamic performance. Rolling resistance (F_R) represents the force caused by shape deformation during the contact of the wheels with the road surface. Aerodynamic drag resistance (F_L) is the resistance generated by air flow during the vehicle's movement. Acceleration resistance (F_a) refers to the resistance encountered by the vehicle during acceleration or deceleration. Regenerative braking force (F_a-) functions by recovering energy during braking to recharge the battery. Accurate calculation of these forces ensures a better understanding of the vehicle's energy consumption and performance. The corresponding equations are shown in (1-4).

$$F_R = m \cdot g \cdot f_R \quad (1)$$

$$F_L = \frac{1}{2} \cdot c_W \cdot A \cdot \rho_L \cdot V^2 \quad (2)$$

$$F_a = m \cdot a \quad (3)$$

$$F_a^- = m \cdot a^- \quad (4)$$

The vehicle parameters of the fuel cell hybrid electric vehicle examined in this study are presented in Table 1. These parameters were integrated into the mathematical model created in the Matlab/Simulink environment, and the desired output results were calculated. The obtained results are presented as graphs in the findings section.

Table 1. Vehicle parameters

Symbol	Parameter	Value	Unit	Symbol	Parameter	Value	Unit
m	Mass	1270	kg	SoC	State of charges	%85	-
A_f	Frontal area	2.86	m^2	P_{FC}	Fuel cell power	1	kW
F_r	Rolling resistance force	0.03	-	A_{FC}	Active area of fuel cell	500	cm^2
ρ	Density of air	1.225	kg/m^3	n_{FC}	Fuel cell cell number	48	1
C_w	Aerodynamic drag coefficient	0.7	-	i_d	Differential gear ratio	2	-
r_w	Wheel radius	0.335	m	i_t	Transmission gear ratio	2.4	-
V	Electric motor voltage	400	V	i_{em}	Electirc motor gear ratio	1	-

2.2. Powertrain Component Models

The power output of the electric motor is calculated by multiplying the total motion resistance forces, as specified above, by time as a function of vehicle speed. The power output formula is given in Equation (5). In the equation, η_m represents mechanical efficiency.

$$P_{EM} = \frac{(F_R + F_L + F_a + F_a^-)}{\eta_M} \cdot V \quad (5)$$

The torque of the electric motor represents the force applied by the motor during rotation and the rotational force in vehicles. After calculating the power requirements, the torque [Nm] produced in the model is determined using Equation (6) and Equation (7). In these equations, *ig* represents the overall gear ratio between the wheel and the electric motor, while *rdyn* represents the dynamic wheel radius [mm] [3].

$$T_{EM} = \frac{(P_{EM} \cdot 9549)}{\eta_{EM}} \quad (6)$$

$$\eta_{EM} = \frac{V}{3.6} \cdot \frac{60}{2\pi} \cdot \frac{i_g}{r_{dyn}} \quad (7)$$

SOC defines the remaining energy in the battery and is commonly expressed as a percentage. That is, when the battery is fully charged, the SOC is considered to be 100% of its nominal capacity, and when it is completely discharged, the SOC is considered to be 0% [4]. The SOC at a specific time can be found using Equation (8).
The main difference between the battery and the fuel cell is that fuel cells generate electricity, while batteries store electricity. As is well known, batteries contain energy-donating chemicals within the system. When the battery's circuit is closed and energy is used, the battery's potential starts to deplete, and eventually, the battery is drained [5].

$$SOC(t) = SOC(0) - \frac{1}{C_{bat}} \cdot \int_o^t P_{bat} \cdot dt \quad (8)$$

In this study, PEM (Proton Exchange Membrane) fuel cell type has been preferred. The PEM fuel cell model has been developed in the Matlab/Simulink environment. Using current (A) as input, the values for voltage (V), power (W), hydrogen consumption (L/min), oxygen consumption (L/min), and water production (L/min) are obtained as outputs.
The cell voltage (V_{cell}) is determined using Equation (9). When a cell supplies power to a load, the Nernst voltage (E_{Nernst}), activation loss (V_{act}), ohmic loss (V_{ohm}), and concentration loss (V_{conc}) reduce the voltage. Hydrogen consumption is influenced by electrochemical reactions and the current demand. The power required by the motor, which is converted into current (I_{motor}, [A]), is provided to the fuel cell model based on the energy management strategy, enabling precise dynamic response modeling under changing conditions [5].

$$V = E_{Nerst} - V_{act} - V_{ohmic} - V_{conc} \quad (9)$$

2.3. Simulation Model

This study presents the model of a T-class fuel cell hybrid electric off-road vehicle developed in the Matlab/Simulink environment for vehicle performance and range evaluation. The structure of the model is shown in Figure 1. The model consists of key subsystems, including vehicle dynamics, powertrain components, fuel cell, and battery. In this hybrid system, the fuel cell is used to charge the battery and supply power to the electric motor, while the battery stores energy to propel the vehicle. The electric motor utilizes the power from both energy sources to drive the vehicle. The simulation uses the Worldwide Harmonized Light Vehicles Test Cycle (WLTC) as a reference. This section presents the mathematical model of the vehicle and the underlying equations in detail.

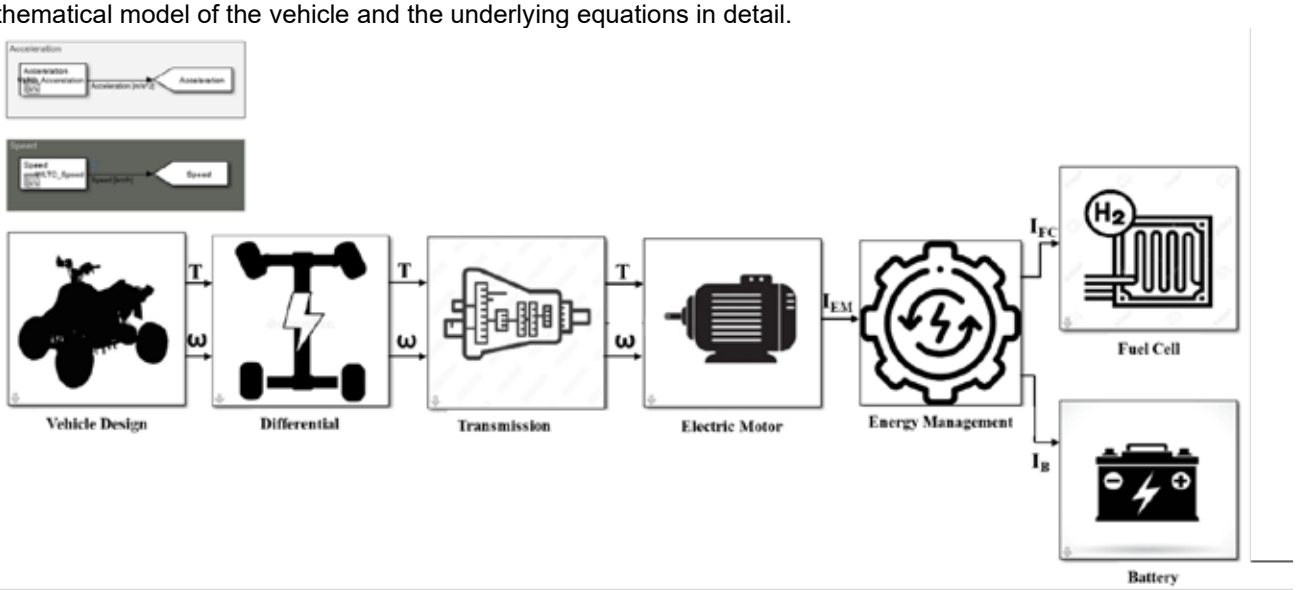

Fig. 1. Matlab/Simulink model for T class fuel cell hybrid electric off-road vehicle (T: Torque, ω: Angular velocity, I: Current)

The Max. SOC-of-FC control strategy is designed to enhance the efficiency of the fuel cell and maintain the SOC at high levels. The fuel cell can stop operating under certain conditions. In this case, the SOC comes into play to meet the vehicle's power demand. When the fuel cell stops operating, and the vehicle's SOC reaches a predetermined upper limit, the energy needs are met solely by the SOC. This prevents overloading the fuel cell, thereby increasing efficiency. Conversely, when the SOC reaches its lower limit, the fuel cell is reactivated to recharge the SOC, ensuring that the powertrain operates continuously and efficiently. This control strategy allows for the separate management of the fuel cell and SOC, ensuring that both systems operate within their optimal efficiency regions, leading to energy savings and improved performance. This control strategy is illustrated in Figure 2.

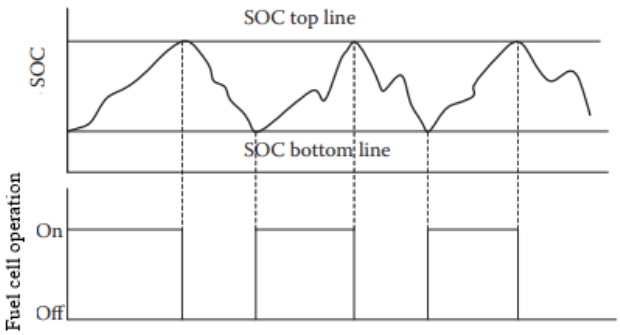

Fig. 2. Illustration of The Maximum SOC-of-FC Control Strategy

3.RESULTS AND DISCUSSION

In the vehicle model developed for the T-Class Fuel Cell Hybrid Electric Off-Road Vehicle, which utilizes a PEM fuel cell and is classified as an off-road vehicle, the vehicle parameters provided in Table 1 have been used. Based on the time-dependent driving cycle speed inputs, the required electric motor power, vehicle speed, hydrogen consumption, and fuel cell power have been calculated for the vehicle components.

As seen in Fig. 3a, the vehicle speed reaches a maximum of 65 km/h and a minimum of 18 km/h. As seen in Fig. 3b, the electric motor power varies between 19000 W and -3000 W. The Fig. 3d, shows that the electric motor torque (Nm)

varies over time and engages periodically. Sudden spikes are related to fluctuations in power demand. In Fig. 3d, the battery current exhibits constant fluctuations, occasionally reaching negative values, indicating regenerative braking. Meanwhile, the fuel cell current is generally positive and follows an irregular pattern, dynamically responding to varying load demands. In Fig. 3e, the battery's state of charge initially remains around 85% and generally maintains this level. However, occasional drops indicate an increase in energy drawn from the battery. The overall stability of the SoC level suggests that the energy management strategy is functioning effectively. In Fig. 3f, hydrogen consumption varies over time, with a noticeable increase observed after the 500th time step. This rise indicates a higher energy demand and greater power drawn from the fuel cell. Between the 600-800 time steps, hydrogen consumption reaches its peak, suggesting that the system relies more on the fuel cell during this period.

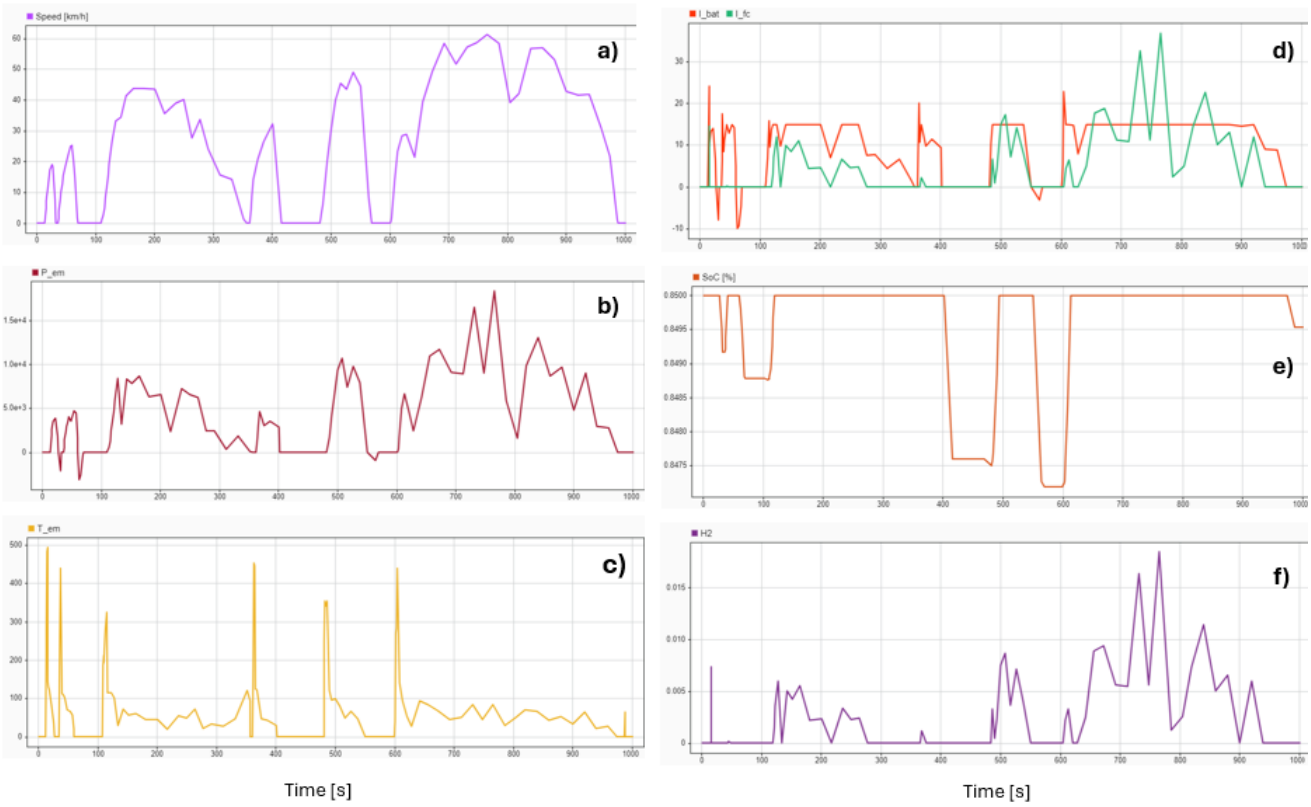

Fig. 3. Simulation results of fuel cell off-road vehicles depending on vehicle speed (a) for electric motor power (b), electric motor torque (c), battery and fuel cell current (d), state of charge (SoC) (e), H_2 consumption (f)

4. CONCLUSIONS

In this study, the performance of a T-Class Fuel Cell Hybrid Electric Off-Road Vehicle was analyzed in the Matlab/Simulink environment. The results demonstrate that fuel cell hybrid powertrains offer advantages in terms of energy efficiency, extended range, and environmental sustainability. The integration of the fuel cell and battery enabled balanced energy management, optimizing power distribution and enhancing vehicle performance. Analyzing vehicle performance plays a critical role in future studies for system optimization and component selection. Different energy management strategies can alter power distribution, leading to various choices in fuel cell and battery sizing. For instance, a larger battery can meet short-term high power demands, while a smaller fuel cell can improve system efficiency. The findings support the feasibility of fuel cell systems in off-road vehicles. Future studies can focus on system optimization and real-world testing to further improve this technology. The widespread adoption of fuel cell vehicles will contribute to reducing carbon emissions and promoting greener transportation alternatives.

ABSTRACT
Proton exchange membrane fuel cells (PEMFCs) offer a clean energy solution but face challenges in thermal and water management that impact performance and durability. A 1D coupled heat and mass transfer model was developed to examine the interactions between temperature distribution and membrane water content under varying conditions. Results indicate that increasing the current density leads to a higher overall temperature, with the most significant temperature gradient observed near the membrane. In other words, the temperature distribution shows a steep rise in temperature in the vicinity of the membrane. Simultaneously, the water distribution is not uniform; instead, water content progressively increases toward the cathode. Maintaining uniform water distribution is crucial for optimal proton conductivity. Imbalances can reduce performance or cause flooding. These findings emphasize the importance of managing both thermal and water profiles to enhance PEMFC efficiency and longevity.
Keywords: PEMFC, temperature distribution, water content, current density, thermal management.

1. INTRODUCTION
Proton exchange membrane fuel cells (PEMFCs) are attracting increased attention due to their high efficiency and zero emissions, with a wide variety of applications including hybrid power systems, electric vehicles, and space missions. They are considered as potential replacements for internal combustion engines due to their high efficiency and quiet operation. However, commercialization is hindered by cost and durability issues, in part caused by inadequate thermal management[1-4].
Temperature distribution in a PEMFC affects key processes, with uneven distribution reducing membrane hydration and proton conductivity, ultimately decreasing cell performance[5]. Secondly, reaction kinetics are directly affected by temperature. Furthermore, temperature gradients impact water management, leading to issues such as membrane dehydration or flooding, both of which can severely affect cell performance and durability[3]. Consequently, maintaining a uniform temperature distribution is vital to avoid performance losses and degradation[4].
Thermal modeling in PEMFCs has advanced from simple models to integrated approaches, recognizing the critical interplay of heat, water transport, and electrochemical reactions for accurate predictions[4, 6]. 1D models remain advantageous for certain applications[2], which can provide a fundamental understanding of the system. Despite progress in PEMFC thermal modeling, gaps remain in understanding the coupled effects of temperature distribution and water content[4].
This work aims to develop a 1D coupled heat and mass transfer model for PEMFCs to explore the relationship between current density, water content, and temperature profiles, accounting for operating conditions and faults to optimize thermal management and improve system performance.

2. MATERIALS AND METHODS

2.1 Model Overview

A model was developed to analyze coupled heat and mass transfer in a PEMFC, incorporating thermal, electrical, and mass transport mechanisms across multiple layers. Model equations were solved to determine temperature distribution, water content distribution, and species concentration under varying operating conditions.

2.2 Assumptions and Parameters

Steady-state conditions were assumed for thermal and mass transport. The thermal and electrical conductivity of the membrane was isotropic. The reaction kinetics were described by classical electrochemical relationships. Water transport in the membrane was described using empirical correlations based on relative humidity. The heat sources included ohmic heating, entropic contributions, and heat generated by water phase change.

Table 1. Input values for PEMFC model

Parameter Category	Component	Value	Unit
Physical Properties	Membrane thickness	51	μm
Relative Humidity	Anode	0.2	-
	Cathode	1.0	-
Thermal Conductivity	Membrane	0.21	W/(m·K)
	Catalyst layers	0.11	W/(m·K)
	Gas diffusion layers	0.6	W/(m·K)

2.3. GOVERNING EQUATIONS

2.3.1 Heat Transfer Model

The total heat generation in the PEMFC comprises multiple interconnected components that are distributed across different functional layers. The primary heat sources include ohmic heating, electrochemical reactions, and mass transport effects. The rate of ohmic heat generation through the membrane, q_{ohm} is given by:

$$q_{ohm} = r_{ohm} . j^2 \qquad (\mathrm{W/m^2}) \tag{1}$$

where j is the current density and r_{ohm} is a function of both the membrane thickness and its effective conductivity (σ_{mem}) given by:

$$\sigma_{mem} = (0.5139\lambda - 0.326).exp(1268 . (\frac{1}{303} - \frac{1}{T})) \tag{2}$$

Effective proton conductivity is computed by averaging the local conductivity profile across the membrane [7, 8]
The rate of electrochemical heat generation includes both reversible and irreversible components. In the catalyst layers, this is expressed as:

$$q_s = \frac{-j .T .\Delta S}{n_e.F} . f \qquad (\mathrm{W/m^2}) \tag{3}$$

where ΔS is the entropy change (-158 J/mol·K), F is Faraday's constant, n_e is the number of electrons transferred, and f is the distribution factor which is 0.8 for anode and 0.2 for cathode.
The rate of heat generation due to latent heat effects, q_{latent}, is computed by tracking water phase changes:

$$q_{latent} = L_v(T). \dot{m}_{evap} \qquad (\mathrm{W/m^2}) \tag{4}$$

where $L_v(T)$ represents the temperature-dependent latent heat of vaporization, and $\dot{m}_{evap}$ is determined from a material balance for water.
Heat flux due to conduction through each layer follows Fourier's law with distinct thermal resistances:

$$q_{cond} = -k. \left(\frac{dT}{dx}\right) \qquad (\mathrm{W/m^2}) \tag{5}$$

where k varies for each layer (membrane, catalyst layers, GDL, bipolar plates) based on material properties and local conditions.

2.3.2 Mass Transport Model

Species transport was modeled using modified diffusion equations that include reaction terms:

$$D_{eff}. \left(\frac{d^2C}{dx^2}\right) = \frac{j}{nF} \tag{6}$$

where D_{eff} represents the effective diffusion coefficient for either oxygen or hydrogen, adjusted for porosity and tortuosity effects in the GDL and catalyst layers.
The molar flux of species, $n"_{water}$,given by Equation (7) is governed by a complex balance between electro-osmotic drag and back diffusion [8]:

$$n"_{water} = n_{drag}. \left(\frac{j}{F}\right) . (\frac{\lambda}{22}) - \left(\frac{\rho_{dry}}{M_m}\right) . D_\lambda . (\frac{d\lambda}{dx}) \tag{7}$$

where n_{drag} is the electro-osmotic drag coefficient (normalized by $(\frac{\lambda}{22})$), λ is the water content, D_λ is the water diffusion coefficient which is a function of both temperature and water content given by[8]:

$$D_\lambda = D_{base} . (2.563 - 0.33\lambda + 0.0264\lambda^2 - 0.000671\lambda^3) \tag{8}$$

The boundary conditions were determined by the water activity at both interfaces, calculated from local temperature and relative humidity conditions, the proton conductivity of the membrane can be evaluated by[8, 9] :

$$\lambda_{eq} = (0.043 + 17.81a - 39.85a^2 + 36.0a^3) . exp((1268). (\frac{1}{T_{ref}} - \frac{1}{T})) \tag{9}$$

where a is water activity and $\boldsymbol{T_{ref}}$ is 303°C.

2.4 Numerical Implementation

The numerical model employs an explicit finite difference scheme for transients and an implicit iteration for steady-state solutions, using Newton-Raphson for nonlinear equations. It defines boundary conditions, computes water content, membrane conductivity, and heat sources, iterating until the temperature profile stabilizes within 0.01 K.

3. RESULTS AND DISCUSSION

3.1 Temperature Distribution Across PEMFC: Effect of Current Density on Temperature Profile

Fig. 1 illustrates the effect of current density (ranging from 0.32 A/cm² to 2.00 A/cm²) on temperature distribution across PEM fuel cell layers, including the Anode GDL, Anode CL, Membrane, Cathode CL, and Cathode GDL. As current density increases, so does the temperature in all layers, particularly near the membrane due to higher electrochemical activity. At the highest current density (2.00 A/cm²), the temperature reaches about 90°C, compared to 75°C at the lowest current density. This gradient is steeper near the membrane, highlighting increased heat generation from higher reaction rates. The results emphasize the importance of effective thermal management, as higher temperatures may lead to

thermal degradation, water evaporation, and reduced proton conductivity in the membrane, ultimately affecting fuel cell performance [10].

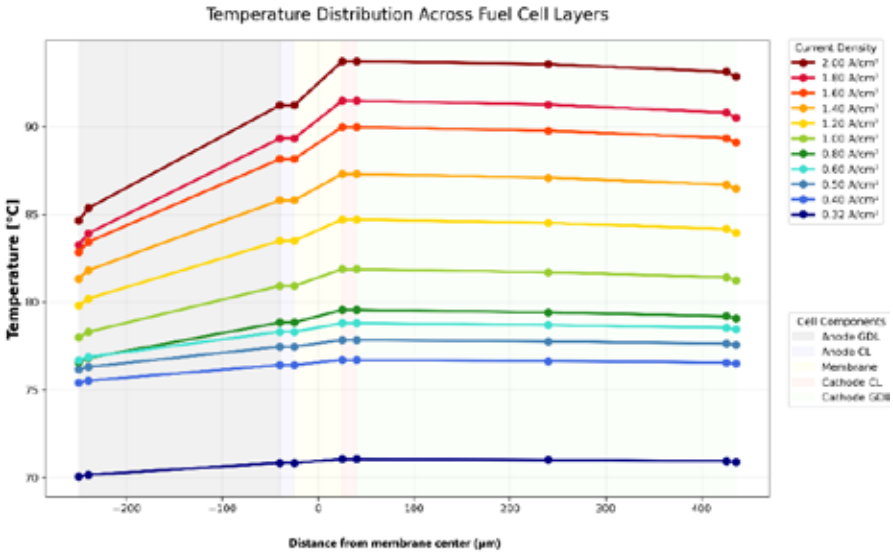

Fig. 1. Temperature distribution across PEMFC

3.2 Membrane Water Content Profile: Influence of Current Density and Humidity Conditions

Fig. 2. shows the water content profile within the PEMFC membrane, which significantly affects its conductivity and performance. At 80°C and 1.00 A/cm² current density, with relative humidity at the anode and cathode set to 0.20 and 1.00, respectively, water content increases towards the cathode (λ ≈ 6.96), while the anode region exhibits lower water content (λ ≈ 1.14), with an average of λ ≈ 4.46. This gradient arises from the water management for the PEMFC which sets the relative humidity of anode to 20% and cathode humidity to 100%. Electrochemical reaction at the cathode produces water, while higher evaporation rates at the anode contribute to dehydration[11]. Maintaining balanced water content is crucial for proton conductivity and fuel cell performance. This study examines near-dry anode conditions to assess boundary conditions and humidification effects, as imbalances can cause dehydration or flooding, reducing efficiency and increasing resistance. Figure 3 illustrates how membrane drying at high current densities creates a persistent temperature gradient, showing the operational malfunction.

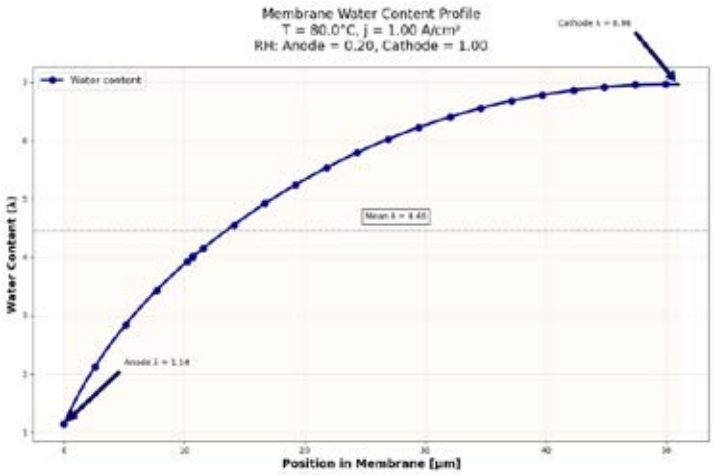

Fig. 2. Membrane water content across PEM

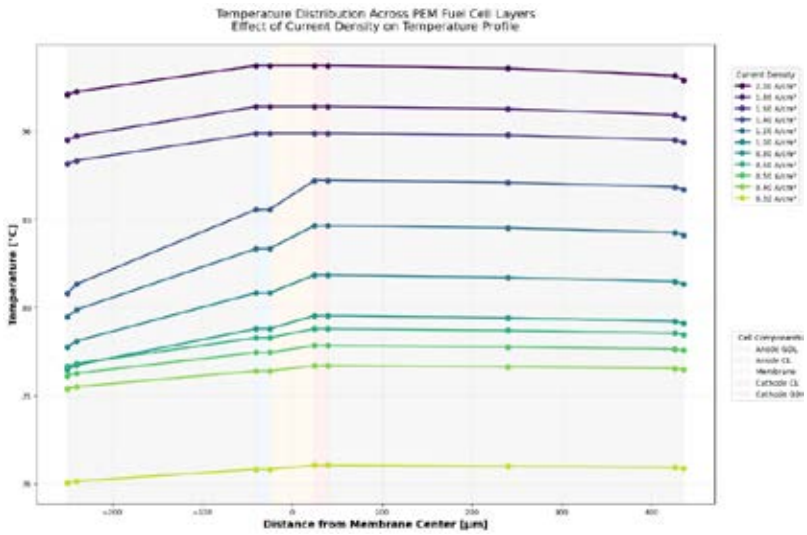

Fig. 3. Temperature distribution across PEMFC

4. CONCLUSIONS

A coupled heat and mass transfer model was developed for analyzing the temperature and water content distribution within PEMFCs. By simulating varying current densities and humidity conditions, the results provide valuable insights into the factors that influence PEMFC performance. The model demonstrates that higher current densities lead to increased temperatures, particularly in the membrane region, which can impact proton conductivity and water retention. Additionally, the water content profile varies across the membrane, with higher values at the cathode, crucial for maintaining membrane hydration and conductivity. These findings emphasize the importance of effective thermal and water management to ensure optimal fuel cell performance and longevity. The study paves the way for future optimization of PEMFC designs, with a focus on addressing the challenges of heat dissipation and water management. Further investigations are recommended to validate these results under more diverse operational conditions and to refine the models for practical applications.

ABSTRACT
This research introduces a hybrid maximum power point tracking (MPPT) technique for proton exchange membrane fuel cells (PEMFC). The suggested system employs a Type-2 Takagi–Sugeno–Kang (TSK) fuzzy logic controller, with the membership function parameters optimized using the GGWO algorithm, which integrates Genetic Algorithm (GA) and Gray Wolf Optimization (GWO). Integrating the robust global search capabilities of the Genetic Algorithm with the rapid convergence proficiency of the Gray Wolf algorithm yields a more balanced and successful optimization process. Type-2 fuzzy logic offers enhanced stability in control performance amidst environmental unpredictability and model ambiguity, while the GGWO algorithm enables systematic and adaptive adjustment of controller parameters. Simulation experiments conducted in the MATLAB/Simulink environment demonstrated that the suggested GGWO-TSK Type-2 FLS structure yields reduced power ripple, diminished settling time, and enhanced tracking accuracy relative to traditional MPPT approaches. The findings indicate that Type-2 fuzzy systems, enhanced by sophisticated intelligence algorithms, offer a viable solution for maximum power point tracking in fuel cell applications.
Keywords: PEMFC Mppt, ggwo-tsk

1. INTRODUCTION

Currently, the swiftly diminishing fossil-based non-renewable energy sources are unable to satisfy the ever-growing global energy demand, alongside their detrimental environmental impact. This predicament has heightened the significance of efficient, sustainable, and eco-friendly renewable energy sources. The production capacity of renewable energy sources, such as solar and wind systems, which are contingent upon weather conditions, have expedited scientific study and investments in this domain. Nevertheless, owing to the substantial expense and intricacy of storing surplus energy generated from renewable energy systems, fuel cells emerge as a prominent alternative clean energy source. Fuel cells possess the capability to deliver continuous electricity irrespective of environmental conditions and seasonal variations, excluding fuel availability. Proton Exchange Membrane Fuel Cells (PEMFC), utilizing hydrogen as fuel, are garnering heightened academic and industrial interest owing to their applicability across diverse sectors. The incapacity of fuel cells to deliver a consistent and stable output power is a notable drawback. The fuel cell's performance exhibits variability based on several operational parameters, including fuel flow rate, operating temperature, gas pressure, and humidity level within the cell. Consequently, maximum power point tracking (MPPT) algorithms are extensively employed to enhance the energy conversion efficiency of PEMFC systems and to identify the greatest power point at the system output.

Various MPPT approaches have been suggested in the conducted investigations. Karami and colleagues [1] evaluated the Perturb and Observe (P&O) and Incremental Conductance (IC) approaches, observing that the IC method had a more steady and rapid reaction. Ahmadi and colleagues [2] devised a PID controller utilizing particle swarm optimization (PSO), resulting in enhanced stability relative to the traditional P&O method. Derbeli and colleagues [3] accomplished rapid and precise MPP tracking across various situations utilizing the backstepping technique. Avanaki and Sarvi [4] devised a WCA-based methodology, attaining superior accuracy and adaptability relative to traditional techniques. Venkateshkumar and associates [5] have enhanced PEMFC efficiency with a fuzzy logic-based control system. Rezk and Fathy [6] attained superior monitoring performance with the VSS-INR approach, which utilizes solely voltage and current sensors. Harrag and Messalti [7] documented a reduced response time and diminished fluctuation with the neuro-fuzzy IC controller in comparison to the conventional IC. Reddy and Sudhakar [8] enhanced maximum power point tracking (MPPT) efficacy with the application of a radial basis function network (RBFN). Mallick and Mukherjee [9] enhanced voltage regulation with a DVR system utilizing artificial neural networks and Type-2 fuzzy logic. Dogan and colleagues [10] established a type-2 fuzzy logic-based MPPT framework, exhibiting a swifter response time, less power fluctuation, and enhanced efficiency relative to the P&O algorithm. Conventional MPPT techniques often face limitations when applied to fuel cell systems, particularly due to nonlinear dynamics and transient fluctuations. Classical methods such as P&O, Type-1 fuzzy logic, and genetic algorithms have shown limited success in accurately tracking the maximum power point under such conditions. As a result, recent research has increasingly focused on hybrid optimization approaches that combine global search and local exploitation capabilities with advanced fuzzy inference systems capable of handling uncertainty, such as Type-2 fuzzy logic.

In this study, a novel GGWO-TSK Type-2 fuzzy logic MPPT controller is proposed for Proton Exchange Membrane Fuel Cell (PEMFC) systems. The controller integrates Genetic Algorithm (GA) and Grey Wolf Optimizer (GWO) within a Type-

2 Takagi–Sugeno–Kang (TSK) fuzzy inference structure to regulate the duty cycle of a boost converter and maximize power output. The proposed algorithm is implemented in MATLAB/Simulink and benchmarked against several conventional and intelligent MPPT strategies.

Simulation results demonstrate that the proposed approach enables the output power to reach the target level quickly and consistently, with a short settling time, limited overshoot, and low ripple. These findings confirm that the GGWO-TSK Type-2 controller offers superior transient and steady-state performance compared to existing MPPT methods in the literature.

2. SYSTEM COMPONENT AND MODELLING

This study employs a comprehensive Proton Exchange Membrane Fuel Cell (PEMFC) model developed in MATLAB/Simulink. The model delivers a power output of 1.26 kW and a nominal voltage of 24 Vdc. A schematic, depicted in Figure 1, was constructed to examine the impact of various control schemes on fuel cell performance. This configuration facilitates an extensive examination of diverse control strategies and their influence on the efficiency and performance of the PEMFC system.

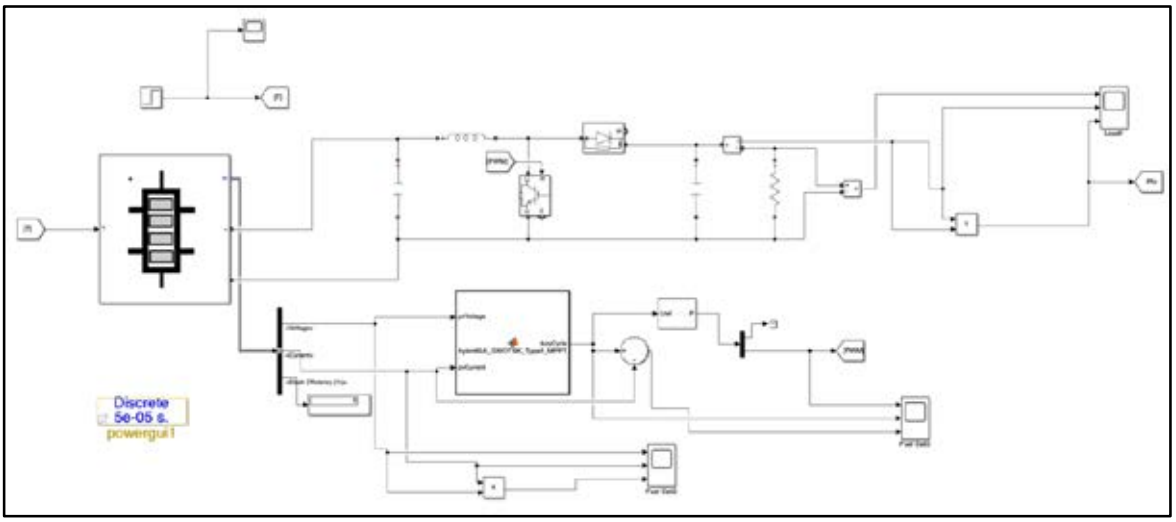

Fig.1. The Configuration of a PEMFC MPPT System

3. GGWO-TSK TYPE-2 FUZZY LOGIC MPPT ALGORITHM FOR FUEL CELL SYSTEM

The pseudocode summary for this control algorithm is shown below. The proposed GGWO-TSK Type-2 Fuzzy Logic MPPT algorithm aims to achieve accurate and robust tracking of the maximum power point (MPPT) in Proton Exchange Membrane Fuel Cell (PEMFC) systems under nonlinear and uncertain operating conditions. This hybrid approach integrates the global search capability of the Genetic Algorithm (GA) with the fast convergence and exploitation strength of the Grey Wolf Optimizer (GWO), while employing a Type-2 Takagi–Sugeno–Kang (TSK) fuzzy inference system to manage the inherent uncertainties in the system.

The algorithm begins with the initialization of a population based on the parameters of Type-2 fuzzy membership functions. Each individual in the population represents a candidate fuzzy system configuration, particularly the antecedent membership function parameters.

At each iteration, the following steps are performed:

1.Fitness Evaluation: The fitness of each individual is calculated based on the squared error and power ripple relative to a predefined reference power value (*P_ref*). This ensures both precision and stability in MPPT performance.

2.Selection, Crossover, and Mutation: Parents are selected using tournament selection, followed by crossover and mutation operations to generate a new offspring population. The best individuals among parents and offspring are retained to form the next generation.

3.Grey Wolf Optimization (GWO): The best-performing individuals from the GA phase are used to initialize the wolf population in GWO. Wolves' positions are updated using the GWO update rules, which involve computing control coefficients (*a*, *A*, *C*) and updating positions relative to the alpha wolf (the best solution).

4.Fuzzy Inference and Duty Cycle Calculation: After GWO convergence, the final alpha wolf's parameters are fed into a Type-2 TSK fuzzy inference system, which takes the fuel cell voltage (*fcVoltage*) and current (*fcCurrent*) as inputs. The system performs Sugeno-style inference to output an optimized duty cycle that drives the boost converter. This iterative procedure continues until a predefined number of generations is reached. The resulting controller not only tracks the

maximum power point with high precision but also demonstrates improved transient performance and robustness compared to conventional and non-hybrid fuzzy MPPT strategies.

4. RESULTS AND DISCUSSIONS

The performance of the proposed GGWO-TSK Type-2 Fuzzy Logic MPPT algorithm was validated through MATLAB/Simulink simulations under dynamic load and environmental conditions. Comparative results among different MPPT strategies, including classical P&O, Type-1 and Type-2 fuzzy controllers, GA-optimized fuzzy controllers, and the proposed GGWO-TSK structure, are presented.

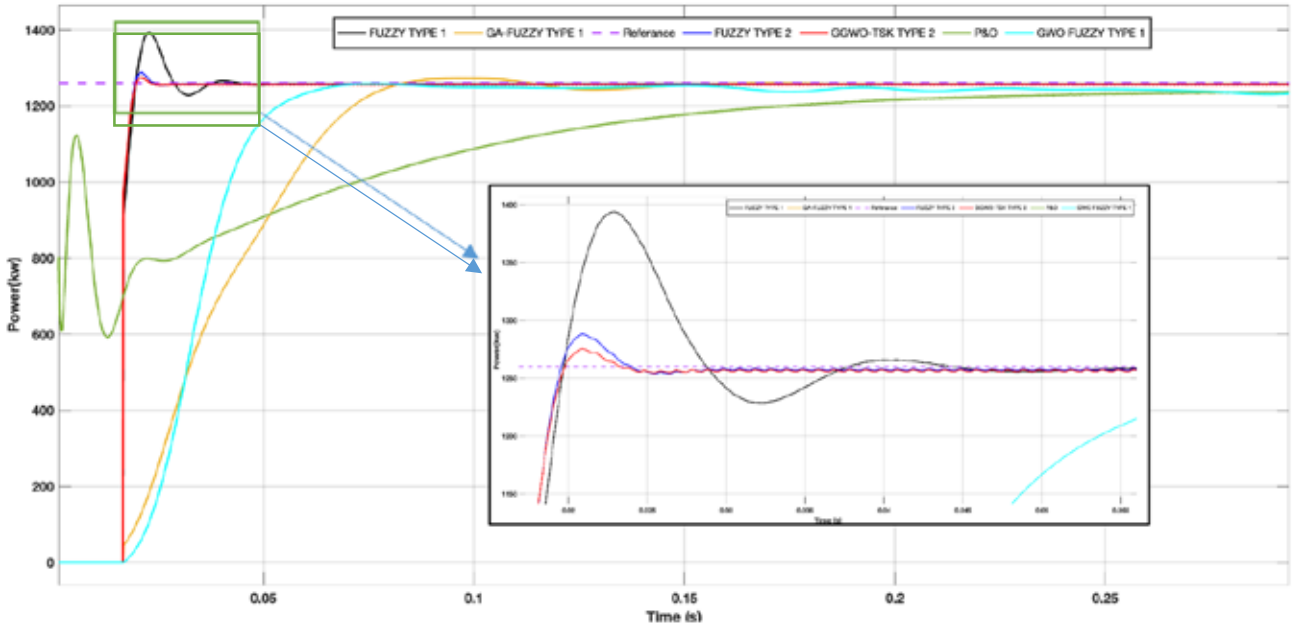

Fig.2. PEMFC MPPT output graph

Table 1. Performance Comparison of Different MPPT Methods for Fuel Cell Applications

	GWO-FUZZY TYPE 1	GGWO-TSK TYPE 2	FUZZY TYPE 2	GA-FUZZY TYPE 1	FUZZY TYPE 1	P&O
Peak Power (W)	1264.4	1275.5	1288.2	1272.7	1393.7	1121.86
Steady-State Power (W)	1243.1	1256.4	1257.3	1258.1	1257.8	1241
Overshoot (%)	1.7161	1.5152	2.4581	1.1627	10.804	0
Rise Time (s)	0.023314	0.0013832	0.0013832	0.043923	0.0018332	0.2
Settling Time (s)	0.05665	0.019115	0.0218	0.07615	0.03355	0.25
Tracking Efficiency (%)	98.658	99.717	99.782	99.846	99.825	98.49

In Table 1, numerical comparisons of key MPPT performance metrics are presented. Although all methods achieved acceptable tracking performance, classical approaches showed significant deficiencies compared to modern optimization-based techniques. The classical P&O algorithm, despite having no overshoot, reached the reference power value slowly and exhibited the lowest steady-state efficiency at 98.49%. Similarly, FUZZY TYPE 1, GWO-FUZZY TYPE 1, and FUZZY TYPE 2 methods exhibited higher overshoot and longer settling times. In contrast, the hybrid GGWO-TSK Type-2 fuzzy logic-based MPPT method demonstrated the best performance, achieving 99.72% tracking efficiency, minimal overshoot, and extremely fast dynamic response. This superior outcome is attributed to the effective combination of the global search ability of the Genetic Algorithm (GA) and the local exploitation strength of the Grey Wolf Optimizer (GWO), alongside the enhanced uncertainty handling capability of the Type-2 Sugeno fuzzy logic structure. Overall, the proposed hybrid GGWO-TSK Type-2 MPPT strategy provides the most efficient and reliable solution for maximum power tracking in fuel cell applications.

V. CONCLUSIONS

This study introduced a hybrid intelligent MPPT control strategy for Proton Exchange Membrane Fuel Cell (PEMFC) systems by combining Genetic Algorithm (GA) and Grey Wolf Optimizer (GWO) within a Type-2 TSK Fuzzy Logic framework. By integrating the global search capabilities of GA with the local exploitation strengths of GWO, the proposed controller effectively optimized the fuzzy membership functions and rule outputs.

The results revealed that the hybrid GGWO-TSK Type-2 fuzzy logic-based MPPT method provided faster dynamic response, lower overshoot, shorter settling time, and higher tracking efficiency compared to all other methods. The hybrid GGWO approach, which combines the global search capabilities of the Genetic Algorithm (GA) with the local fine-tuning abilities of the Grey Wolf Optimizer (GWO), effectively balanced solution accuracy and convergence speed. Additionally, the use of the Type-2 Sugeno fuzzy logic structure allowed for a more accurate modeling of uncertainties compared to classical Type-1 systems, thereby enhancing the system's stability and flexibility. Overall, the proposed hybrid GGWO-TSK Type-2 MPPT strategy stands out as the most effective and reliable solution for maximum power tracking in fuel cell applications.

ABSTRACT
Island microgrids encounter considerable technical and regulatory challenges in sustaining system frequency and voltage stability owing to high swings and uncertainties in energy supply and demand. The intermittent characteristics of renewable energy sources, especially the erratic output patterns of photovoltaic (PV) systems, hinder stability and demand rapid and efficient control strategies for independent operation from the main grid. This research seeks to develop and enhance a hybrid Takagi-Sugeno Type 2 fuzzy logic controller (TS-T2F) for voltage and frequency regulation in an isolated microgrid incorporating photovoltaic systems, batteries, and fuel cells, utilizing the genetic grey wolf optimization method (GGWO). The battery enhances system reliability by mitigating production discrepancies, while the fuel cell ensures energy continuity by delivering consistent power during periods of low photovoltaic output. The system has implemented a load shedding and reconnection technique based on voltage levels for three distinct loads. The GGWO-TS-T2F approach has shown enhanced frequency stability relative to the Droop V/F and GGWO-TS-T1F methods, and it has also yielded beneficial outcomes in voltage regulation and load shedding/restoration procedures. This research introduces a novel control methodology for autonomous microgrids.
Keywords: Voltage-frequency control, ggwo-tsk type 2

1. INTRODUCTION
Island microgrids face serious technical and regulatory challenges in maintaining system frequency and voltage stability due to significant fluctuations and uncertainties in energy supply and demand [1]. The intermittent nature of renewable energy sources such as photovoltaic (PV) systems leads to unpredictable production profiles, while dynamic load changes further complicate system stability [2]. Operating independently of the main grid, these microgrids need fast and robust control strategies for reliability and operational safety, as they lack a support to buffer such disorders. Conventional control methods, such as droop control, are often insufficient to provide the quick response required to manage these challenges, resulting in frequency and voltage deviations that can compromise system performance.
The literature categorizes the methods for voltage and frequency management in islanded microgrids into three groups: classical methods, fuzzy logic-based methods, and optimization-based methods. Among the traditional methodologies, droop control and PI/PID-based controllers are prominent. Droop control enables load sharing; nevertheless, it is inadequate in mitigating frequency variations caused by the variability of renewable energy sources. Furthermore, it has been noted that PI/PID controllers are employed for frequency management in islanded microgrids; however, their ability to adapt to dynamic changes is constrained [3]. Conversely, fuzzy logic-based approaches offer benefits in representing system uncertainty and nonlinear dynamics. Takagi-Sugeno (TS) fuzzy logic models, particularly those with Type 2 (T2F) configurations, are often favored in microgrid control due to their superior capacity to manage uncertainty [3]. A T2F-based controller enhances voltage management in photovoltaic and fuel cell systems. The efficacy of fuzzy logic controllers is significantly contingent upon parameter optimization [4]. At this juncture, optimization-based methodologies are employed. Genetic algorithms (GA), particle swarm optimization (PSO), and grey wolf optimization (GWO) are meta-heuristic methods that have been successfully employed to optimize control settings [5]. For instance, it has been documented that PSO yields superior outcomes by optimizing the parameters of fuzzy controllers in frequency regulation [6]. Nonetheless, a singular optimization strategy typically struggles to deliver equitable performance in both exploration and exploitation phases.
Hybrid optimization techniques have yielded substantial progress in addressing these constraints. Hybrid methodologies such as Genetic Grey Wolf Optimization (GGWO) integrate the social hierarchy and hunting tactics of Grey Wolf Optimization (GWO) with the mutation and crossover processes of genetic algorithms, resulting in accelerated convergence and enhanced capacities for identifying global optima. This benefit facilitates the precise modification of control settings, particularly in intricate systems characterized by uncertainty [7]. This paper seeks to address this deficiency by providing a hybrid TS-T2F controller optimized using GGWO for voltage and frequency regulation in an isolated microgrid incorporating photovoltaic systems, batteries, and fuel cells. The controller improves the system's dynamic performance and ensures dependability by compensating for battery output deficits; the fuel cell maintains energy continuity by delivering consistent power during periods of low photovoltaic production. A load shedding and reconnection approach predicated on voltage levels has been instituted to preserve system stability during critical circumstances. The proposed method will be evaluated against Droop V/F and GGWO-TS-T1F techniques to illustrate

the superiority of the hybrid approach in voltage and frequency regulation.

2. SYSTEM COMPONENT AND MODELLING

The proposed microgrid configuration, as illustrated in Fig.1, is designed to operate entirely in islanded mode, independently from the main utility grid. The system comprises renewable energy generation units, an energy storage system, measurement devices, and an intelligent load management mechanism. On the generation side, the microgrid integrates photovoltaic (PV) panels, a fuel cell, and a battery energy storage system (BESS). While the PV system provides intermittent power depending on environmental conditions, the fuel cell offers stable and continuous power generation. The battery system plays a crucial role in maintaining system balance by supplying or absorbing power during rapid load changes. All power sources are connected to the microgrid through DC/AC power electronic converters (inverters).

Voltage and frequency measurements are continuously monitored via dedicated sensors, and the data is processed by a Type-2 Fuzzy Logic Controller. This controller determines the operating status of loads based on optimized voltage and frequency thresholds. The load management unit then actuates three switching elements (SW1, SW2, SW3), enabling selective load shedding or reconnection according to system conditions. Through this coordinated operation, the microgrid maintains supply-demand balance, ensures voltage and frequency stability, and operates reliably in standalone mode using only its local energy resources.

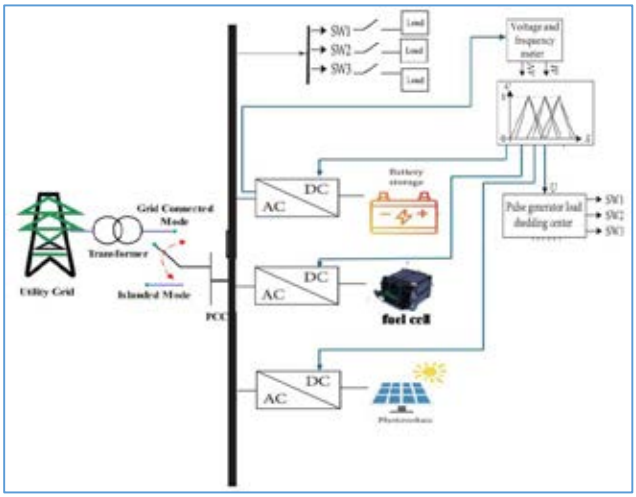

Fig.1. The Configuration of an Islanded Microgrid System

3. GGWO-TSK TYPE-2 FUZZY LOGIC ALGORITHM FOR V/F CONTROL

The control structure executes the operation of the TS-T2F controller designed for voltage and frequency control in an islanded microgrid in a step-by-step manner. Initially, voltage deviation (ΔV) and frequency deviation (ΔF) are taken as inputs. These inputs are processed by the TS-T2F controller using optimized parameters, and a fuzzy inference is performed to calculate a duty cycle. This duty cycle then regulates PV generation. Next, the generation deficit is determined by comparing the total load with the PV generation. If the duty cycle is below a certain threshold, the fuel cell activates, providing constant power; otherwise, the fuel cell remains inactive. The remaining deficit is balanced by the battery, which either discharges or charges, with the state of charge being updated accordingly. Finally, ΔV and ΔF are compared against fixed thresholds to decide on load shedding or reconnection. The system outputs the duty cycle, load states, battery power, fuel cell power, and state of charge.

Data: Parameters: maxIterations, wolfCount, populationSize, crossoverRate, mutationRate, DeltaV, DeltaF
Constants: voltageThresholds, freqThresholds, voltageReconnect, freqReconnect, Pload, maxPpv, K_SOC
Result: Outputs: U, loadStates, Pbatt, Pfc, SOC

% Step 1: Optimize TS-T2F parameters using GGWO
Initialize: Randomly create a population of size populationSize (centers, sigmaU_V, sigmaL_V, sigmaU_F, sigmaL_F, ci)
t ← 0
while t < maxIterations do
Step 2: Evaluate fitness of population (minimize DeltaV and DeltaF deviations)

```
    Step 3: Select parents via tournament selection, perform crossover and mutation
    Step 4: Update population with best individuals
    Step 5: Initialize GWO with best individuals as wolf positions
    while gwoIteration < maxIterations do
        Step 6: Identify alpha wolf, update each wolf's position using GWO formula
        gwoIteration ← gwoIteration + 1
    end
    t ← t + 1
end
Optimization result: Best parameters (centers, sigmaU_V, sigmaL_V, sigmaU_F, sigmaL_F, ci)

% Step 2: System control using TS-T2F controller
Initialize: prevLoadStates ← [1, 1, 1], soc ← 1.0
Step 7: Perform TS-T2F fuzzy inference
    for i ← 1 to 5 do
        muU_V(i), muL_V(i), muU_F(i), muL_F(i) ← Gaussian functions
    end
    W_upper ← muU_V' * muU_F, W_lower ← muL_V' * muL_F
    Normalize W_upper, W_lower
    y ← (sum(W_upper .* ci) + sum(W_lower .* ci)) / 2
Step 8: Calculate PV generation: Ppv ← y * maxPpv
Step 9: Compute generation deficit: Pgap ← Pload - Ppv
Step 10: Fuel cell control
    if y < 0.4 then
        Pfc ← 5
    else
        Pfc ← 0
    end
Step 11: Battery control
    if Pgap - Pfc > 0 and soc > 0.2 then
        Pbatt ← min(Pgap - Pfc, 2)
    elseif Pgap - Pfc < 0 and soc < 0.95 then
        Pbatt ← max(Pgap - Pfc, -1)
    else
        Pbatt ← 0
    end
    soc ← soc - 0.1 * K_SOC * Pbatt
    soc ← max(0, min(1, soc))
    SOC ← soc
Step 12: Load shedding/reconnection
    for i ← 1 to 3 do
        if DeltaV <= voltageThresholds(i) or DeltaF <= freqThresholds(i) then
            loadStates(i) ← 0
        else
            loadStates(i) ← prevLoadStates(i)
        end
    end
    if DeltaV >= voltageReconnect and DeltaF >= freqReconnect then
        loadStates ← [1, 1, 1]
    elseif DeltaV >= voltageReconnectHyst and DeltaF >= 0 then
        loadStates ← max(loadStates, prevLoadStates)
    end
    prevLoadStates ← loadStates
return y, loadStates, Pbatt, Pfc, SOC
```

4. RESULTS AND DISCUSSIONS

Simulation results are presented in Figures 2a, 2b, and 2c, illustrating the system's dynamic behavior under load shedding and reconnection scenarios. Figure 2a shows the voltage response, Figure 2b depicts the frequency response, and Figure 2c illustrates the load shedding and reconnection events. The proposed GGWO–Type 2 Fuzzy controller

successfully maintains system stability by limiting voltage and frequency deviations and ensuring rapid recovery. Specifically, during the load shedding events at 0.7 s, 1.0 s, and 1.3 s, and the load reconnection at 1.6 s, the controller minimizes transient fluctuations and restores system parameters to nominal levels. The GGWO–Type 2 Fuzzy controller limits frequency deviations within ±0.25 Hz, outperforming both the GGWO–Type 1 Fuzzy and the Droop V/F methods, which exhibit larger deviations of up to ±0.35 Hz and ±0.4 Hz, respectively, along with longer settling times. In terms of voltage response, the proposed method demonstrates lower overshoot and faster stabilization compared to alternative approaches. Furthermore, the load management strategy effectively preserves critical loads while shedding non-essential loads, ensuring system stability without unnecessary disruptions. Overall, the results confirm that the GGWO–Type 2 Fuzzy control approach provides superior dynamic performance, achieving faster frequency and voltage recovery, lower deviations, and more stable system operation compared to conventional methods.

5. CONCLUSIONS

This study proposed a voltage-frequency regulation method for an islanded microgrid based on a Takagi-Sugeno Type 2 fuzzy logic controller (TS-T2F) optimized by Genetic Grey Wolf Optimization (GGWO). In the system, the battery mitigates production discrepancies, while the fuel cell ensures continuous power supply during periods of low PV generation. The voltage-based load shedding and reconnection strategy preserves system stability by managing three distinct loads under disturbance scenarios. Simulation results demonstrate that the GGWO-TS-T2F controller maintains frequency deviations within ±0.25 Hz, outperforming the Droop V/F and GGWO-TS-T1F methods. Moreover, the proposed controller achieves lower voltage overshoot and faster recovery times. Overall, the GGWO-TS-T2F approach provides an effective, fast, and reliable solution for voltage and frequency regulation in islanded microgrids.

ABSTRACT
In this study, the predictive machine learning models were developed for tri-reforming of biogas with the help of steam and dry reforming of methane data and compared with a model developed using only the tri-reforming of bigas data to test the applicability of transfer learning approach for the new energy production systems with limited data availability. CH_4 conversion for tri-reforming process was predicted by transferring knowledge from steam and dry reforming by using 58 descriptors including catalyst properties and reaction conditions; the results showed that high predictive powers can be maintained by transfer learning when using limited number of data points in the original dataset.

Keywords: biogas reforming, tri-reforming, machine learning, transfer learning, CH4 conversion

1. INTRODUCTION
Currently, although the majority of hydrogen is produced from fossil fuels, green hydrogen production through renewable sources and biogas valorization offers significant benefits [1]. In recent years, tri-reforming of methane (TRM) has gained considerable attention as a promising yet challenging method for sustainable hydrogen production. TRM combines steam reforming (SRM), partial oxidation (POX), and dry reforming (DRM), leveraging the economic benefits of SRM, the energy efficiency of POX, and the environmental advantages of DRM [2]. Together with these advantages TRM has also advantage for producing syngas in customizable H_2/CO ratio depending on the desired final product. The process feed can be varied to get a low H_2/CO ratio around unity for dimethyl ether production, or H_2/CO ratio of around 2 for methanol production, or a high H_2/CO ratio of 3 for ammonia synthesis [3-5].
Machine learning (ML) has become a valuable tool for analyzing large datasets and identifying trends. ML models have demonstrated high accuracy in given tasks; however, they require substantial amounts of data. However, data scarcity and the high cost of data acquisition especially from laboratory experiments, often limit their predictive power and generalizability of models developed using traditional supervised learning methods [6]. ML models for predictive purposes on chemical reactions, need extensive labelled datasets to avoid overfitting or underfitting, which can result in low accuracy and transferability [7]. Transfer learning (TL) enables the development of data-driven models for tasks with limited data by sharing information from a related task. This approach is beneficial when (i) data for a particular target task is limited, (ii) there are one or more related tasks with well correlated (though not identical) domains or distributions, and (iii) a substantial amount of data is available for these related tasks. By transferring features, model structure, or parameters from related tasks, the performance of ML models for the target task can be enhanced [6]. To illustrate the approach, the following analogy can be used [8]: Two individuals learning to play the piano: one with no prior musical experience and the other with extensive guitar-playing knowledge. The individual with a music background will learn piano more efficiently by transferring their existing musical knowledge to this new task [8]. Similarly, TL operates on the principle of leveraging knowledge from related tasks to improve learning efficiency on the target task. TL process involves pre-training a model with sufficient data in a related task. In ANN models, the underlying features are learned in the first few layers. To transfer knowledge, structure and the corresponding parameters of these initial layers are transferred to the new model. The parameters are either frozen or fine-tuned. Afterwards, a few additional layers are added, and the model is trained with the limited data of the target task. This way, the number of parameters that need to be tuned for the target model is minimized [6]. Previously TL is utilized in chemical engineering in applications as; prediction and knowledge extraction of cyanobacterial bloom growth characteristics [9], prediction of temperature-dependent reaction rate constants [10], prediction of molecular properties [6].
In this work, we present a model that uses TL to predict the CH_4 conversion in TRM using the model developed for steam and dry reforming data.

2. METHOD
For TL studies, datasets are adopted from previous works done by our research group. Source datasets are adapted from DRM [11], and SRM [12] processes. Detailed explanation of data curation methods and processes are explained in the corresponding articles. TRM dataset, constructed by reviewing scientific papers sourced from “Web of Science” database, has a total of 938 data points, originating from 116 experiments across 29 articles. SRM dataset has a total of 1249 data points, originating from 175 experiments across 41 articles. DRM dataset has a total of 3301 data points, originating from 593 experiments across 101 articles. Input variables (descriptors) are chosen as the type of catalyst, catalyst preparation conditions and method, reaction conditions and feed gas compositions, while CH_4 conversion (%)

was designated as output (target) variable. All datasets are completed to 58 descriptor variables by adding the missing variables in the corresponding datasets as O_2 and H_2O in the reactant medium for DRM, and CO_2 and O_2 for SRM as 0. The variables in the dataset are presented in Table 1.

Table 1. Variables available in dataset and used in models

Category	Variables
active metal	Ni, Co, Pt, Rh, Mo, Fe, Ru, Cu, B
support type	ZnO, La_2O_3, Al_2O_3, $MgAl_2O_4$, MgO, CeO_2, ZrO_2, SrO_2, β-SiC, cordierite, SBA-15, Y_2O_3, KNO_3, Sm_2O_3, Nb_2O_5, MWCNT, TiO_2, hydrotalcite (Mg-Al-C), SiO_2, Gd_2O_3
catalyst preparation conditions	calcination time (h), calcination temperature (°C), H_2% in reduction medium, reduction time (h), reduction temperature (°C)
reaction conditions	time on stream (TOS) (min), W/F, reaction temperature (°C)
feed composition	CH_4%, CO_2% (0 in SRM), H_2O% (0 in DRM), O_2% (0 in DRM and SRM), H_2%, inert %

DRM and SRM models are used as source models, while TRM dataset serving as the target model for TL. Afterwards, we systematically applied ANN models to extract detailed insights for predicting outcomes under unstudied conditions. Fig. 1 illustrates the overall scheme followed in the study.

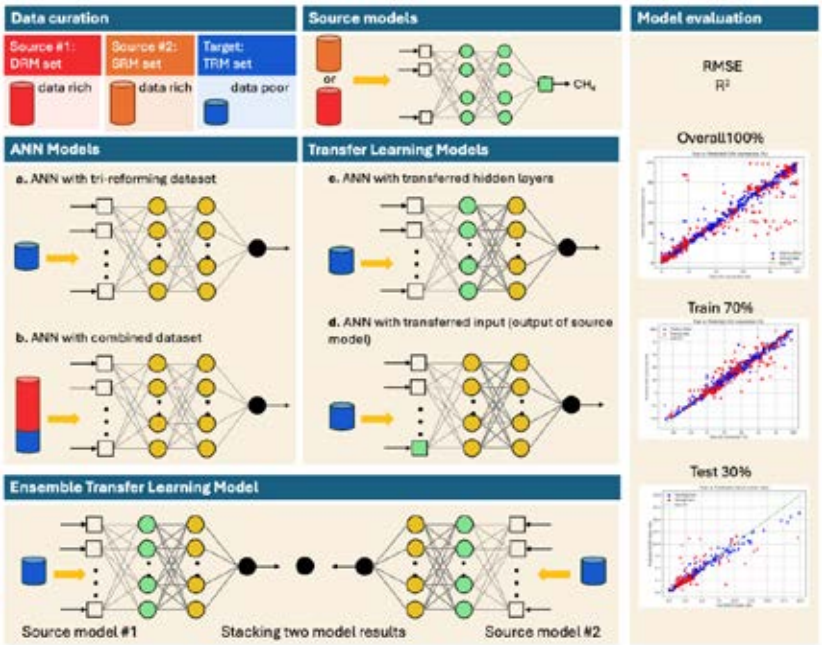

Fig.1. Structure of the study for TL approach with ANN

3. RESULTS AND DISCUSSION

ANN models were developed using the Python programming language and the Keras package. The study is divided into three main parts. In the first part, four ANN models were constructed to investigate the effect of transferring different layers for predicting CH_4 conversion. A model developed exclusively from TRM data served as the base model. Subsequently, a model using DRM data was developed as the source model. TL algorithms were then applied by transferring various layers from the source model to predict CH_4 conversion in TRM. Additionally, a general model was created by combining both datasets. In the second part of the study, TRM dataset was reduced to 75%, 50%, and 25% of its original number of datapoints. Models were developed to assess the impact of smaller datasets on the performance of both the base model and the TL models. In the last part, SRM data was also incorporated as a second source model to develop TL model. TL models of SRM and DRM datasets are combined with different merging methods and double sourced TL models are developed to enhance model performance of CH_4 conversion in TRM.

3.1. Comparison of CH_4 conversion models

For model optimization and tuning, parameters such as activation functions, learning rates, batch sizes, number of neurons per layer, and the number of layers were investigated. Activation functions (tanh, sigmoid, relu, softmax) and learning rates (0.0001, 0.001, 0.005) were tested The "relu" function with a learning rate of 0.0001 and a batch size of 80 was found to be the most robust and effective across all datasets. Data was split at a ratio of 70:30 for training and testing, except for source model development (80:20). Each layer in all models contained 70 neurons. The base model (using only TRM data) was optimized with 3 hidden layers and 180 epochs. DRM model used 5 hidden layers and 100 epochs. The combined dataset model had 3 hidden layers and 180 epochs. TL models were also optimized with 180 epochs. Various combinations of hidden layers and transferred layers were analyzed for optimum TL model. Optimal TL

configurations identified were: (1) 3 new layers with the last layer transferred (3 hidden layers total), (2) the first layer transferred and 3 new layers added (3 hidden layers total), and (3) the first and second layers transferred with 4 new layers added (5 hidden layers total). The models and their R^2 values are presented in Fig. 2. Data points from the training set are depicted in blue, while those from the test set are shown in red.

Base model developed by using solely TRM dataset demonstrated the highest predictive power. TL models varied based on which layer was transferred, with the most successful being the model where the last layer was transferred. Although in ML models the initial layers typically contain the most information and are therefore crucial, transferring these initial layers resulted in decreased overall model accuracy. It can be concluded that the TRM dataset alone was sufficient to predict the general behavior of CH_4 conversion in TRM. Additionally, model developed using the combined dataset also exhibited good predictive power, but requiring higher computational resources.

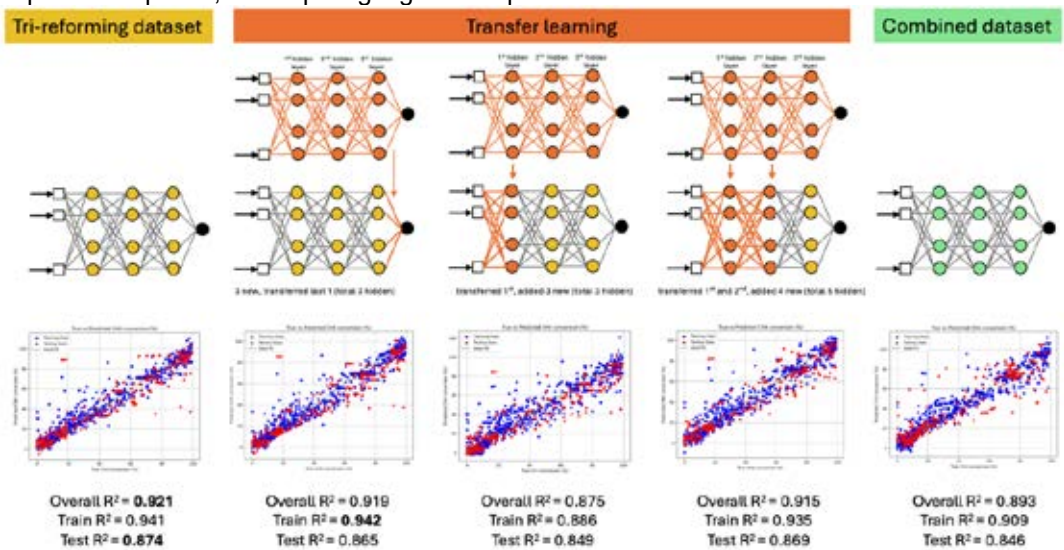

Fig. 2. Results of CH_4 models

3.2. Effect of number of datapoints in the target model

To evaluate the effectiveness of TL, the number of datapoints in the TRM dataset was reduced during model training. ANN and TL models were developed using 75%, 50%, and 25% of the TRM dataset. The results indicated that while TL may not be essential for the full dataset (with minor improvements observed when transferring only the last layer), its predictive power becomes significantly higher than only modeling with target model when fewer datapoints are available. Although transferring the last layer was the most effective TL approach for the complete dataset, this method proved less successful with reduced datasets, as it closely resembled the original model. When data is limited, leveraging knowledge from a source model becomes crucial. As presented in Fig. 3, the highest accuracy for a reduced dataset (25% of the original size) was achieved by transferring the first two layers from the source model.

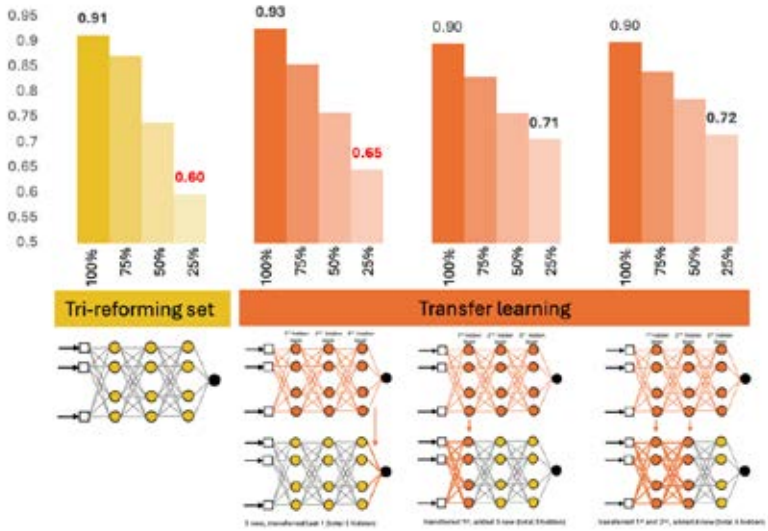

Fig. 3. Results of CH_4 TL models

3.3. Transfer learning with two source models

Merging machine learning models can be accomplished through various methods, with the most common being bagging, boosting, and stacking. In this study, stacking was utilized as a double sourced learning technique. Stacking was performed by applying regression models to the final output predictions of the two models. The results are presented in Table 2. The base model is built with 3 layers and 70 neurons each. Single and double source TL models are built by transferring first 2 layers from source model and training 3 additional layers.

The results indicate that employing a second source model did not significantly improve the overall accuracy of the CH_4 conversion predictions for TRM reaction if linear regression is used as stacking method. Although this lack of improvement can likely be attributed to many factors, and can only be guessed, most probably reasons are discussed. First, the low number of datapoints in the second source dataset (similar to the target set) may result in favoring this dataset in regression. Additionally, the physical conditions of the target model exhibit more DRM characteristics than SRM, as most studies were conducted in low H_2O and high CO_2 environments. However, an important result is achieved in gradient boosting regression (GBR), and random forest regression (RFR). The predictive power of the model is significantly improved, and even the 25% data is used from the TRM dataset, R^2 values were around 0.8 in total dataset.

Table 2. Results of CH_4 single and double sourced TL models

Data used from TRM set	Benchmark model	Single Source TL Model	Double Source TL Models		
	(only TRM dataset)	(source model: DRM)	(with LR merging)	(with GBR merging)	(with RFR merging)
100%	0.914	0.882	0.882	0.913	**0.934**
75%	0.872	0.856	0.864	0.892	**0.891**
50%	0.740	0.825	0.844	0.848	**0.871**
25%	0.598	0.737	0.729	0.796	**0.804**

4. CONCLUSIONS

In this study, the effectiveness of TL in predicting CH_4 conversion for TRM was demonstrated, utilizing DRM and SRM datasets as sources. While a model trained solely on TRM data showed high predictive accuracy, TL proved particularly valuable when data availability was limited. The most effective TL strategy involved transferring the final layers from a pre-trained model, preserving relevant features while adapting to the target dataset. Additionally, ensemble techniques such as gradient boosting and random forest regression improved predictive performance, especially with reduced datasets. These findings highlight the potential of TL in optimizing catalytic reaction modeling, reducing the need for extensive experimental data, and enhancing predictive capabilities for sustainable syngas production.

ABSTRACT
Hydrogen is a promising energy carrier due to its high energy density and low harmful emissions. Consequently, the production and storage of hydrogen have significant potential in the energy sector. Boron fuels such as sodium borohydride ($NaBH_4$) and ammonium borane (NH_3BH_3) have high hydrogen content and release hydrogen at mild conditions. Due to their abilities, they are widely used for hydrogen storage and transportation. However, efficient catalyst development is crucial to achieving controlled hydrogen release at the desired time and location. The electrospinning method is an advanced technique for synthesizing catalysts in nanofiber structures and is based on the application of controlled electric field force to the polymer solution. The electrospinning method provides enhanced or altered high surface area, porous structure, nano-sized morphology, surface area-to-volume ratio, and superior catalytic properties for catalyst production. Also, this technique demonstrates low cost and high efficiency. In this study, the impact on the efficiency of hydrogen production from boron fuels in batch and continuous flow systems was assessed via hydrolysis of $NaBH_4$ and NH_3BH_3 over synthesized Co-based carbon nanofiber catalysts (Co@CNF, Co@GCNF, CoRu@CNF, CoRh@CNF, CoRu@GCNF, and CoRh@GCNF). It is observed that CoRh@GCNF shows the best activity towards hydrogen production in the batch system (5.68 and 6.26 L/min·gcat, respectively) for $NaBH_4$ and NH_3BH_3.

Keywords: Electrospinning, Nanofiber catalysts, Hydrogen production, Boron fuels

1. INTRODUCTION
Global environmental pollution, climate change, and increasing energy crises prompt research and commercial sectors to develop clean energy materials. With this purpose, studies have focused on the development of materials consisting of catalysts, storage media, electrode membranes, separators, collectors, supercapacitors, etc. A safe and effective solution for hydrogen storage and release is essential to reduce the cost of hydrogen in industrial applications. Boron fuels have advantages in the storage of hydrogen and the release of stored hydrogen [1, 2]. Various boron-based hydrogen storage compounds with their high hydrogen content are used especially in mobile power generation systems such as fuel cells, military, and space applications. The first study on $NaBH_4$'s capacity to store and transport molecular hydrogen (10.8 wt.%) was published by H.I. Schlesinger in 1973. Research on the synthesis of novel boron-based compounds continued in the late 1990s. The US Department of Energy emphasized in 2007 that $NaBH_4$ is a significant hydrogen storage medium for vehicle applications and that research on NH_3BH_3, another possible hydrogen storage material for direct fuel cells, is also essential. Nowadays, NH_3BH_3 is still a strong candidate for in-vehicle applications because of its advantages such as high hydrogen storage capacity (19.6wt.%), low molecular weight (30.9 g mol^{-1}), high stability in air and water, and controllable reaction conditions [3]. A hydrogen storage system needs to release hydrogen in sufficient quantities and at a proper rate to power a fuel cell. Depending on the intended application, two methods are applied to release the hydrogen stored in boron fuels: hydrolysis and thermolysis (Table 1).

Table 1. Hydrogen production methods for potential applications of $NaBH_4$ and NH_3BH_3 [3].

Application	$NaBH_4$		NH_3BH_3	
	Thermolysis	Hydrolysis	Thermolysis	Hydrolysis

Stationary	✓	✗	✓	✗

Cost-effective and active catalysts are crucial for producing hydrogen at the desired location and time. For this purpose, metal, metal oxides, nanoalloys, and nanocomposite catalysts have been investigated [4, 5]. Electrospinning has gained significant attention in hydrogen energy systems. Electrospun fiber catalysts with smaller pores and higher surface area have been successfully applied to provide pure hydrogen gas for hydrolysis reactions of metal hydrides. Since the early

2000s, hydrolysis reactions have extensive attention, especially focusing on catalytic materials. Chemical reduction, wet impregnation, sol-gel, and precipitation techniques are used to synthesize catalytic noble and non-noble metals, metal oxides, bimetal nanoparticles, and porous powders. These materials are particularly attractive for hydrogen applications due to their large surface areas and high catalytic activities. In addition, metal oxides are more stable against atmospheric degradation and moisture than metallic forms. Metals in their oxide forms, their deposition on various supports, or their doping in polymeric environments provide high catalytic activity. Moreover, elemental boron is capable of being integrated into metal oxides to improve their activity [6]. In this study, Co-based carbon nanofiber catalysts doped with/without Rh and Ru were synthesized using the electrospinning technique, and their hydrogen production from boron fuels was investigated under batch and continuous operating conditions.

2. MATERIALS AND METHODS

Within the scope of the experimental study, the following studies were carried out to synthesize composite nanofiber catalysts using the electrospinning technique and hydrogen production and investigate their hydrogen production rate (Fig. 1).

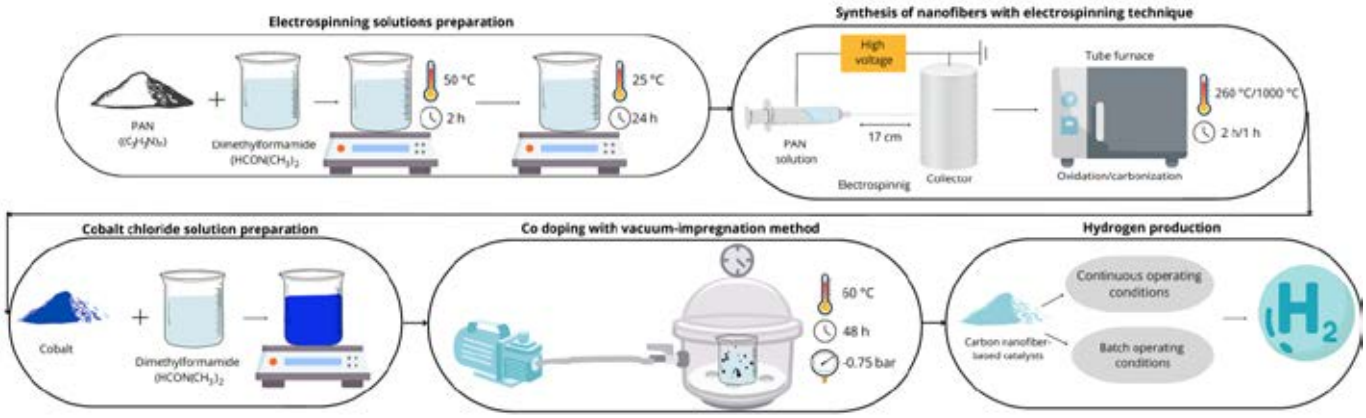

Fig. 1. Experimental methodology nanofiber catalysts synthesize and hydrogen production operations.

2.1. Synthesis of Co-Based Carbon Nanofiber Catalysts with Electrospinning Technique

In the experimental studies, two different electrospinning solutions were prepared to obtain composite nanofibers: containing PAN ($(C_3H_3N)_n$, Sigma-Aldrich, 99.995% purity) and containing graphene-doped PAN. Dimethylformamide ($HCON(CH_3)_2$, Merck) was employed as a solvent to dissolve 9wt.% PAN. The mixture was stirred continuously at 50 °C for 2 hours and at room temperature for 24 hours to obtain a homogeneous solution. Graphene-doped PAN electrospinning solution with 1 wt% graphene (Nanografi, 99.9% nanoplatelet) was prepared following a similar procedure. The electrospinning device sets the voltage (0–40 kV), the distance between the plate and the needle (1–30 cm), and the solution flow rate (0.01–1000 mL/h) automatically. Initially, electrospinning parameters such as voltage, solution flow rate, and needle-to-collector distance were optimized to obtain homogeneous and continuous fibers. PAN and graphene-doped PAN solutions were exposed to an electric field in the electrospinning device (Basic System-Nanospinner), and the formed PAN (P) and graphene-doped PAN (GP) fibers were collected on the collector. The optimal electrospinning conditions for fiber production were determined as 17 kV voltage, 2.2 mL/h solution flow rate, and 17 cm needle-to-collector distance. P and GP fibers were pre-dried under atmospheric conditions and then subjected to oxidation (2° C/min heating rate, 260 °C, 2 hours) and carbonization (5 °C/min heating rate, 1000 °C, 1 hour) processes for stabilization and activation in a furnace, respectively. After oxidation and carbonization, the Oxidized PAN (PO) and Oxidized graphene-doped PAN (GPO) fibers were transformed into electrospun carbon nanofibers (CNF) and graphene-supported carbon nanofibers (GCNF). CNFs and GCNFs were stored in a desiccator to be employed as catalytic support. Cobalt loading was performed on the synthesized CNFs and GCNFs structures using the vacuum-impregnation method. Initially, a 10 mL cobalt chloride solution was prepared to contain 15 wt.% Co and doped to CNFs and GCNFs. Subsequently, they were kept under vacuum (-0.75 bar) at 60 °C for 48 hours. The doped fibers (Co@CNFs and Co@GCNFs) were activated at 450 °C for 1 hour under a nitrogen atmosphere.

2.2. Hydrogen Production

The H_2 production performance tests of the nanofiber catalysts were carried out under batch and continuous operating conditions and with catalytic hydrolysis reactions from $NaBH_4$ and NH_3BH_3 solution ($NH_3BH_3 + 2H_2O \rightarrow NH_4(BO_2) + 3H_2$ and $NaBH_4 + 4H_2O \rightarrow NaBO_2 + 4H_2$). Firstly, a batch hydrogen production system was established for hydrolysis reactions. The reactions were performed at 60 °C in a temperature-controlled (±2 °C) glass reactor with an internal volume of 20 mL, under continuous stirring at 500 rpm using a magnetic stirrer. The volume of produced H_2 was monitored based on the principle of water displacement with an equal volume and recorded over time to generate a

batch reaction rate profile. Subsequently, a continuous-flow system was designed for continuous operation. The system included a peristaltic pump (Cole Parmer MasterFlex L/S 7518-40, ±0.1), silicone tubing, a packed-bed reactor, a specially designed liquid-gas separation unit, a heat exchanger, and a gas measuring cylinder. The reaction was carried out under conditions equivalent to batch operation conditions.

3. RESULTS AND DISCUSSION

3.1. Morphological properties of fibers

SEM analysis was performed to determine the fiber formation in the samples and to examine the morphologies. The samples were coated with gold-palladium under a high vacuum for analysis. It was observed that white PAN fibers were formed successfully when the PAN solution was electrospun. Additionally, GP maintained its homogeneous white color distribution that indicating the nanolayered graphene was distributed homogeneously in the PAN solution. It was determined that both the P and GP samples turned brown after the oxidation and after carbonization, black fibers specific to carbon fiber were obtained.

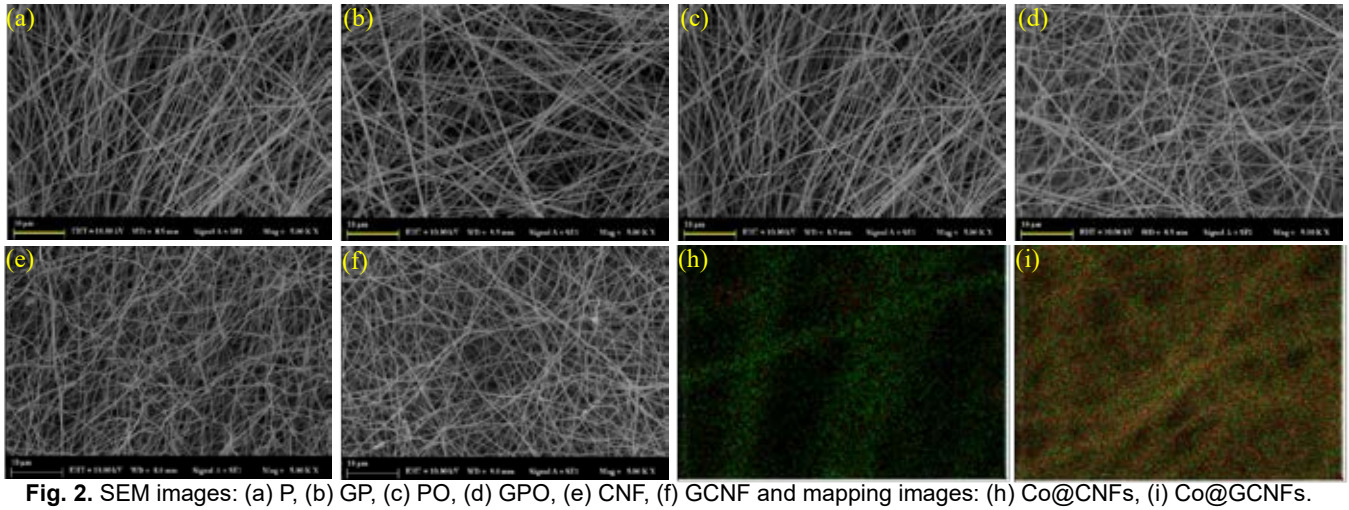

Fig. 2. SEM images: (a) P, (b) GP, (c) PO, (d) GPO, (e) CNF, (f) GCNF and mapping images: (h) Co@CNFs, (i) Co@GCNFs.

SEM and mapping images of samples at 5000x magnifications are given in Fig. 2. SEM and mapping images show that fibers with a homogeneous, spun, continuous, interwoven network structure and three-dimensional morphology are successfully synthesized. Notably, the network structure remained intact and was preserved after stabilization and activation. Furthermore, it was determined that the homogeneous, curved, continuous, interwoven network structure of fibers was not damaged after the Co doping on the fibers. However, the mapping-SEM analysis performed to determine the distribution of impregnated Co in the fiber structure reveals clustered regions. This suggests that the Co was distributed homogeneously on the fiber surface after doping. The dimensions of the fiber diameters were measured from the SEM images. Under the applied electrospinning parameters, PAN fibers were synthesized at <400 nm. The average diameter of the electrospun PAN-based carbon nanofibers obtained after stabilization and activation was measured at 177 nm. The decrease in diameters is attributed to insufficient oxidation. It was found that the addition of graphene led to the development of carbon fibers with a thicker diameter. This can be explained by graphene doping increasing the electrospinning solution's viscosity. Also, it was noted that the diameters did not significantly change after Co doping.

3.2. Batch and Continuous Hydrogen Production Profiles

Firstly, hydrogen production was carried out based on $NaBH_4$ and NH_3BH_3 hydrolysis in the presence of Co@CNFs and Co@GCNFs catalysts under batch production conditions. The reaction rates were calculated by plotting batch hydrogen production rate profiles. The hydrogen production rates for NH_3BH_3 and $NaBH_4$ hydrolysis with Co@GCNFs catalyst were calculated to be 3.50 and 2.96 L/min·gcat, respectively. These values are approximately 3.6 and 2.4 times higher than hydrogen production rates with the catalyst without graphene doping. It shows that graphene-doped carbon nanofibers synthesized as catalyst support material are effective for accumulating a sufficient amount of cobalt particles [7]. Subsequently, Co@GCNFs and Co@CNFs were utilized for Ru and Rh doping and hydrogen production rates were calculated using batch hydrogen production profiles (Table 2).

Ru and Rh doping were found to enhance the hydrogen production rate. Co@GCNF doped with Rh doped the lowest reaction time and the highest H_2 production rate. The H_2 production rate was determined as Rh>Ru>Co. It concluded that Rh doping into the carbon nanofiber structure significantly improves the catalytic properties of the nanoparticles for the hydrolysis of $NaBH_4$ and NH_3BH_3.

Table 2. Hydrogen production rates of catalysts with $NaBH_4$ and NH_3BH_3 hydrolysis.

Catalyst	H_2 Production Rate, L/min·gcat	
	NH_3BH_3 Hydrolysis	$NaBH_4$ Hydrolysis
Co@CNF	0.97	1.26
Co@GCNF	3.50	2.96
CoRu@CNF	4.39	3.86
CoRh@CNF	5.07	6.41
CoRu@GCNF	4.11	3.81
CoRh@GCNF	5.68	6.26

Hydrogen production from boron fuels under continuous operating conditions was conducted with the most active catalyst (CoRh@GCNF) from batch operation conditions and obtained a similar H_2 production rate. When the system is operated in a continuous flow, the active sites of the catalysts are emptied with the flow. Additionally, the continuous flow removes the reaction byproducts such as sodium metaborate ($NaBO_2$), diammonium borane hydrate ($H_4B_4O_9{\cdot}2(H_4N){\cdot}1.4(H_2O)$, and ammonium boron oxide hydroxide hydrate ($(NH_4)(B_5O_6(OH)_4)(H_2O)_2$) from the reaction environment and improves the interaction between the reactants.

4. CONCLUSIONS

In this study, the hydrolysis reaction of Co, Rh, and Ru doped carbon nanofiber catalysts synthesized using an electrospinning technique with $NaBH_4$ and NH_3BH_3 under batch and continuous operating conditions was investigated and the effect of the synthesized catalysts on hydrogen production efficiency from boron fuels was evaluated. The results of this study represent a significant step forward in the field of hydrogen energy. The findings indicate that Co, Rh, and Ru-doped carbon nanofiber catalysts synthesized by electrospinning are effective in hydrogen production from boron fuels. Moreover, it was determined that the Rh-doped catalyst with an H_2 production rate for $NaBH_4$ is 6.26 L/min·gcat and NH_3BH_3 is 5.68 L/min·gcat had the most effective performance. These experimental results confirm that carbon nanofiber-based catalysts suitable for continuous and batch operating conditions were successfully synthesized.

ABSTRACT

This study is about the thermodynamic analysis of an integrated combined system supported by biomass energy for clean electricity, heating, and hydrogen production. This system consists of an olive pit biomass-sourced Brayton cycle, a Rankine cycle, and high-temperature steam electrolysis. To produce clean and sustainable hydrogen, a comprehensive thermodynamic analysis of this renewable energy-supported system is considered, and also parametric studies are carried out. The analysis findings determined that the energy efficiency of the entire system was 53.61%. In addition, 0.00546 kg/s of green hydrogen can be produced with this system. It can be thought that the combination of integrated systems with renewable energy sources in the fight against environmental problems gives good results in terms of efficiency.

Keywords: Biomass, HTSE, exergy, Rankine cycle, hydrogen

1. INTRODUCTION

With increasing population and economic development, energy consumption around the world is also increasing, which has serious effects on the environment. In particular, the use of fossil fuels, which is still effective today, releases large amounts of greenhouse gases, especially carbon dioxide. As a result of greenhouse gas emissions, many environmental problems have emerged, such as global warming, acid rain, and melting glaciers [1]. Renewable energy sources are an important option to overcome and reduce these environmental problems. Renewable energy sources are natural and have no negative impact on the environment, such as solar, wind, geothermal, wave, tidal, and biomass. Biomass is also a biological renewable energy source [2]. Moreover, this energy source can generally be used for many purposes such as heating, cooling, and electricity generation, and can be integrated with multi-energy conversion systems.
A multigeneration system is used to produce more than three useful products with a single energy input. Therefore, these systems have an important place in energy efficiency. There are numerous studies in the literature on this subject, especially on the thermodynamic, economic, and environmental impact analysis of biomass-supported multigeneration systems. There are also comparative analyses of different biomass types to achieve higher efficiency. In general, products such as electricity, heating, cooling, clean water, hydrogen, and ammonia can be obtained with these systems. Some of the studies on the analysis of biomass-supported integrated systems conducted in 2024 and 2025 are presented here [3-6].
In this study, the thermodynamic performance analysis of heating, electricity, and hydrogen production with a combined system supported by olive pit biomass is investigated. High-temperature steam electrolysis (HTSE) was used for hydrogen production. System performance is determined by applying a detailed energy and exergy analysis method.

2. SYSTEM DESCRIPTION AND ANALYSIS

In this study, a combined system with biomass support is considered, as given in Fig. 1. The system basically consists of a Brayton cycle with intercooled and reheated supported by biomass, a Rankine cycle, and HTSE units. Electricity production is obtained from the gas turbines 1 and 2 (GT-1 and GT-2) in the Brayton cycle and the steam turbines (ST) in the Rankine cycle. Water in the vapor phase at point 21 enters the HTSE, where hydrogen and oxygen production take place. In this study, olive pits are preferred as a biomass source, and the chemical properties are also given in Table 1.

Table 1. Chemical properties of olive pits [7]

Fuel type	Value
C	48.81
H	6.23
O	43.48
N	0.36
S	0.02
HHV	21390
Moisture	-

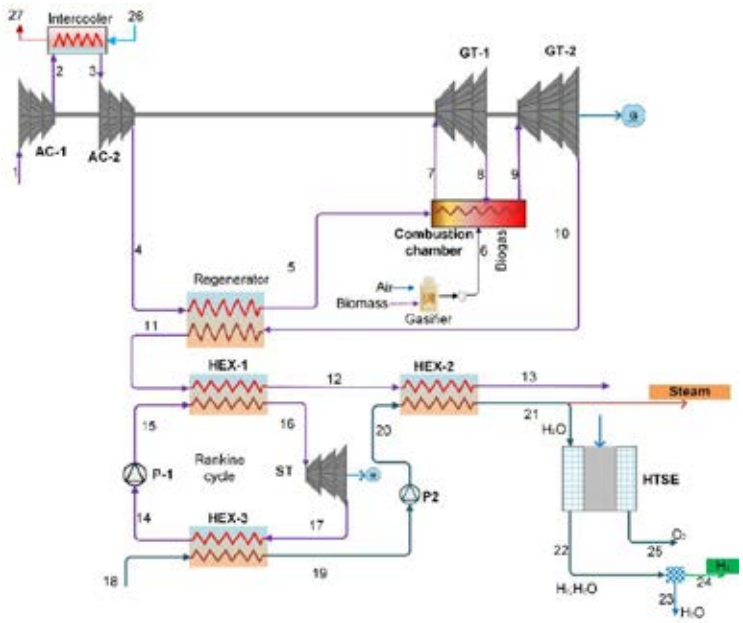

Fig.1. Schematic flow chart of the combined system

For detailed thermodynamic analysis, refer to the articles in the references [8-9]. The basic energy and exergy efficiency of the system can be formulated as follows;

$$\eta_{sys} = \frac{\dot{W}_{net} + \dot{Q}_{heating} + \dot{m}_{H_2} LHV_{H_2}}{\dot{m}_{biomas} LHV_{biomass}} \quad (1)$$

$$\psi_{sys} = \frac{\dot{W}_{net} + \dot{E}x_{Q,heating} + \dot{m}_{H_2} ex_{H_2}}{\dot{m}_{biomas} ex_{biomass}} \quad (2)$$

The net power can be written as;

$$\dot{W}_{net} = \dot{W}_{GT-1} + \dot{W}_{GT-2} + \dot{W}_{ST} - (\dot{W}_{AC-1} + \dot{W}_{AC-2} + \dot{W}_{P1}) \quad (3)$$

3. RESULTS AND DISCUSSION

A comprehensive thermodynamic analysis is performed for the developed biomass-supported integrated system's power, heating, and hydrogen production. The analysis result is illustrated in Fig. 2. Here, this system's energy and exergy efficiencies are calculated as 53.61% and 23.97%, respectively. In addition, this system can produce 3233 kW net electricity at these efficiencies.

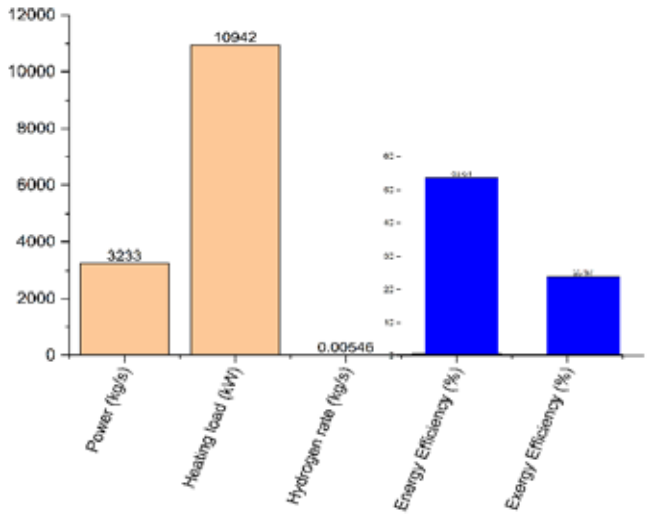

Fig. 2. Analysis results of the developed system

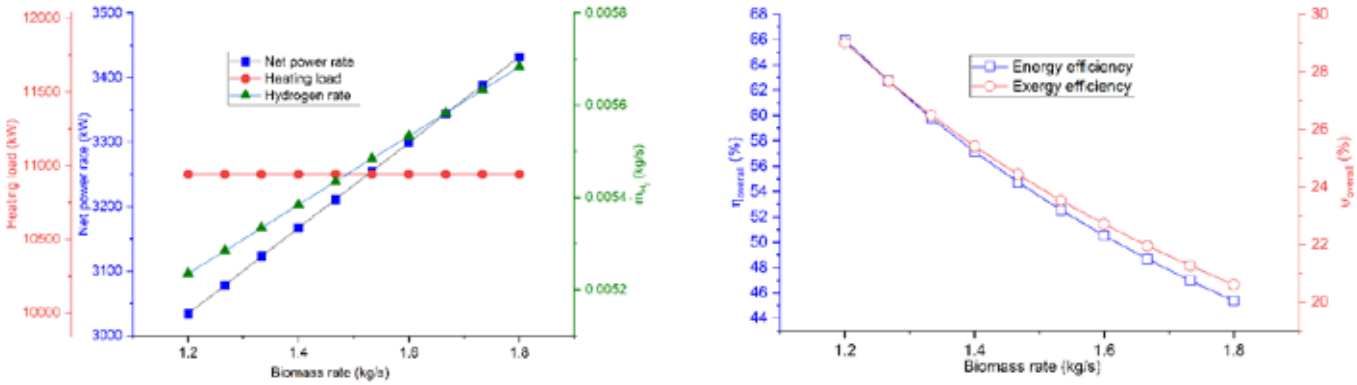
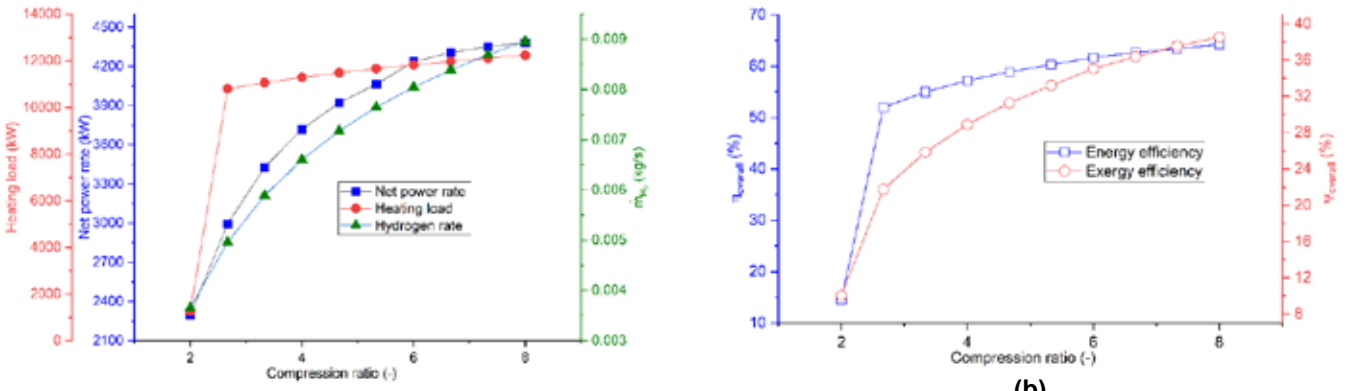
To examine the changes in efficiency and useful outputs in this system, the biomass mass change is examined parametrically and is presented in Fig. 3 (a-b). While the increase in biomass mass increased the useful outputs, it negatively affected the system efficiency.



(a) (b)

Fig. 3. Impact of the biomass mass flow rate on the system products(a) and system's efficiency(b)

Fig. 4 (a and b) shows the increase in both the useful outputs produced in the system and the system efficiency by increasing the compressor compression ratio (r_p). There is a linear increase until the r_p value reaches approximately 4-4.5, then this increase rate decreases. The main reason for this situation can be interpreted as the compressors consuming more energy as the r_p value increases.



(a) (b)

Fig.4. Relationship between r_p and system variables

Finally, the effect of the combustion chamber outlet temperature (T_7), namely the turbine inlet point, on the system efficiency is analyzed and presented in Fig. 5. As the T_7 temperature increased between 900 and 1200 ℃, the energy efficiency of the whole system increased from approximately 50% to 58%, while the exergy efficiency increased from approximately 20% to 27%. It is known that increasing the turbine inlet generally increases the efficiency of power generation systems.

4. CONCLUSION

In this study, thermodynamic analysis of a new biomass-supported integrated system to produce clean and sustainable hydrogen, power, and heating is performed according to energy and exergy efficiency.

- As a result of the analysis, it is indicated that the system produced 3233 kW of net electricity. In addition, it can produce 10942 kW net heat load and 0.00546 kg/s green hydrogen. Moreover, the energy efficiency of the whole system was calculated as 53.61% and the exergy efficiency as 23.97%.
- The highest irreversibility is seen in the combustion chamber.

Renewable energy sources such as biomass are used to overcome environmental problems. These systems will be indispensable for the future, especially for sustainable energy.

ABSTRACT
The effective use of renewable energy resources is one of the indispensable methods for overcoming environmental problems. For this reason, this study focuses on a comprehensive thermodynamic analysis of power, heating, cooling, hydrogen, and clean water production with an integrated system supported by a solar tower. The system is driven thermally by a solar tower system. Parametric analyses are performed to examine the energy and exergy efficiency changes in the system. According to the findings of the research, this system has 51.83% energy efficiency and 48.41% exergy efficiency while producing 5135 kW of net electricity and 0.0079 kg/s of green hydrogen**.**

Keywords: Energy, exergy, green hydrogen, solar tower, multigeneration.

1. INTRODUCTION

Global warming and environmental problems are among the most important threats to societies in the world's future. The main source of these problems is the efficient and widespread use of carbon-based fossil fuels in energy production and consumption. As a result of this use, global temperature increases are occurring worldwide, and limiting this increase to a maximum of 1.5 ℃ by 2100 is vital for sustainability. At this point, the renewable energy sources have gained much more importance. Among renewable energy systems, solar and wind-based systems have attracted significant attention, and significant cost reductions have been achieved through research and development activities [1]. Furthermore, another important way to struggle with the environmental problem is through energy efficiency methods, like the multigeneration energy conversion plants. Multigeneration plants present more than three beneficial products by using the same energy input. In recent years, many researchers have been focused on the renewable energy-based multigeneration plant.

Özlü and Dincer [2] have addressed the performance evaluation of a new solar energy-based multi-generation system and examined it from a thermodynamic perspective. The energy and exergy efficiency of the whole system were calculated as 36% and 44%. In 2024, the thermodynamic evaluation of combined cooling, heating, hydrogen, and power multi-generation systems for full-spectrum solar energy utilization was studied by Fang et al [3]. Moreover, Yilmaz et al. [4] presented a proposal for an advanced hybrid multigeneration power plant using solar energy for sustainable hydrogen production: They presented a thermodynamic and environmental analysis. Some of the studies on integrated solar energy-supported systems carried out in 2025 are collected here [5-7].

This study focuses on the investigation of a comprehensive thermodynamic performance analysis of an integrated solar tower-supported system. For this reason, detailed energy and exergy analyses are conducted to determine the system performance criteria and beneficial products. Furthermore, the system aims to produce clean and sustainable products as well as green hydrogen.

2. MATERIALS AND METHODS

In this study, a solar tower-supported multigeneration energy conversion system is proposed and investigated for the production of beneficial products (see Fig. 1). The system consists of 6 subsystems: solar tower cycle, Rankine cycle with two turbines, organic Rankine cycle, multi-effect desalination unit, absorption cooling unit, and hydrogen generation and compression unit.

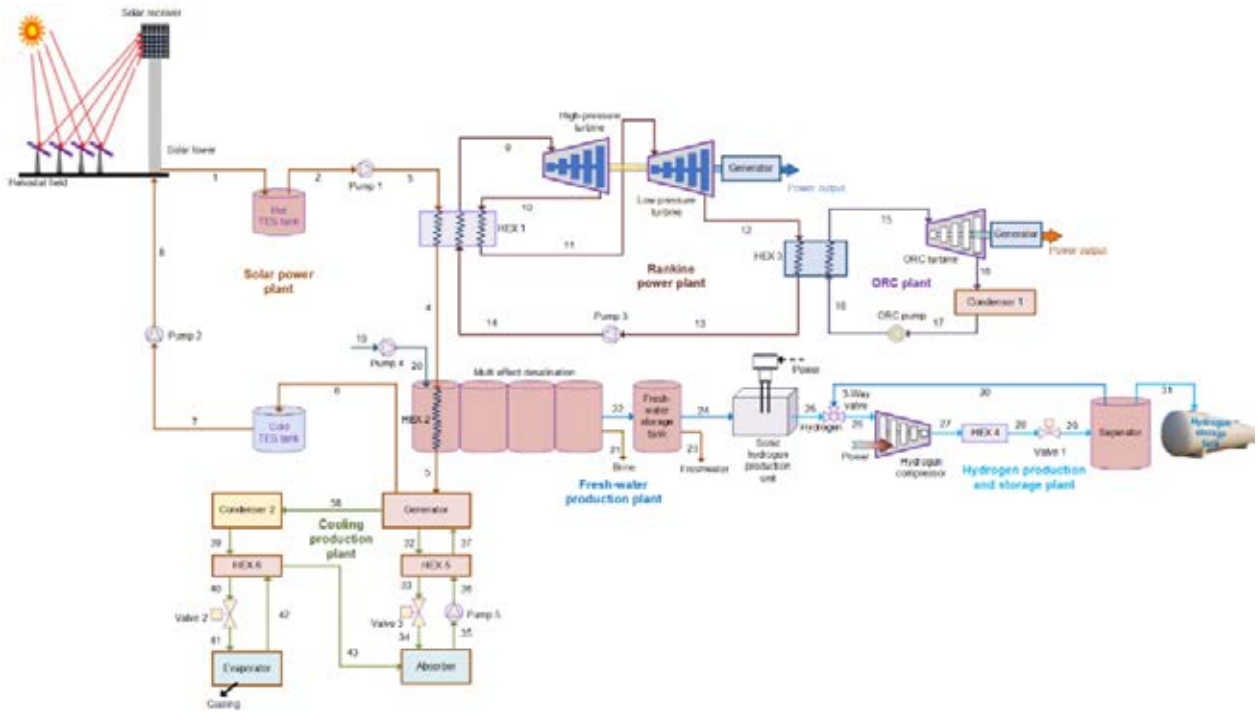

Fig. 1. A schematic diagram of the renewable energy-based integrated plant.

Here, a detailed thermodynamic analysis method is discussed. For this analysis method, it is assumed that the entire system is a steady-state flow condition. In addition, kinetic and potential energy changes are not taken into account, pumps and turbines have isentropic efficiency, and pressure loss between system elements is neglected. Following these assumptions, the general mass, energy, entropy, and exergy balance equations can be formulated as follows [8-9];

$$\dot{m}_{in} = \dot{m}_{out} \tag{1}$$

$$\dot{Q}_{in} + \dot{W}_{in} + \sum \dot{m}_{in} h_{in} = \dot{Q}_{out} + \dot{W}_{out} + \sum \dot{m}_{out} h_{out} \tag{2}$$

$$\sum \dot{m}_{in}\, s_{in} + \sum \left(\frac{\dot{Q}_{in}}{T_s}\right) + \dot{S}_{gen} = \sum \dot{m}_{out}\, s_{out} + \sum \left(\frac{\dot{Q}_{out}}{T_s}\right) \tag{3}$$

$$\dot{Ex}^{\dot{Q}_{in}} + \dot{Ex}^{\dot{W}_{in}} + \sum \dot{m}_{in} ex_{in} = \dot{Ex}^{\dot{Q}_{out}} + \dot{Ex}^{\dot{W}_{out}} + \sum \dot{m}_{out} ex_{out} + \dot{Ex}_D \tag{4}$$

Overall system;

$$\eta_{sys} = \frac{\dot{W}_{net} + (\dot{m}_{H_2} LHV_{H_2}) + (\dot{Q}_{heating}) + (\dot{Q}_{cooling})}{\dot{Q}_{solar}} \tag{5}$$

$$\psi_{sys} = \frac{\dot{W}_{net} + (\dot{m}_{H_2} ex_{H_2}) + (\dot{Ex}_{Q,heating}) + (\dot{Ex}_{Q,cooling})}{\dot{Ex}_{Q,solar}} \tag{6}$$

3. RESULTS AND DISCUSSION

The results of the thermodynamic analysis performed in this designed study are presented in Table 1. The net electricity production capacity of this system is calculated as 5135 kW. In addition, the amount of hydrogen and clean water obtained in the system is 0.0079 kg/s and 0.3319 kg/s.

Table 1. The generation capacities of the proposed integrated plant.

Productions	Quantity	Unit
Power	5135	kW
Heating	2173	kW
Cooling	1338	kW
Hydrogen	0.0079	kg/s
Freshwater	0.3319	kg/s

In parametric analysis, the effects of the reference temperature change are included to determine the effects of the change in the ambient temperature on the system. The changes in the energy efficiency, exergy efficiency, and exergy destruction of the reference temperature change on the subsystems and the entire system are shown in Fig. 2. It has been observed that it positively affects both energy and exergy efficiency.

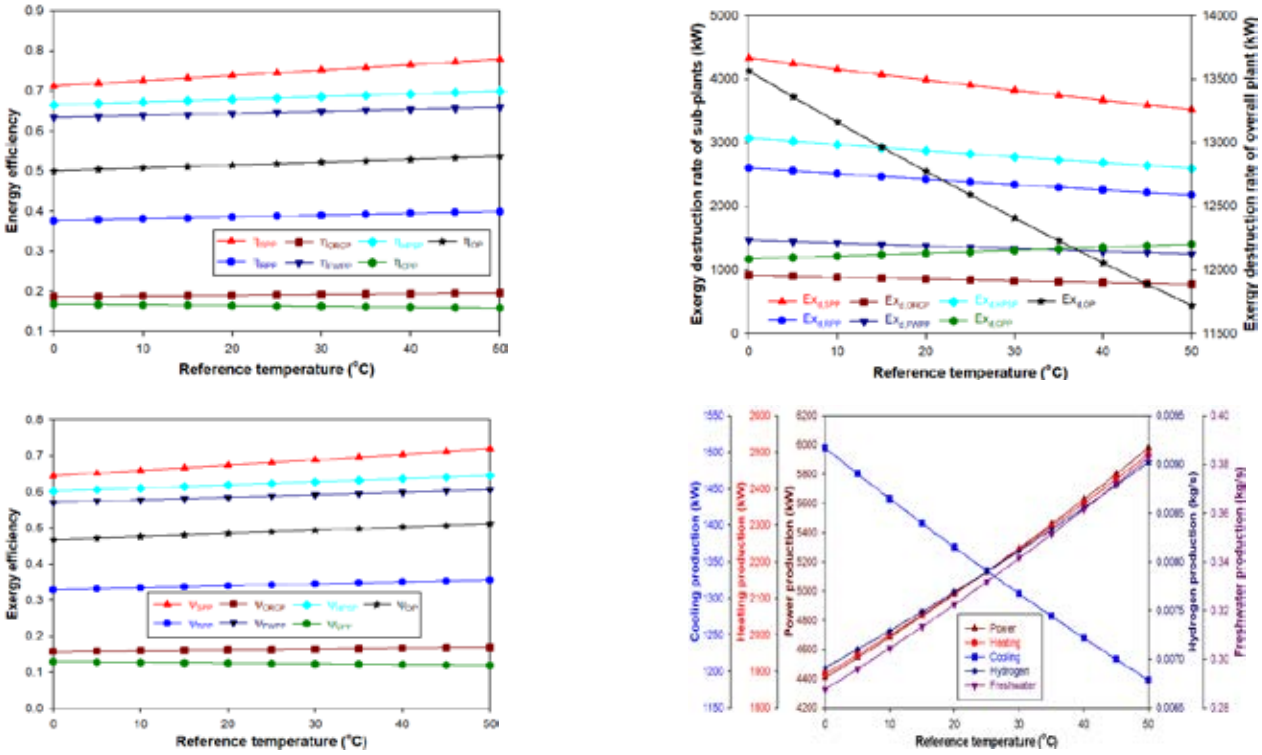

Fig. 2. Effect of the reference temperature on the system efficiency, beneficial products, and exergy destruction rates

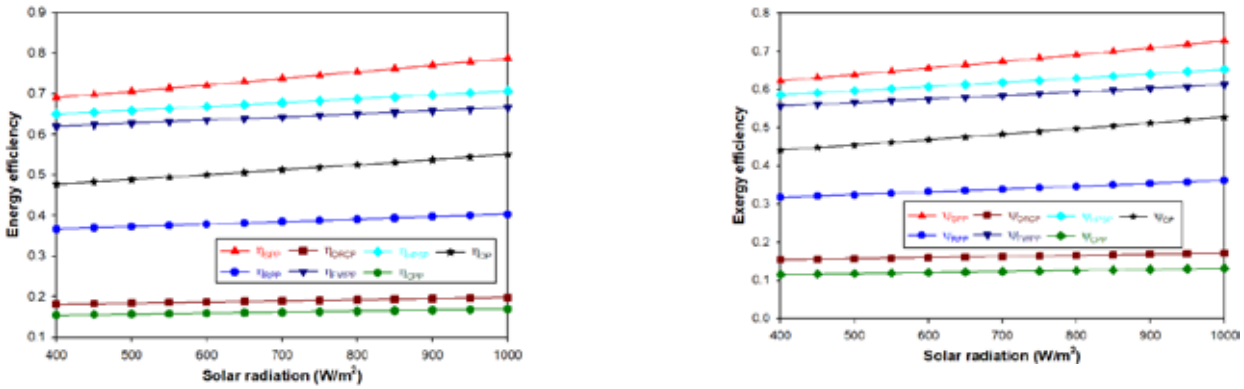
The effect of the change in the solar radiation value on the energy and exergy efficiencies of the system as well as the total irreversibility and useful outputs produced by the system is presented parametrically in Fig. 3. The increase in the solar DNI value is the positive effect on the developed system. With these increment ratios, the net power generation rate is increased by about 4000 to 6500 kW.



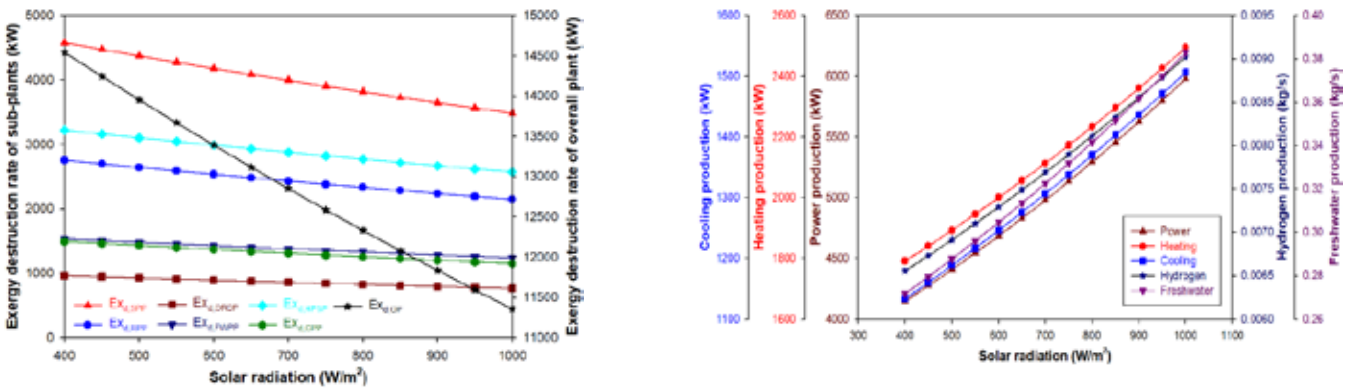


Fig. 3. Effect of solar radiation on the system efficiency, beneficial products, and exergy destruction rates

4. CONCLUSION

It is important to obtain more than one product with renewable energy-supported combined systems because it is both more efficient and has lower emissions. In this study, a new solar tower-supported integrated system is designed, and detailed parametric analyses are performed in terms of thermodynamic methods. The results obtained can be summarized as follows:

- The net electricity, heating, cooling, and hydrogen production capacity of the integrated system is 5135 kW, 2173 kW, 1338 kW, and 0.0079 kg/s.
- This system can also produce 0.3319 kg/s of drinkable clean water.
- The energy efficiency of the entire system was calculated as 51.83% and 48.94%. The total exergy destruction rate is 12591 kW and the highest value was observed in the solar tower.

ABSTRACT

Hydrogen has emerged as a critical industrial and energy resource with increasing importance in various production technologies. From an astrobiological perspective, hydrogen dominated the early universe and played a pivotal role in the evolution of life as early microorganisms such as methanogens and sulfate reducers used hydrogen as an electron donor. Geological theories, like the hydrothermal reactor hypothesis suggest that early life forms utilized hydrogen and CO_2 in primitive metabolic pathways. Today, biohydrogen production especially through dark fermentation, has attracted significant interest due to its similarity to anaerobic digestion systems. Despite over 3,000 studies on dark fermentation in the past 20 years no commercial-scale system has been realized mainly due to low yields, substrate requirements and operational challenges. Furthermore, geopolitical factors, such as Europe's reliance on Russian natural gas, have accelerated the shift toward green hydrogen, especially in Germany. Electrolyzers, using water and electricity to produce pure hydrogen are now favored for large-scale deployment. However, biological hydrogen production remains limited by microbial metabolism especially hydrogenase enzyme dynamics and hydrogen-consuming species like methanogens. Although pretreatment methods aim to suppress these species they introduce additional technical and economic burdens. Thus, hydrogen's biological production faces both ancient and modern challenges in reaching industrial viability.

Keywords: Dark Fermentation, Limitation, Biohydrogen, Inoculum, Low-yield

1. INTRODUCTION

Hydrogen is an industrial and energetic tool that is increasingly with different methods and technologies day by day. When the formation of the universe is considered from an astrobiological perspective, it is thought that there was around 75% hydrogen in the universe when the Big Bang first began [1]. Considering the age of the world, which is 4.6 G years, it is also known that there was no atmospheric oxygen for half of this period. The first microorganisms that formed until this period were extremophiles that remained alive anaerobically (methanogen, sulphate reducer, etc.). In this period (Great Oxidation event), in which oxygen did not form for about 1 G year, it is thought that the first autotrophs/lithotrophs that used inorganic compounds such as CO and H_2 and CO_2 as electron acceptors could begin using the Wood-Ljungdahl pathway, according to the "isotopic partition model" [2].

Another geological study, under the name of hydrothermal reactor hypothesis (serpentization), argues that CO_2 formed by volcanic leakage in the seas and hydrothermal H_2, metal-catalysed reactions and the synthesis of Acetyl-CoA from inorganic metabolites and then acetate, ethanol, etc. are realised. It is also thought that this reaction was first chemical and then biochemical enzyme-catalyzed 3.8 G years ago [3]. These strict anaerobes called homoacetogens formed the first carbon building blocks using CO_2 and H_2. Another strict anaerobe, hydrogenotropic methanogens are archaitic microorganisms that produce methane with the same substrates. Similarly, groups such as sulfate reducers, nitrate reducers and syntropic propionate reducers are H_2-dependent and use H_2 as an electron donor. In this point, there is stong affinity of the usage of hydrogen by microorganism since the orign of life. Hydrogen is widely used in anaerobic environments which produced by suppressing or disabling consumer species has been an exciting topic for the last 30 years. Especially biohydrogen production via dark fermentation has been studied extensively due to its similarity to existing biogas systems [4]. In a one of the bibliometric study, it was observed that approximately 3071 dark fermentation studies were conducted in the last 20 years and almost all of them were lab-scale (max TRL 3-4-). There is no commercially operating dark fermentative pilot plant yet and some of the published trials have some techno-economic question marks that have been methodologically ignored [5,6]. In addition, the necessity of purify impurities in the obtained biohydrogen (carbon dioxide), suitable organic raw materials demads with high sugar content and operational difficulties still continue to prevent commercial biohydrogen production.

On the other hand, political and other energy-related developments in the world encourage hydrogen production in different ways. In the war that Russia started with to annex Ukraine in 2021, Europe's dependence on Russian natural gas was seriously revealed. Approximately 40% of the natural gas used in Europe is imported from Russia [7]. A series of measures have been taken within the scope of the Green agreement (10-point plan) to prevent this dependence and the gas which imported is planned to be gradually reduced by 2030 [8]. Russia's aggression against Ukraine has forced Europe to accelerate its energy transition which means that Russia has unintentionally encouraged European climate policy [9]. Reasons such as unreliability of Russia, hydrogen production based on natural gas in the industrial sector, the need to store energy critically in line with geopolitical energy security and climate goals that accelerated green hydrogen

studies both socially and academically and it has been publicly accepted, especially in Germany [10]. Because the war revealed the economic fragility of the Germans who were largely dependent on Russian gas. That's why Germany is trying to prevent this by switching to green hydrogen instead of natural gas in energy production. For this reason, encouragement for the use of electrolyzers has increased which is so simple of installation, use of water as raw material, high efficiency pure hydrogen production capacity and operation only with electricity. Therefore, electrolysers have begun to be preferred over dark fermentation as a source of green hydrogen production.
As the political and static energy security trends in the world change, the difficulties of hydrogen production by fermentation are also becoming apparent again. The theoretical maximum yield that can be achieved by dark fermentation is 4 moles H_2 per 1 mole of glucose, given as the Thauer limit [11]. This yield was increased up to 6.1 and 11.6 moles in some manipulated (by changing enzyme syntheses or metabolic pathways through genetic means) combined pure culture medium and a single species, respectively [11,12]. Apart from these special efforts (fully controlled microbial environment), the yields obtained using mixed inoculum culture (anaerobic sludge, biogas digestate etc.) have always remained below the limit. Many factors play a role in this inefficient process, where a very small portion of the substrate used energetically is converted into gas. Hydrogenase enzymes play the most important role in this process because they can catalyze hydrogen formation, consumption and sensing bidirectionally. In genomic and metagenomic studies (51 bacterial and archeal phylum hydrogenases were found), it is known that molecular hydrogen is an important electron donor for respiration in both anoxic and oxic ecosystems and therefore the main energy source for respiration in many ecosystems (geothermal, atmospheric, biological) [12]. This process could have been crucial for the emergence of autotrophic life forms, which can synthesize their own organic compounds from inorganic sources. One of the difficulties is due to the fact that H_2 output represents an energy loss for the cell and that microbial metabolic network has evolved for rationalization of energy use and optimization of specific growth rate and uptake hydrogenase [13].
The most important of that preparation phase of the inoculum culture. As it is known, some pre-treatments must be carried out to prepare the inoculum and substrate for microbial activity to start and adapt. Pre-treatments like thermal, chemical, pH, aeration etc. applied to the inoculum that are based on the principle of deactivating the species that consume hydrogen in the inoculum and activating the producers. These pre-treatments have many technical, economic and energetic handicaps. Nevertheless, these methods cannot prevent the consumption of hydrogen, especially by methanogens, homoacetogens and other species.

The Importance of Microbial H_2 metabolism

H_2 metabolism plays a crucial role in soil, sludge, aquatic systems, animal guts, and hydrothermal vents. Specific hydrogenases dominate different ecosystems:

- Aerobic soils: High abundance of oxygen-tolerant uptake hydrogenases.
- Anoxic environments (sediments, guts, bogs): More fermentative and respiratory hydrogenases.

The primordial role of H_2 as an energy source supports the theory that H_2 was one of the first electron donors for life. The great diversification of hydrogenases over time allowed microbes to adapt to different energy and environmental conditions. There types of Hydrogenases take a serious role in microbial hydrogen metabolism [13]. Those are listed below.

[NiFe]-Hydrogenases (22 subgroups)

- The most diverse and widespread type, primarily involved in H_2 oxidation for respiration.
- Subdivided into:
  - **Group 1 & 2:** Respiratory hydrogenases, involved in aerobic and anaerobic H_2 uptake.
  - **Group 3:** Bidirectional hydrogenases, capable of both H_2 production and consumption.
  - **Group 4:** H_2-evolving enzymes, essential in fermentation and energy transduction.

[FeFe]-Hydrogenases (6 subtypes)

- Primarily found in anaerobic bacteria, archaea, and unicellular eukaryotes.
- Often linked to fermentation and electron bifurcation (simultaneously directing electrons to multiple pathways).
- Includes bifurcating hydrogenases, which split electron flow to enhance metabolic efficiency.

[Fe]-Hydrogenases

- A less diverse and functionally constrained class, found only in methanogens.
- Plays a key role in CO_2 reduction and hydrogen cycling in archaea to produce methane.

2. RESULTS AND DISCUSSION

Thermodynamic and other barriers are limiting the maximize of dark fermentative hydrogen production. Some of these factors are given in below.

- **Inoculum preperation:** Inoclums are have to be pre-treated to kill or suppress hydrogen consumer microorganism such as methanogens. However most of the technics are utilizing huge amount of energy and chemicals then eventually they are not efficiently success for microbial hydrogen consumption [14,15]. In batch culture, it can be managed somehow but when new substrate adding to the reactor brings their own consumer and later becoming dominant and changing the balance of the media.
- **pH and Temperature:** Maintaining pH in optimal conditions (5.5-6.5) is always challenging during fermentation because of the alkalinity of the medium which requires chemicals continuously and mostly causing a foam formation too. Temperature is an other issue to keep reactor in same level need energy depending operation degree (themophilic etc.).
- **Sensing and Analysis:** Regular analysis of the fermentation metabolites like volatile fatty acid and other related metabolic product also curial to maintain hydrogen yield which can be perfomed well only in equipt laboratories.
- **Gibbs Free Energy:** Hydrogen production during dark fermentation is only thermodynamically favorable when the Gibbs free energy change is negative. This requires specific conditions, including a low hydrogen partial pressure. As hydrogen accumulates, the $^{o}\Delta G$ becomes less negative eventually reaching a point where further hydrogen production becomes thermodynamically unfavorable. Also process shift that stimulates butrate production is related with partial hydrogen production that allow only 2 mols of hydrogen per mol of glucose consumption.
- **Metabolic Pathways:** The specific metabolic pathways employed by fermentative microorganisms influence the amount of hydrogen that can be produced from a given substrate. Some pathways (Wood-Ljungdahl, Direct Interspices Hydrogen Transfer, Syntropic Acetate/Propionate Oxidation, Sulphate Reduction etc.) lead to the formation of by-products like acetate, butyrate, H_2S or ethanol which compete with hydrogen production for electrons and reduce the overall hydrogen yield
- **Hydrogenase Enzyme Activity:** Hydrogenases the enzymes that responsible for catalyzing hydrogen production are sensitive to environmental conditions like pH and temperature. Optimal hydrogenase activity is essential for efficient hydrogen production and deviations from these optimal conditions can hinder the process.
- **Substrate Concentration and Type:** Increasing the easy degradable carbohydrates content allows high substrate concentrations (high sugar-shock loading) which is necessary to perform hydrogen production but it may also lead to product inhibition too. On the other side, complex substrates may require additional processing steps (pre-treatment) before they can be utilized by fermentative microorganisms. Less substrate concentration also can shift the metabolism to microbial growth instead of hydrogen production. It has to be maintained well balance.
- **Gas heterogenity:** During dark fermentative hydrogen production, hydrogen is not the major gas that ocur in reactor. Besides hydrogen, considerable amount of carbondioxide can be formed during process. Stoichiometrically, each moles of glucose fermentation can produce 2 moles of CO_2 and in mixture it can be formed up to 50%. This situation has to be solved by further downstream processes like gas filtration and purification if the gas mixture wont be used in internal combustion engines.

3. CONCLUSIONS

Hydrogen production by dark fermentation is still promising renewable green hydrogen production way but some of serious operational, microbial and process modifications has to be solved.

Diversifying the substrate sources and using easily degradable sugars or performing pre-treatments to reveal potential carbohydrates in some raw materials is necessary. In addition, since it is known that hydrogen production occurs only form at high carbohydrate concentrations, the integration of remaining sugars into other processes such as anaerobic biogas, microbial fuel cells and photofermentation which can increase total energy efficiency of the process. Innovative reactor designs, such as continuous stirred-tank reactors, immobilezed, sequencing batch or packed-bed reactors can improve hydrogen production by optimizing substrate utilization, mass transfer and hydrogen of removal. Two-phase combine hydrogen-methane (biohytane) system is an another alternative way to perform energy efficiency too. In situ hydrogen removal like continuously removing hydrogen from the fermentation broth can alleviate product inhibition and shift the thermodynamic equilibrium towards further hydrogen production. Methods like gas sparging or membrane separation can be employed for in situ hydrogen removal. Microbial community composition of the fermenter plays a crucial role in hydrogen production. A diverse community with a balance of hydrogen-producing and hydrogen-consuming microorganisms can lead to more efficient hydrogen production. Furthermore, combining some pure strains or genetically modified microorganism cultivation to maintain high hydrogen yield like above Thaur limit is an another microbial modification. Maintainig the temperature and pH at optimum levels for ideal hydrogen production is a very critical process which has to be considered under energy efficiency and less chemical usage for sustainability. Checking of the fermentation process to avoid unfavarouble pathways like butyrate/ethanol production which cause a low hydrogen yield has to be monitored regularly by automation and regular analysis (feed back inhibition by H_2 build up and inhibitors etc).

As a results, over the decades, there was a serius academic studies was carried out to produce sustainable hydrogen production by dark fermentation. However, as we mentioned during the whole paper that researcher need to overcome serious technical, microbial and political bariers to use hydrogen in commercial systems as green hydrogen sources.

ABSTRACT

Renewable hydrogen production offers a clean and sustainable alternative to fossil fuels. This study investigates the potential of *Thermotoga maritima* to produce biohydrogen from wheat straw, a low-cost and abundant agricultural residue. Batch experiments were conducted at concentrations ranging from 2.5 to 35 g VS/L, demonstrating successful substrate degradation without pretreatment. The bacterium achieved net biohydrogen production reaching its highest at 14.6 ± 2.6 mL at 25 g VS/L. The dark fermentation effluent, rich in acetic acid, was further processed in a microbial electrolysis cell (MEC) using *Geoglobus acetivorans*. Initial MEC tests confirmed the utilization of effluent acetate for current production. These findings highlight the potential of coupling dark fermentation with MEC technology to improve biohydrogen yields from agricultural waste.

Keywords: Dark fermentation, Biohydrogen, *Thermotoga maritima*, Bioelectrochemical systems

1. INTRODUCTION

The amount of energy derived from fossil fuels make up 80% of the world energy consumption. Heavy reliance on fossil fuels accelerates their depletion, increases energy costs, and contributes to environmental issues such as air pollution and greenhouse gas emissions [1]. To ensure energy security and address environmental concerns, attention has turned to renewable energy sources. Hydrogen is a promising clean energy alternative due to its lack of CO_2 emissions during combustion and its high theoretical energy output [2]. While the hydrogen market is rapidly expanding, with a 10% annual increase in usage, current production methods rely on energy-intensive processes [3,4]. In biological hydrogen production methods like dark fermentation (DF), various types of waste can be used to achieve high biohydrogen yields, enabling both energy production and waste management [5]. Despite its potential, the rate and yield of biohydrogen production through DF remain low. In order to develop economically viable and sustainable H_2 producing bioprocess, production rate and yield should be increased.

To make the DF process practical, abundant and low-cost feedstocks like agricultural wastes may be used as raw material. Wheat straw (WS), a byproduct of wheat production offers high biodegradability and high carbon content, making it an economical and renewable raw material for biohydrogen production. In 2020, Turkey's wheat production reached 20.5 million tons; indicating a high potential to the use of WS as a feed to DF process [6].

Thermotoga maritima is a hyperthermophilic microorganism (≥70°C) with a wide range of thermostable hydrolytic enzymes essential for breaking down complex carbohydrates. Its high growth temperature provides several advantages, including faster hydrolysis of complex substrates, higher H_2 production rates, and reduced contamination risk from H_2-consuming microorganisms [7]. The fermentation process produces CO_2, acetate, lactic acid, and H_2, approaching the theoretical maximum yield of 4 mol H_2 per mol of glucose [8]. Under optimum conditions, fermentation results in 2 mol acetate/ mol glucose Eq. (1), that the bacteria are unable to further convert to H_2. Thus, during the fermentative production of H_2, conversion efficiency is 33% and remaining organic matter is wasted as acetic acid, despite a theoretical stoichiometric potential of 12 mol H_2/mol glucose Eq. (1) [9].

Bioelectrochemical systems (BES), such as Microbial Electrolysis Cells (MECs), utilize electro-active microorganisms to produce H_2. The electrons in MEC are involved in the H_2 evolution reaction at the cathode, and the exoelectrogens that are present as a biofilm on the anode are oxidizing organics and using this electrode as an electron acceptor Eq. (2) and Eq. (3) [10]. This process, known as electrohydrogenesis, extracts H_2 from the chemical energy stored in various substrates, including organic acids, complex organic compounds, and DF effluents. However, conversion of acetate to H_2 is not spontaneous and requires an external voltage of at least 0.14 V [11]. Yet, compared to other common H_2 production methods such as water electrolysis, energy requirement is significantly lower in electrohydrogenesis [12].

$$C_6H_{12}O_6 + 2H_2O \rightarrow 4H_2 + 2CO_2 + 2C_2H_4O_2 \quad (1)$$
$$CH_3COO^- + 4H_2O \rightarrow 2HCO^- + 9H^+ + 8e^- \quad (2)$$
$$8H^+ + 8e^- \rightarrow 4H_2 \quad (3)$$

This study focuses on biohydrogen production through the DF of wheat straw using *Thermotoga maritima*. To improve

overall H_2 yields, the DF effluent, which contains residual acetate, will be further processed in an MEC via electrohydrogenesis. This integrated strategy aims to use abundant and cheap lignocellulosic substrate to maximize biohydrogen production.

2. MATERIALS AND METHODS

2.1. Microorganisms and culture conditions

T. maritima DSM 3109 and *Geoglobus acetivorans* (DSM 21716) were purchased from the German Collection of Microorganisms and Cell Cultures (DSMZ), Braunschweig, Germany. *T. maritima* culture was grown in a medium from [13] with the following modifications: increasing the reducing agent to 1 g/L L-cysteine and adjusting the overall pH to 6.8. The growth medium included 5 g/L cellobiose as pure substrate, which is a repeating unit in lignocellulosic biomass. *G. acetivorans* was initially grown with 10 mM acetate as an electron donor, and 56 mM ferric citrate as an electron acceptor. Hyperthermophile archaea growth medium was prepared as given elsewhere to grow *G. acetivorans* culture [10]. The mediums were prepared anaerobically under N_2: CO_2 (80%:20%) atmosphere.

2.2. Experimental design and sets

To determine biohydrogen production potential, batch operations were set up using serum bottles with a total volume of 110 mL (active volume of 60 mL). The reactors included (i) pure substrate (PS), (ii) seed control (SC), (iii) waste test (WT), and (iv) negative controls (NC). The PS reactors, containing 5 g/L cellobiose as the substrate, were set up to evaluate the activity of the microbial culture. SC reactors were prepared without any carbon source (C-source) to determine background gas and metabolite production. WT reactors were supplied with WS as the C-source in two concentration sets: low dose (LD) and high dose (HD). LD concentrations were 2.5, 5, and 7.5 g VS/L, while HD concentrations were 15, 25, and 35 g VS/L, designed to assess the degradability of WS by *T. maritima*. NC reactors were designed to verify that hydrogen production resulted specifically from the activity of *T. maritima* rather than native microorganisms in WS. These reactors contained the same C-source concentrations as WT reactors but lacked *T. maritima* inoculum. All reactors were set up in triplicate, the pH adjusted to 6.8, and incubation maintained at 80°C. The experimental design is given in Table 1.

Table 1. The experimental design of Wheat Straw Set

Reactors	Inoculum	C-source	C- Source Dose
Pure Substrate (PS)	*T. maritima*	Cellobiose	5 g/L
Seed Control (SC)	*T. maritima*	-	-
Wheat Straw Test (WS)	*T. maritima*	Wheat Straw (WS)	2.5, 5 ,7.5 g VS/L and 15, 25 ,35 g VS/L
Negative Control (NC)	-	Wheat Straw (WS)	2.5, 5 ,7.5 g VS/L and 15, 25 ,35 g VS/L

G. acetivorans was tested in 5 mL active volume reactors using two different acetate sources: pure acetate and dark fermentation (DF) effluent. The two media used contained a total of 10 mM acetate. In the reactors, a graphite plate (GM-10 grade, dimensions: 1.5 cm x 1.0 cm x 0.3 cm) was used as the anode and a stainless-steel mesh (Type 304, mesh size 50, dimensions: 1.5 cm x 1.0 cm) as the cathode material. The experimental design is detailed in Table 2. The objective of this study was to evaluate the ability of *G. acetivorans* to utilize acetate from different sources. The DF effluent used in the experiments was obtained from *T. maritima* pure substrate fermentation. The initial phase of the experiment assessed whether *G. acetivorans* could use the acetate present in the DF effluent as an electron donor. Reactors (PA_DF) were first operated with pure acetate and then transitioned to DF effluent acetate in subsequent cycles to determine if biofilm formation occurred prior to the introduction of DF effluent. Current density was monitored throughout the experiment to evaluate reactor performance.

Table 2. The experimental design of G. acetivorans Mini MEC Set

Reactors	Inoculum	Cycle 1 to 3 electron donor	Other Cycles Electron Donor	Applied voltage (V)
Pure Acetate Dark Fermentation acetate (PA_DF)	*G. acetivorans*	10 mM Pure Acetate	10 mM DF Acetate	0.7
Dark Fermentation acetate (DF)	*G. acetivorans*	10 mM DF Acetate	10 mM DF Acetate	0.7

2.3. Analysis

The Wheat Straw (WS) was sourced from a local farmer, the sample was blended for 15 minutes to make it homogenous, and no other treatment was applied. The Standard Methods (APHA et al., 2005) were followed for the TS (Section 2540B), VS (Section 2540E), and chemical oxygen demand (COD) (Section 5220D). Neutral detergent fiber (NDF), acid

detergent fiber (ADF), and acid detergent lignin (ADL) are three major components of the fiber content of the wheat straw. WS samples were sent to NutriLab (Konya, Turkey) to determine fiber composition via a fiber analyzer (ANKOM Technology, USA).

Total gas production was measured using a liquid displacement device. The compositions (H_2, CH_4, CO_2, and N_2) of the headspace gas samples were determined via a gas chromatograph (Shimadzu 2010-Pro) equipped with a thermal conductivity detector (TCD). Volatile fatty acids (VFAs) were analyzed using a gas chromatograph (Shimadzu 2010-Pro) with a flame ionization detector (FID).

Solubilization was performed at the end of the experiment for each reactor. This is a common gravimetric method for solubilization of plant biomass; this study used it to analyze WS degradability in the test reactors. The solubilization assay for fermentation of selected waste was implemented according to [14] with minor modifications.

The contents of the reactor were filtered by vacuum filtration through coarse filter paper and washed twice with DI water. The coarse filter was dried in an oven at 75^{0}C, and its mass was measured. Given the initial mass in the reactor, an extra reactor was prepared under the same conditions (T_0) and the same solubilization protocol was followed before the reactor was operated. The degree of solubilization in the reactor was then determined from the difference between the initial mass (T_0) and the mass at the end of the process.

3. RESULTS AND DISCUSSION

The low dose WS set was operated for 31 days while the high dose set was operated for 18 days. During the operation, hydrogen production was observed, and the net H_2 production was determined by subtracting the H_2 produced in the SC reactors from that in the test reactors. The net H_2 production in the low concentration of WS did not reach the lowest net H_2 production in the high WS concentration even though they were operated for an additional 13 days, as shown in Figure 1.A. The average net hydrogen production at high dose reactors (≥ 15 g VS/L), was around 60% higher compared to the low dose reactors (≤ 7.5 g VS/L) indicating suitability of the selected feedstock for this process.

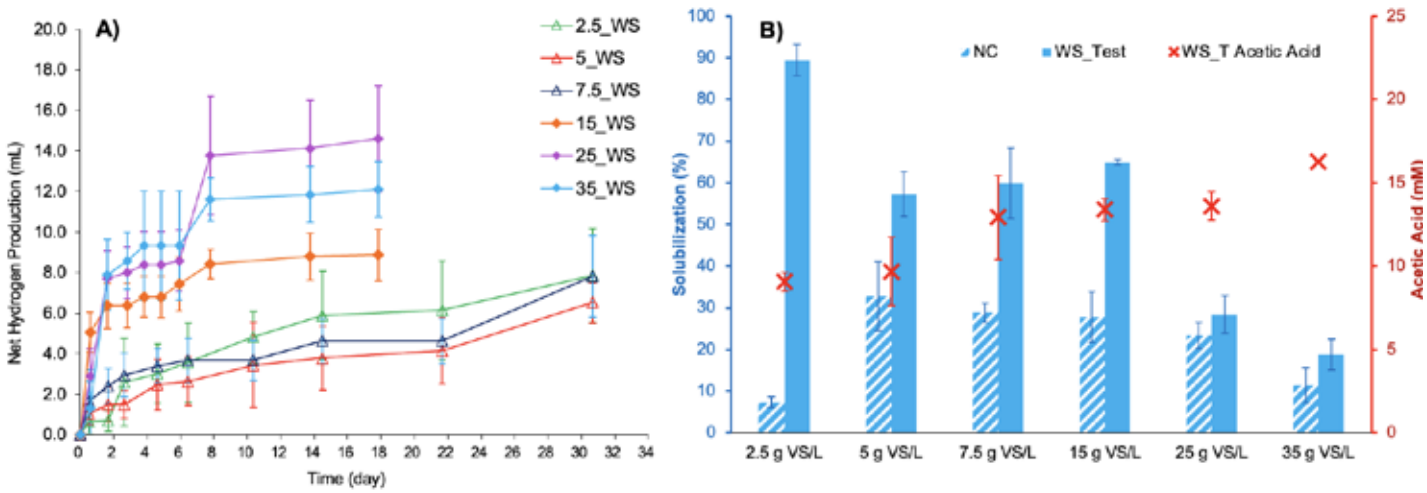

Fig.1. A) Net hydrogen production of WS set, **B)** WS set solubilization degree (%) and acetic acid concentration (mM)

At the end of the experiment, solubilization and acetic acid measurement are done (Figure 1.B). The results show that solubilization percentages tend to decrease as the concentration increases, possibly due to substrate saturation or resource limitations, where essential nutrients become insufficient for further degradation. The solubilization obtained in the NC reactors at each VS concentration is due to other processes unrelated to *T. maritima* activity such as thermal degradation of the waste. As the concentration of the feed increases the negative control solubilization rate is decreasing which may imply that there is only a certain degree of solubility achieved due to abiotic processes. The acetic acid production increases as concentration increases, test reactors average acetic acid production was relatively similar with an average of 12.5 ± 2.7 mM. The acetic acid was only detected at NCs of higher VS concentration reactors, with the maximum around 4 mM. The net acetic acid production on 35 g VS/L reactor was three times higher than respective NC.

G. acetivorans was inoculated into Mini MEC reactors containing 10 mM pure acetate and DF effluent derived from the pure substrate, cellobiose. As shown in Figure 3, the peak current densities observed were 1.64 ± 0.11 A/m² for DF_DF and 1.32 ± 0.58 A/m² for PA_DF. In the final cycle, the acetate source for the PA_DF reactors was switched to DF effluent, resulting in current densities of approximately 0.4 A/m² for both reactors. These results demonstrate that *G.*

acetivorans can utilize acetic acid present in DF effluent as an electron donor.

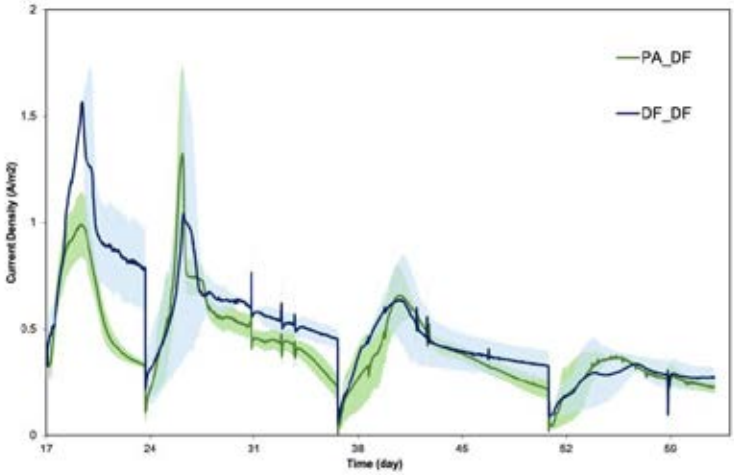

Fig.3. Current Density of Mini-MEC

4. CONCLUSIONS

The hyperthermophilic bacterium *T. maritima* effectively degraded WS without any pretreatment, even at high concentrations of up to 35 g VS/L. The highest net biohydrogen production, 14.6 ± 2.6 mL, was achieved at a concentration of 25 g VS/L, with a production rate of 4.35 mL/day. The DF effluent from these reactors was analyzed for acetic acid, which was then used as a feed in MECs. Initial tests with the MEC setup demonstrated that *G. acetivorans* could utilize the DF effluent from *T. maritima* reactors. Future stages of this study will focus on using WS DF effluent in MECs to further enhance biohydrogen production.

ACKNOWLEDGMENT

ABSTRACT

Integrating renewable energy sources into the transportation sector is essential to achieving targeted reductions in greenhouse gas emissions. While electric vehicles are promoted as an environmentally sustainable solution, the increasing battery weight associated with extended range highlights a key limitation. This challenge has driven the development of fuel cell-based hybrid electric vehicles as a viable alternative. In recent years, the simulation of powertrain systems in electric, hybrid, and fuel cell hybrid vehicles has become increasingly popular for assessing vehicle performance and powertrain efficiency. Studies on fuel cell hybrid vehicles typically focus on improving a specific powertrain component or a particular hybrid configuration, often assuming a flat road profile. In this study, a powertrain system model incorporating a battery and a fuel cell was developed and simulated in the Matlab/Simulink environment under the WLTP Class 2 driving cycle on an inclined road. The simulations provided key performance metrics, including the power output of powertrain components, battery state of charge (SoC), and hydrogen consumption. This study aims to offer a realistic simulation approach that closely reflects real-world driving conditions, achieving the desired performance in hybrid vehicles.

Keywords: Fuel cell hybrid vehicle, Battery, Hydrogen, Drive cycle simulation, Matlab/Simulink

1. INTRODUCTION

Electric vehicles (EVs) have gained significant attention as a sustainable alternative to conventional internal combustion engine vehicles due to their zero-emission operation and high energy efficiency. They utilize electric motors powered by batteries or hybrid energy sources, reducing reliance on fossil fuels and contributing to lower greenhouse gas emissions. However, range limitations and insufficient charging infrastructure remain major challenges for the widespread adoption of EVs. In this context, hydrogen-based Fuel Cell Electric Vehicles (FCEVs) have emerged as a viable solution, offering longer driving ranges and shorter refueling times than Battery Electric Vehicles (BEVs). FCEVs generate electricity through a Proton Exchange Membrane (PEM) fuel cell by converting hydrogen into electrical energy to power the motor. Despite their advantages, issues related to hydrogen production , storage, safety, and refueling infrastructure hinder their large-scale deployment. Recent advancements in fuel cell technology, such as improved catalyst materials and system integration, have significantly enhanced the efficiency and durability of FCEVs. Moreover, integrating renewable energy sources for hydrogen production improves the environmental benefits of these vehicles. EVs and FCEVs represent crucial innovations in sustainable transportation, each addressing different energy consumption and emissions challenges. Alpaslan et al. [1] investigated the driving cycle simulation performance of electric, hybrid and fuel cell powertrains of a small vehicle. Different combinations of energy sources, such as batteries, supercapacitors, and fuel cells were evaluated, and their effects on component efficiencies and vehicle range were analyzed . Dhanalakshmi et al. [2] have discussed the modeling and simulation of the electric powertrain of a hybrid electric vehicle. In the study, an effective electric powertrain design for hybrid electric vehicles is presented using permanent magnet synchronous motor (PMSM) and space vector pulse width modulation (SVPWM) techniques . Ancuta and Danciu [3] consider the modeling and simulation of an electric propulsion system equipped with a fuel cell. The model was developed using the MATLAB Simulink software and was based on the structure of the Toyota MIRAI. The simulation results include the evolution of the fuel cell and the important parameters of the vehicle over time . Wu et al. [4] developed optimal energy management strategies for hybrid electric vehicles using reinforcement learning. The proposed method was integrated with FASTSim, an open-source vehicle simulation tool, and was shown to be effective in improving energy efficiency under different vehicle models and driving cycles . Shubham and Ganguly [5] discuss a series-parallel hybrid electric vehicle's architecture and different operating modes. A standard series-parallel HEV is simulated using Matlab Simulink and its fuel consumption is estimated for different driving cycles. The results show that hybrid electric vehicles are a viable intermediate solution for the transition to full electric vehicles in developing countries . This study analyzed the performance of a hybrid electric vehicle powered by a fuel cell and a battery on a road with a different slope angle throughout the driving cycle. When the vehicle speed exceeded 30 km/h, the fuel cell was activated and speed control was performed with adaptive PID.

2. MODELING OF HYBRID ELECTRIC VEHICLE

Several forces act on an EV during its operation, influencing its dynamic behavior, energy consumption, and overall performance. A comprehensive understanding of these forces is essential for accurately modeling, controlling, and optimizing EV systems. The main forces acting on an EV include aerodynamic drag, rolling resistance, gravitational force, and inertial force. Each of these forces is described below with the corresponding mathematical expressions.

2.1. Aerodynamic Drag Force

Aerodynamic drag is the resistance exerted by air on the vehicle as it moves. It increases quadratically with vehicle speed and depends on vehicle shape and frontal area.

$$F_{aero} = {}^{1}/_{2}\, \rho C_d A_f v^2 \quad (1)$$

where F_{aero} is the aerodynamic drag force (N); ρ is the air density (kg/m³); C_d is the drag coefficient; A_f is the frontal area of the vehicle (m²); v is the vehicle speed (m/s).

2.2. Rolling Resistance Force

Rolling resistance arises due to the deformation of the tires and road surface. It is generally proportional to the vehicle's weight.

$$F_{roll} = m.g.C_r \cos\theta \quad (2)$$

where F_{roll} is the rolling resistance force (N); C_r is the rolling resistance coefficient; m is the vehicle mass (kg); g is the gravitational acceleration (9.81 m/s²); θ is the road incline angle (rad).

2.3. Gravitational Resistance Force

This force results from driving on an inclined road and depends on the slope angle. It increases the load on the powertrain during uphill motion and reduces it during downhill motion.

$$F_{grade} = m.g.\sin\theta \quad (3)$$

where F_{grade} is the grade resistance force (N)

2.4. Inertial Force

This force is associated with the acceleration or deceleration of the vehicle. It represents the force required to change the velocity of the vehicle mass.

$$F_{inertia} = m.a \quad (4)$$

where $F_{inertia}$ is the inertial force (N); a is the vehicle acceleration (m/s²)

2.5. Total Tractive Force

The total tractive force required at the wheels is the sum of all the aforementioned resistive forces. This force determines the power demand from the electric powertrain.

$$F_{tractive} = F_{aero} + F_{roll} + F_{grade} + F_{inertia} \quad (5)$$

Once the total tractive force is determined, it is possible to calculate the required torque on the wheels. Through the transmission system, this torque must be delivered by the electric drivetrain, ultimately by the Brushless DC (BLDC) motor. The wheel torque required to overcome the total resistive forces is calculated in Eq. 6.

$$T_{wheel} = F_{tractive}.R \quad (6)$$

where T_{wheel} is the required torque at the wheel (Nm); $F_{tractive}$ is the total tractive force (N); R is the effective wheel radius (m)

In most EVs, the torque generated by the BLDC motor is transmitted to the wheels via a gear reduction system. Therefore, the required motor torque can be derived from the wheel torque, considering the gear ratio.

$$T_{motor} = {}^{T_{wheel}}/_{\eta_{drivetrain}.G} \quad (7)$$

where T_{motor} is the motor torque (Nm); G, is the gear ratio; $\eta_{drivetrain}$ is the drivetrain efficiency

In this study, simulations were performed by calculating the total force and required engine torque for the WLTP Class 2 driving cycle Low part on an inclined road. Driving Cycle and slope angles are shown in Fig. 1(a). The vehicle and

simulation parameters are also given in Table 1. The model that calculates the forces acting instantly on the vehicle and the required engine torque according to the driving cycle was created in Matlab/Simulink according to the parameters in Table 1. The schematic diagram of the model is given in Fig 1(b). The primary energy source of the vehicle was determined as the battery. When the speed exceeds 30 km/h, the Perturb and Observe (P&O) algorithm controls the PEM fuel cell and supports the battery at maximum power.

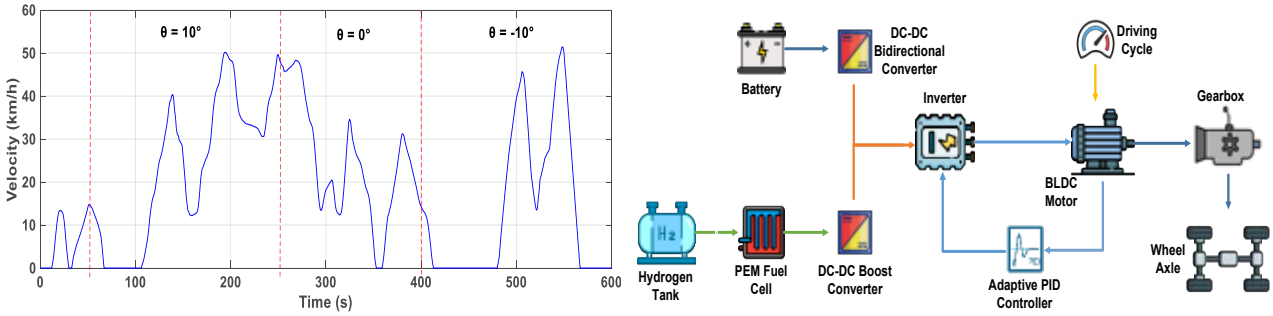

Fig. 1. (a) WLTP Class 2 low part and slope angle change **b)** The schematic diagram of the hybrid electric vehicle model

Table 1. The vehicle and simulation parameters

Definition	Parameter	Value	Unit
Vehicle Mass	m	500	kg
Rolling Resistance Coefficient	C_r	0.0015	-
Aerodynamic Resistance Coefficient	C_d	0.4	-
Vehicle Projection Area	A_f	2	m^2
Battery Capacity	Q_{Bat}	6	kWh
Initial Battery Charge	SoC_i	80	%
Maximum Fuel Cell Power	P_{FCmax}	3.48	kW
Mechanic Efficiency	$\eta_{drivetrain}$	90	%

3. RESULTS AND DISCUSSION

In this study, a Matlab/Simulink model was developed to analyze energy and vehicle performances of hybrid electric vehicles under slope change. In the simulations performed for the first flat road, the maximum battery power consumption during the driving cycle was 7 kW, while this value dropped below 6 kW in the hybrid system. Then, the vehicle performance was analyzed using battery power as the only energy source. Fig. 2(a) illustrates the battery power profile, whereas Fig. 2(b) presents the variations in the reference and the actual vehicle velocity. The change of SoC value throughout the cycle is given in Figure 2(c).

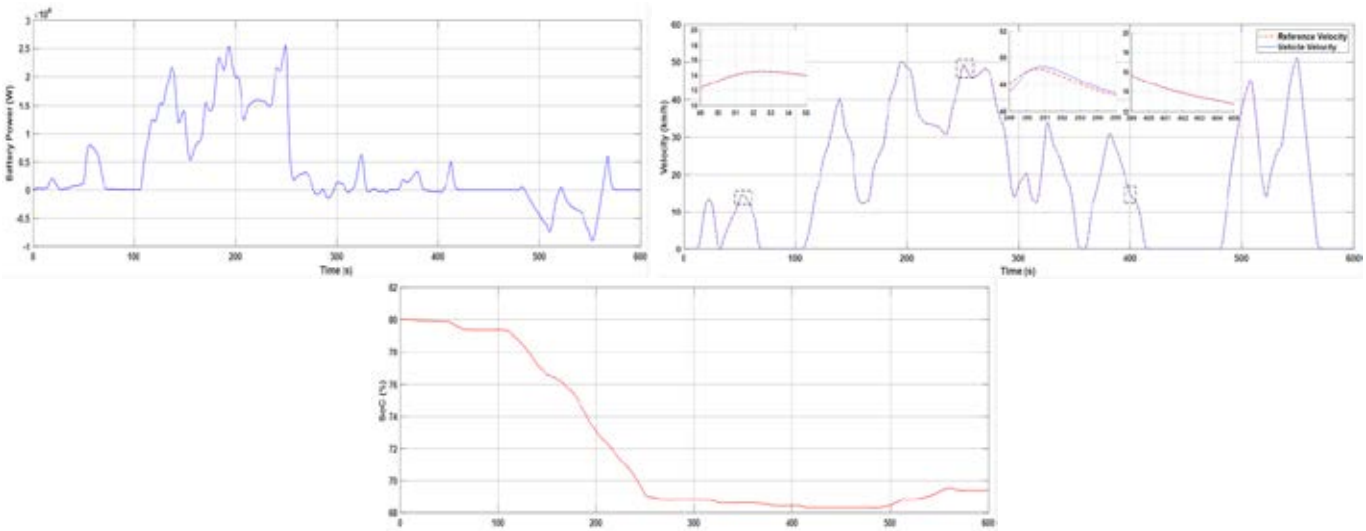

Fig. 2. (a) Battery power, **(b)** Reference and vehicle velocity, and **c)** SoC of the battery

The battery power and the reference velocity and actual vehicle velocity graphs for the vehicle operating under the hybrid power drive system are presented in Figures 3(a) and 3(b), respectively. The SoC value of the battery and the fuel cell power are also shown in Fig. 3(c) and (d).

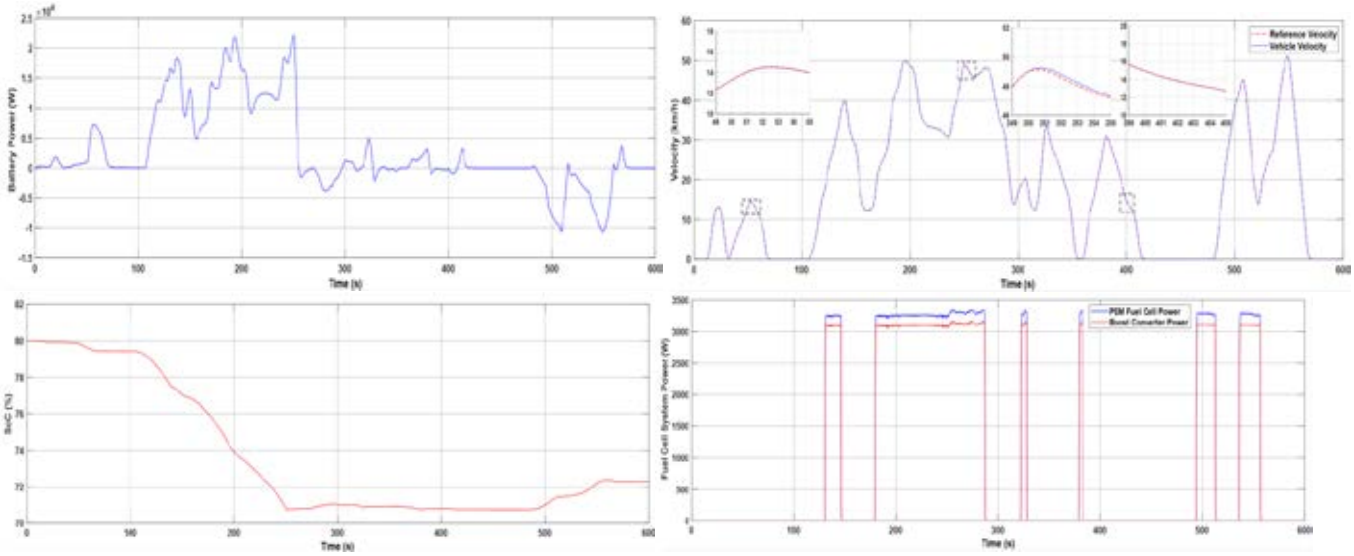

Fig. 3. (a) Battery power **(b)** Reference and vehicle velocity **c)** SoC of the battery, and **d)** PEM fuel cell power

As seen in Fig. 2(a), when the vehicle has only the battery, there is a power consumption of 25 kW according to the speed, while in Fig. 3(a) this consumption remains at a maximum of about 22 kW thanks to the fuel cell. While the slope change at low speeds caused minimal deviations from the reference speed thanks to the adaptive PID, the slope change at the 400th second, which occurred at a relatively higher speed, caused a departure from the reference speed for a few seconds. This situation is seen in Fig. 2(b) and Fig. 3(b). While the SoC value was below 70 in Fig. 2(c), it was completed above 72 due to the decrease in battery discharge when the fuel cell was activated, as in Fig. 3(c). Especially after the 500th second, the increase in the battery SoC value is because the energy generated as a result of regenerative braking due to the road slope angle being -10° charges the battery via the bidirectional converter.

4. CONCLUSIONS

In the proposed study, the WLTP Class 2 low section—representing approximately 3 km of driving for a hybrid electric vehicle—was simulated to analyze two powertrain configurations: one powered solely by a battery and the other combining a battery with a PEM fuel cell.To enhance the ability of the vehicle to accurately track the reference velocity, an adaptive PID controller was developed, in which the control parameters dynamically vary based on the instantaneous operating conditions. As can be seen from the results, the powertrain system using the fuel cell and battery together ensures that the battery capacity is used less and sudden discharges are prevented when higher velocities higher than 30 km/h are required. During hybrid operation, the fuel cell consumed approximately 210 L/min of air and 125 L/min of hydrogen to provide the required maximum power. Although the simulated inclined road model generally shows that power consumption increases compared to the case where the road is not sloped, it provides an analysis of a situation similar to real-world conditions.

ABSTRACT

The growing global energy demand, when met by fossil fuels, propels the planet toward an irreversible climate crisis. Transitioning to renewable energy sources is essential to mitigate this trend. Due to the intermittent nature of renewable resources, an energy carrier that can be utilized on demand is required. Recently, environmentally friendly hydrogen has increasingly filled this gap. Hydrogen energy is becoming more popular for electricity generation through fuel cells without causing greenhouse gas emissions. This study models and evaluates a hybrid system consisting of a Proton Exchange Membrane (PEM) fuel cell, a photovoltaic (PV) panel array, and a battery to meet energy demand. For this purpose, a 1.26 kW PEM fuel cell, a 1.1 kW PV panel array, and a 12 kWh battery were integrated on a 48 V DC bus via appropriate converters in the Matlab/Simulink. The Perturb and Observe (P&O) algorithm controlled the PV panel array to achieve maximum power under varying solar irradiance and temperature conditions. Additionally, another Perturb and Observe (P&O) algorithm was employed to reduce the power output of the PEM fuel cell intentionally. This approach aims to decrease the hydrogen consumption of the fuel cell in response to specific solar radiation levels.

Keywords: Hybrid renewable energy system, Energy management, PEM fuel cell, Matlab/Simulink

1. INTRODUCTION

Fossil fuels, including coal, oil, and natural gas, have been the dominant global energy sources, but their extensive use in the 20th century has caused severe environmental damage. A global shift towards renewable energy is underway to address climate change and growing energy demand, aiming to eliminate greenhouse gas emissions. Solar energy emerges as a key alternative due to its abundance, environmental advantages, and applicability in off-grid systems. Nevertheless, the intermittent nature of solar energy necessitates integrating effective energy storage systems to ensure a consistent energy supply [1]. In this context, hydrogen stands out as a groundbreaking energy carrier. Hybrid solar and hydrogen systems, in particular, present a transformative solution for addressing energy poverty, mitigating climate change, and fostering sustainable development [2]. Integrating solar and hydrogen improves off-grid power stability by managing energy fluctuations and offers a scalable alternative to conventional batteries, addressing capacity and degradation issues. Recent studies have focused on ensuring uninterrupted electricity supply in off-grid applications. Ismail et al. [3] focused on developing a mathematical model to estimate and predict global solar radiation intensity in Egypt where solar energy is abundant year-round. Due to insufficient measurement stations, the model is validated against published solar radiation data. The results demonstrate accurate predictions of solar radiation intensity, improved system efficiency, and increased hydrogen production. The simulation outcomes align well with experimental data, validating the model . Doumbia et al. [4] introduce a dynamic simulation model developed in Matlab/Simulink to analyze the behavior of renewable energy systems with hydrogen storage. The system integrates sub-models for PV arrays, wind turbines, batteries, electrolyzers, fuel cells, and power conditioning units, suitable for both transient and steady-state analysis based on voltage, current, and temperature. The global model facilitates optimal system sizing and effective control design. Validation was performed using a state-of-charge (SoC) control method, and the simulation results aligned well with previous experimental test bench measurements . Raj and Rajasree [5] explored a hybrid energy system combining fuel cells and solar energy for electricity generation, which was modeled and simulated in Matlab/Simulink. Solar panels serve as the primary energy source, but due to their intermittency during nighttime or rainy conditions, fuel cells are utilized as an auxiliary source to ensure system reliability. Simulation results confirm the capability of the system to meet both electrical and heat demands under dynamic conditions . Yılmaz and Gençoğlu [6] focused on a hybrid system integrating solar and hydrogen energy, modeled using Matlab/Simulink. Mathematical models for a 200 W PV panel and a 100 W PEM fuel cell were developed. DC-DC boost converter models were designed for both energy sources connected in parallel to power a resistive load. The hybrid system delivered 500 W, with 3.795 A from the fuel cell and 6.205 A from the PV panel . In this work, the current study aims to meet the electrical needs of a DC load by adding a more powerful panel array, fuel cell, and battery to the system. The energy management algorithm was developed to accomplish this objective by monitoring the electricity generated from solar and hydrogen energy sources.

2. SYSTEM DESCRIPTION AND MODELING

The PV panel, which generates electricity based on changes in solar radiation and temperature, along with the fuel cell,

powers a 48 V DC bus in coordination with the battery. The variable output voltages of the PV panel and the fuel cell were regulated through boost converters, while the battery was integrated using the bidirectional converter. The energy management system (EMS) controlled the switching signals for all converters. The panel and the fuel cell were managed using the P&O algorithm to achieve their maximum power point (MPP). During periods when the power of the panel array exceeds 400 W, the duty cycle in the algorithm was reduced to decrease hydrogen consumption by the fuel cell. The control of the battery converter was implemented using a PI controller. A 1.5 Ω resistor was selected as the DC load. The characteristics of the PV array, PEM fuel cell, and battery used in the system are provided in Table 1. The design parameters for the boost converters of the PV panel and fuel cell, as well as the bidirectional converter for the battery, were calculated based on the parameters of the sources listed in the table. In the simulation, energy management was performed according to solar radiation and temperature for 9 hours between 10:00 and 19:00. Fig. 1 (a) illustrates the schematic representation of the system consisting of the PEM fuel cell, the PV panel array, and the battery. The flow chart of the P&O energy management algorithm is given in Fig. 1 (b). Solar irradiance and temperature curves are given in Fig. 2.

3. RESULTS AND DISCUSSION

This study realized the energy management of a hybrid renewable energy system consisting of a PV panel, a PEM fuel cell and a battery. For this purpose, a model developed in Matlab/Simulink was used to obtain the voltage, current, and power waveforms of the sources connected to a DC load under varying solar radiation and temperature conditions based on the EMS algorithm. The power curves of the PEM fuel cell and the PV array are given in Figs. 3(a) and (b). As seen in these graphs, when the power of the PV panel exceeds 400 W, the duty cycle of the boost converter is reset to zero to reduce the amount of hydrogen consumed. In addition, Fig. 3 (c) shows the hydrogen and air consumption in the fuel cell, and Fig. 3(d) shows the DC bus voltage.

4. CONCLUSIONS

This study examines a hybrid renewable energy system integrating solar energy, hydrogen energy, and a battery to meet the load demand via a DC bus. To maximize power extraction from both hydrogen and solar sources, the switching of the MOSFETs in the converter is controlled using the P&O algorithm. The P&O algorithm implemented in the Matlab/Simulink model is modified to facilitate energy management. Consequently, hydrogen consumption is significantly reduced when sufficient solar energy is available, while the fuel cell and battery continue to supply the load during periods of insufficient solar energy.

ABSTRACT
Excessive use of fossil fuels increases the concentration of carbon dioxide (CO_2) in the atmosphere, leading to major environmental problems such as global warming and climate change. In this context, the conversion of CO_2 into valuable chemicals is of great importance in terms of reducing carbon emissions and promoting a sustainable chemical industry. International agreements such as the Paris Agreement and the European Green Deal mandate the reduction of carbon emissions in order to achieve the goal of creating a carbon-neutral economy [1, 2]. In particular, the industrial sector needs to turn to innovative technologies and adopt low-carbon production processes. In this study, a highly selective catalyst system for the conversion of CO_2 to methanol using borohydride as a reducing agent to facilitate catalyst activation and hydrogenation steps was investigated in detail. Within the scope of this review, the effects of different perovskite catalyst structures, synthesis methods, activation techniques, and reaction conditions on methanol yield and selectivity were examined in detail.

Keywords: Sustainability**,** Borohydrides, CO_2 emission reduction, Methanol synthesis in liquid phase, Perovskite nanocatalysts

1. INTRODUCTION
The Paris Agreement, which was signed in 2015 to reduce the effects of global warming, was approved by the 196 countries party. Based on the limited analysis of the Intergovernmental Panel on Climate Change (IPCC), the scientific community agrees that the 1.5°C scenario will significantly reduce the negative effects on poverty and sustainable development, including food security, compared to the 2°C global warming scenario. For example, at a temperature increase of 1.5°C, the number of people expected to be exposed to extreme heat waves (which occur once every at least 20 years) is about 700 million, which accounts for 9.0% of the global population. In contrast, an increase of 2°C in temperature is expected to cause more than 2 billion people, i.e. 28.2% of the world's population, to be exposed to similar heat waves. The Paris Agreement aims to limit the global temperature increase to 1.5°C by 2050 and reduce greenhouse gas emissions to net zero. In addition, in this direction, the European Green Agreement announced by the European Union (EU) in 2019 reveals its goal of being a carbon-neutral continent by 2050. A carbon limit tax on the EU industry will require the replacement of high-emission production processes with low-carbon and innovative manufacturing technologies. In this context, industrial methanol production is becoming a critical sector [1-3].
These accepted global agreements require a strict reduction in CO_2 emissions and the creation of a closed-loop carbon economy. While CO_2 capture and storage (CCS) continues to be an important emissions reduction strategy, the conversion of CO_2 into valuable chemicals such as methanol is extremely important for a sustainable chemical processing industry. Perovskite nanocatalysts offer a promising approach to sustainable methanol production in CO_2 conversion thanks to their adjustable structural properties and high catalytic activities. Borohydrides, especially sodium borohydride ($NaBH_4$), have been widely studied as effective reducing agents in catalytic processes, due to their ability to donate hydride ions and facilitate the formation of active metal species. While the use of borohydrides has positive effects on reaction kinetics and selectivity, it has the potential to increase energy efficiency and provide more sustainable reaction conditions in the transformation of CO_2 into methanol thanks to its synergistic interactions with perovskite nanocatalysts [4]. In this context, a detailed study of reduction mechanisms and their interactions with perovskite nanocatalysts is of great importance.
In this study, the effectiveness of perovskite-type nanocatalysts in the production of methanol by conversion of CO_2 will be discussed in detail. Catalyst synthesis and characterization process, determination of active regions and borohydride-based reduction mechanism will be examined comprehensively; parameters and optimization strategies affecting catalytic performance will be evaluated. Thus, the potential of perovskite-type catalysts for high-yield methanol production processes with low carbon footprint will be revealed.

2. REACTION MECHANISM
The synthesis of methanol via the conversion of CO_2 represents a crucial process in the valorization of CO_2 into valuable chemicals. This is primarily because methanol serves not only as an alternative fuel but also as a key intermediate in the production of long-chain hydrocarbons and various high-value chemicals. The utilization of CO_2 as a feedstock enables

the conversion of large amounts of greenhouse gases, thereby contributing to environmental sustainability.
The conversion of CO_2 to methanol is a complex process that involves multiple reaction pathways and intermediate species. The reaction mechanism is highly dependent on the nature of the catalyst, reaction conditions, and the solvent environment. The overall reaction for CO_2 conversion can be expressed as follows:

$$CO_2+3H_2 \rightleftharpoons CH_3OH+H_2O \text{ , } \Delta H^o=-50 \text{ kJ mol}^{-1} \quad (1)$$

However, in addition to this overall equation, the process consists of the following intermediate reaction steps:

$$CO_2+H_2 \rightleftharpoons CO+H_2O \text{ , } \Delta H^o=-39 \text{ kJ mol}^{-1} \quad (2)$$

$$CO+2H_2 \rightleftharpoons CH_3OH \text{ , } \Delta H^o=-91 \text{ kJ mol}^{-1} \quad (3)$$

Methanol synthesis is an exothermic reaction and releases heat [5]. Compared to the realization of CO_2 conversion in the gas phase and the realization in the liquid phase, the liquid phase is more advantageous for various reasons such as thermodynamic advantages, reaction efficiency, heat transfer, and CO_2 capture/activation. The low temperature and high-pressure conditions of the liquid phase are more conducive to the formation of methanol due to the exothermic nature of the reaction, and the reaction balance progresses towards the formation of the product. On the contrary, unreacted gas in the gas phase needs to be recovered, which increases energy consumption. In addition, while the liquid phase process provides a more stable environment, the capture and activation of liquid phase CO_2 provides a more efficient conversion process. When all these factors are evaluated, CO_2 conversion in the liquid phase is more advantageous than in the gas phase [6].
Given the complex nature of CO_2 conversion to methanol, the selection of the catalyst and the method of catalyst activation play a decisive role in the reaction's efficiency and selectivity. In recent years, borohydrides—particularly sodium borohydride ($NaBH_4$)—have attracted considerable attention as strong reducing agents in catalytic processes. Rather than serving directly as a hydrogen source, $NaBH_4$ is primarily used to reduce metal precursors during catalyst preparation or activation, leading to the formation of highly dispersed and active metal nanoparticles. This enhanced dispersion significantly improves catalytic activity and selectivity in the conversion of CO_2 to methanol. Additionally, borohydride-induced reduction can alter the electronic and surface properties of catalysts, thereby influencing reaction intermediates and kinetics [4].

When the reaction temperature exceeds 240 °C in CO_2 conversion, the formation of various hydrocarbons by-products with carbon monoxide (CO) is also observed. It is of great importance to develop appropriate catalysts to ensure that the reaction progresses with high selectivity by minimizing the formation of by-products. In addition, the CO_2 molecule is kinetically inert due to its high stability, which requires the use of an effective catalyst for the reaction to progress. In recent years, it has been reported that perovskite-type nanocatalysts exhibit high activity and selectivity in the CO_2 conversion reaction. These catalysts stand out as promising materials for sustainable methanol production thanks to their adjustable structural properties and high thermal stability [7]. In our study, their catalytic performance in synthesis, characterization, and CO_2 conversion of perovskite-type catalysts will be examined in detail.

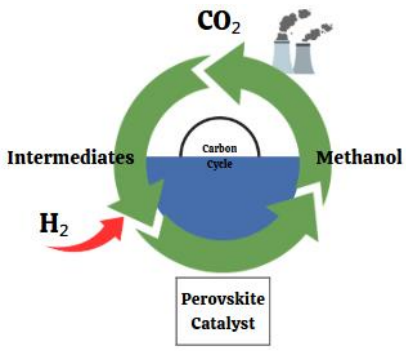

Fig. 1. Schematic representation of the reaction mechanism

3. PEROVSKİTE NANOCATALYST

The term perovskite is a general name used for oxides with ABO_3 and/or A_2BO_4 structure. In the unit cell of the ideal cubic perovskite crystal (Fig. 2.), the larger A cation is located at the corner points of the structure, while the smaller B cation is located in the center of the octahedron. O represents the anion that binds both cations together [8].

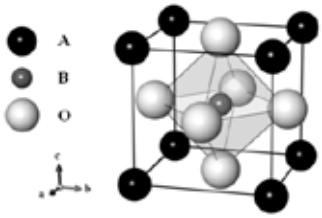

Fig. 2. Ideal crystal structure of perovskite oxides with ABO_3 composition [8]

Synthesis methods used in the synthesis of perovskite nanocatalysts directly affect the properties of the obtained materials, such as morphology, particle size, surface area, and active site distribution. Therefore, the selection of the appropriate method for the synthesis of catalysts with desired properties is critical.

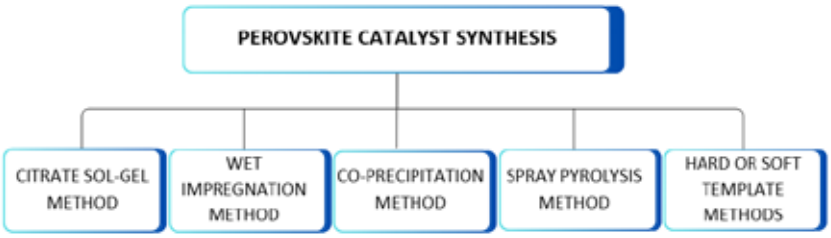

Fig. 3. Perovskite catalyst synthesis methods

In the citrate sol-gel method, which is one of the synthesis methods, after the formation of metal-citrate complexes, polymerization is carried out with a polymerization agent such as ethyl alcohol. The resulting gel structure is converted into a perovskite structure by drying and calcination processes. This method is less preferred than other methods due to its long process time and negative environmental effects. In the wet impregnation method, metal salts are impregnated into the perovskite precursor and the perovskite structure is obtained by applying calcination and reduction process. In this method, which is widely used due to its low cost, difficulties are encountered in ensuring homogeneous distribution of metal particles and preventing agglomeration. In the co-precipitation method, which is another synthesis method, cation salts A and B are dissolved in a suitable solvent and a precipitating agent (e.g. hydroxide) is added to precipitate to form perovskite. The resulting precipitate is then subjected to washing, drying, and calcination to obtain the final perovskite catalyst structure. By carefully adjusting the precipitation conditions, a homogeneous catalyst with the desired particle size can be obtained. In the spray pyrolysis method, which is also one of the synthesis methods, a homogeneous solution is prepared by dissolving the salts of metal cations in a suitable solvent, and this solution is sprayed onto a hot surface. The sprayed droplets evaporate rapidly, and the metal salts thermally decompose to form metal oxides. These oxides combine at high temperatures to form the perovskite crystal structure. High temperature and equipment costs are disadvantages of this synthesis method. In hard and soft template methods, porous materials or organic molecules are used as templates. Perovskite precursors are filled into the pores of the templates and then the perovskite structure is shaped by removing the templates. This method provides precise control of pore size and distribution but requires additional synthesis and removal steps [7,9,10].

Various analysis methods should be applied to analyze the structural and chemical properties of the synthesized perovskite catalysts to understand and optimize the basic mechanisms of their catalytic performance. In line with this purpose, various characterization techniques such as transmission electron microscopy (TEM) are applied to analyze the shape, size, and distribution of the nanoparticles of the catalyst, X-ray diffraction (XRD) to determine the crystal structure and phase composition, nitrogen adsorption (BET) to evaluate the surface area and pore structure, X-ray photoelectron spectroscopy (XPS) to determine surface chemical states and concentrations, temperature programmed reduction (TPR) to evaluate the reduction properties of metal oxides and metal-support interactions [9, 10].

The catalytic performance of perovskite nanocatalysts in the CO_2 conversion reaction is affected by various factors and these can be divided into internal and external factors. Internal factors include the composition, structure, surface area, porosity, metal distribution, and surface basicity of the catalyst. The type and distribution of metal ions in regions A and B of the perovskite structure determines the electronic structure of the catalyst and therefore the catalytic activity. The high surface area and porous structure facilitate reactant access and increase the number of active zones, which facilitates reactant diffusion and increases catalytic performance [9, 10]. LaCuZnX and La-M-Cu-Zn-O perovskite-like catalysts are produced by citrate sol-gel and co-precipitation methods and are used for methanol synthesis by CO_2 conversion in the liquid phase [7,11]. In this context, nano-sized metal particles offer high surface area and active zone density. Well-dispersed and nano-sized metal particles also provide high catalytic activity. Surface basicity and strength

also affect CO_2 adsorption and activation. Within the scope of external factors, there are factors such as the reactor type used and the temperature, pressure, flow rate, and H_2/CO_2 feed ratio of the reaction [7,9]. The optimum reaction conditions determined in these contexts maximize the activity and selectivity of the catalyst. In this study, multi-criteria decision analysis (MCDA) was used to select the appropriate perovskite-type catalyst for methanol production via CO_2 conversion [12].

4. CONCLUSIONS

It has been concluded that the use of $NaBH_4$ as a reducing agent facilitates the formation of active metal phases during catalyst preparation and enhances methanol selectivity by promoting metal dispersion and preventing agglomeration due to the reduction of methanol production reaction of CO_2 in the liquid phase due to thermodynamic advantages, reaction efficiency, and energy saving; preventing the growth of Cu particles in the liquid phase by reducing method using $NaBH_4$ and achieving high Cu distribution; It has been concluded that the use of perovskite-type catalysts as a catalyst for the reasons of high activity and selectivity is appropriate due to its more sustainable advantage.

Abstract
Anion exchange membrane water electrolyzers (AEMWE) are an emerging and focused technology in the production of hydrogen from water by electrolysis. One of the most important advantages of AEMWE technology is the use of low-cost transition metal catalysts instead of noble metal catalysts and cheaper membranes. However, AEMWEs have some limitations such as low ionic conductivity and stability of the membrane due to the harsh alkaline environment. This study aims to develop polybenzimidazole (PBI)-based zeolitic imidazolate framework (ZIF8) and modified ZIF8 AEMs with high ionic conductivity and durability for green hydrogen production. Structural and electrochemical properties of membranes were investigated by FTIR, XRD, mechanical testing and EIS method. Synergistic effects between polymer and MOF structures combined the advantages of the materials and enabled the development of anion exchange composite membranes with high hydrogen production potential.

Keywords: Anion exchange membrane water electrolysis, composite anion exchange membrane, Metal-organic frameworks, hydrogen production

1. INTRODUCTION

Global warming, climate change and environmental pollution are the most critical issues of the 21st century that are primarily driven by greenhouse gas emissions from fossil fuels [1,2]. Therefore, renewable energy sources are gaining importance in achieving net zero emission targets. Among renewable sources, hydrogen energy stands out with high energy density and zero emissions. Hydrogen energy also can be considered a sustainable source that can replace fossil fuels. There are various methods to produce hydrogen, such as hydrocarbon reforming, pyrolysis, biomass processes, and water electrolysis. Among these methods, water electrolysis has the major advantages of high efficiency, zero emissions and high purity production. Additionally, using the electricity generated from renewable energy sources during electrolysis positively affects sustainability.

Four main water electrolysis systems are used to produce hydrogen: alkaline water electrolysis (AWE), proton exchange membrane water electrolysis (PEMWE), solid oxide water electrolysis (SOWE) and anion exchange membrane water electrolysis (AEMWE) (Park et al., 2019). Among them, AWEs work with liquid alkaline electrolytes and are low-cost (David et al., 2019). PEMWEs can produce high-purity hydrogen with high efficiency. However, PEMWEs need high-cost noble metal catalysts for operation and the acidic electrolyte causes corrosion of catalyst layers and other components (Feng et al., 2021). SOWEs allow the use of high-temperature electrolyzers with high efficiency and good stability but have limitations in large-scale applications, such as bulky system design, and safety issues with electrodes and sealing (Sebbahi et al., 2022).

Over the past decade, AEMWEs have been developed as alternative water electrolysis systems. AEM water electrolysis holds important advantages of water electrolysis technology such as low-cost catalysts, low operating temperature and the presence of a solid membrane. The solid membrane in AEMWE inhibits the gas migration and allows high purity in products. However, the high pH of alkaline media leads to a reduction in electrochemical performance and stability. To overcome these challenges, research and development of new membranes are ongoing. Polymers with benzimidazole groups as repeating units in their backbone are referred to as PBIs. PBIs have a tight chain structure based on strong hydrogen bonds and π-π interactions between polymer chains. With these bonds and interactions, PBIs offer superior thermo-mechanical properties. Their favorable properties render them suitable for AEM applications in AEMWE systems [3]. In pristine form, PBI shows low ionic conductivity for electrolysis applications and low mechanical stability in highly alkaline media. Composite membranes are being produced to overcome these limiting factors. MOF structures are interesting as polymer fillers due to their large surface area, porosity, high conductivity and easy processability. Furthermore, with chemical modifications, the properties of MOFs can be improved. In this study, the PBI/ZIF8 and PBI/mZIF8 composite membranes were prepared and their characteristics were investigated for AEMWE applications.

2. EXPERIMENTAL PROCEDURE

a. ZIF-8 Preparation: In the synthesis of ZIF8, firstly, the solution of $Zn(NO_3)_2.6H_2O$ and methanol was added to the

solution of 2-methyl imidazole and methanol and stirred at room temperature for 1 hour. The white crystals formed were separated by centrifugation with methanol and dried.

b. **Modified ZIF-8 (mZIF-8) Preparation**: In the synthesis of mZIF8, ZIF8 crystals and NBu_4OH (tetrabutylammonium hydroxide) solution were prepared and stirred at 70 °C for 24 hours. At the end of the reaction, mZIF8 was separated from the solution and dried.
c. **Composite Membrane Preparation:** PBI-based composite membranes were prepared by solution casting method with PBI polymer and different weight ratios of MOF (0, 2.5, 5.0 and 7.5 wt. %) contents.

3. ANALYSIS

The structural characterization of the polymer, ZIF8 and mZIF8 and composite membranes was performed by, Fourier transform infrared spectroscopy (FTIR), X-ray Diffraction (XRD) methods and mechanical test. The electrochemical characterization was conducted by Electrochemical Impedance Spectroscopy (EIS).

4. RESULTS AND DISCUSSIONS

Fig. 1a shows FTIR spectra of synthesized ZIF-8 and mZIF-8 particles. Both MOF structures have four characteristic peaks at 2926, 1600, 1145, and 995 cm^{-1}, assigned to vibrations of C−H, C=N, and C−N in the imidazole ring, respectively [4]. Fig. 1b shows the FTIR spectra of the PBI polymer. The polymer exhibited characteristic adsorption bands at approximately 795 and 850 cm^{-1} due to the ring vibration of C-H groups, C=C/C/N stretching between 1500-1650 cm^{-1}. Additionally, the polymer exhibited characteristic bands at 2000 and 3050 cm^{-1} due to the C-H and C-H vibrations respectively [5,6].

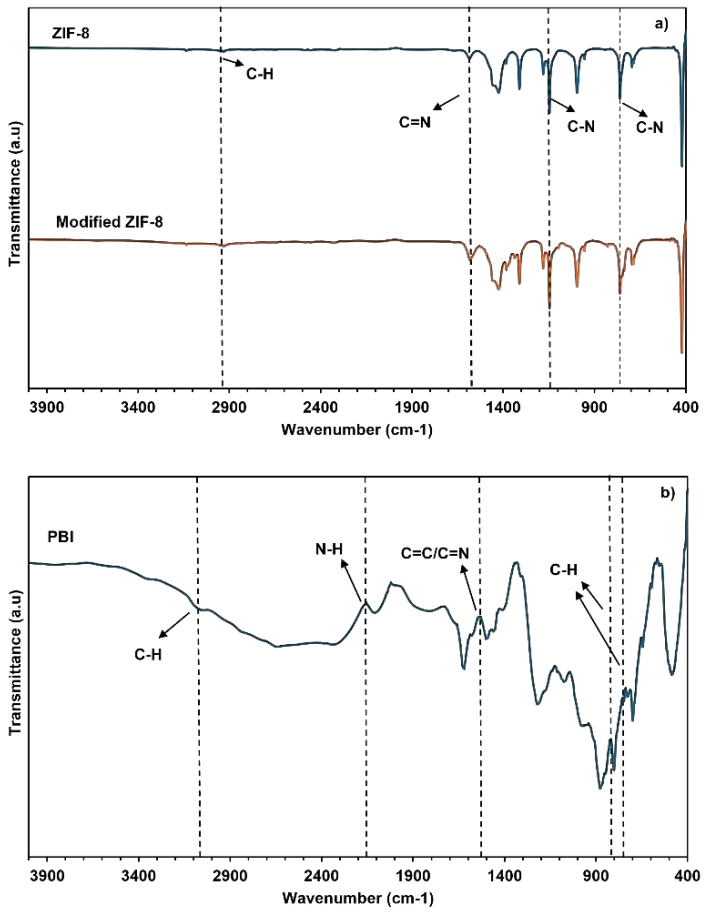

Fig 1. FTIR of a) ZIF8 and mZIF8 particles, b) PBI polymer

The XRD analysis was performed to determine the crystal structure of ZIF8 and mZIF8 (Fig 2.a). The strong peaks of ZIF8 show good agreement with the literature. The peaks at 2θ= 7.3°, 10.35°, 12.70°, 14.80°, 16.40° and 18.00° correspond to the planes (110), (200), (211), (220), (310), and (222) respectively [7]. The diffraction patterns of the modified ZIF-8 structure do not show a significant difference from the unmodified sample. This proves that the MOF

structure does not decompose in a highly alkaline environment (pH > 14) and shows high chemical stability. The decrease in the intensities of the peaks indicates that the atomic arrangement of ZIF8 was modified by tetrabutylammonium hydroxide, but the crystal structure was preserved during the process [8]. Fig 2.b shows X-ray diffraction patterns of PBI, PBI/ZIF8 and PBI/mZIF8 composite membranes. The amorphous PBI membrane exhibits a broad peak at 2θ=23.4°. In PBI/ZIF8/2.5 and PBI/mZIF8/2.5 composite membranes exhibit 2θ= 7.4°, 12.8° and 22.1° which confirm the presence of ZIF8 particles in the polymer matrix.

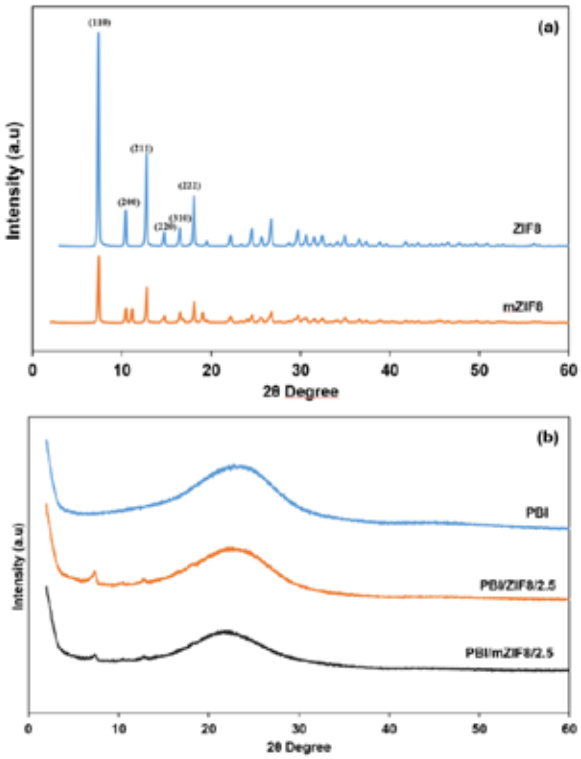

Fig 2. XRD patterns of a) ZIF-8 and mZIF-8 particles, b) PBI and composite membranes

Ionic conductivity is an important parameter for high hydrogen production in AEMs. Figure 3 shows the OH- conductivities of 1 M KOH doped PBI, PBI/mZIF8/2.5 and PBI/mZIF8/2.5 composite membranes for different temperatures. The ionic conductivity of pure PBI membrane was determined as 55.02 mS/cm. Upon the addition of ZIF8 and mZIF8 to the membrane, the ionic conductivity increased to 146.4 and 474.1 mS/cm for PBI/mZIF8/2.5 and PBI/mZIF8/2.5 membranes, respectively.

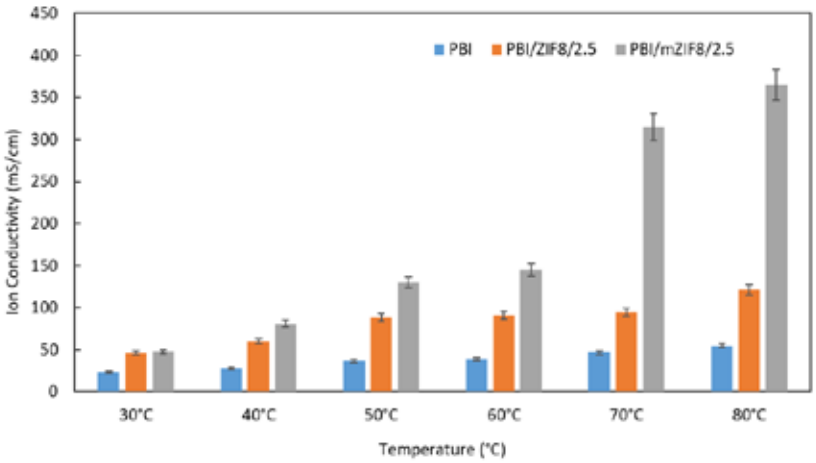

Fig. 3. Ionic conductivities of 1M KOH doped pristine PBI and composite membranes.

Mechanical properties of AEMs play important roles in AEMWE applications. AEMs need to be durable and stable in harsh alkaline conditions. Doping with alkaline solutions decreases the mechanical strength of PBI membranes due to

partial disintegration of hydrogen bonding networks [9]. Therefore, it is important to investigate the effect of alkaline aging on the mechanical properties of membranes. The aging of membranes was performed in 2 M KOH at 80 °C for 200 hours. Fig. 4a. and Fig. 4b. present the tensile strength and elongation of membranes before and after aging treatment. Before the aging test, the tensile strengths of PBI, PBI/ZIF8/2.5 and PBI/mZIF8/2.5 membranes were reported as 69.7, 87.4, 83.03, 65.6 and 61.1 MPa respectively. After the aging test, while PBI membrane preserved its 43.4% tensile strength, PBI/ ZIF8/2.5, and PBI/mZIF8/2.5 membranes preserved their tensile strength of 35.5%, and 52.2% respectively. Additionally, elongation of membranes increased with aging treatment due to the plasticizing effect [10]. The results showed that the membranes containing mZIF8, have improved mechanical stability and durability because metal-containing units of modified ZIF8 formed strong bonds between the PBI matrix and ZIF8 nanoparticles [11].

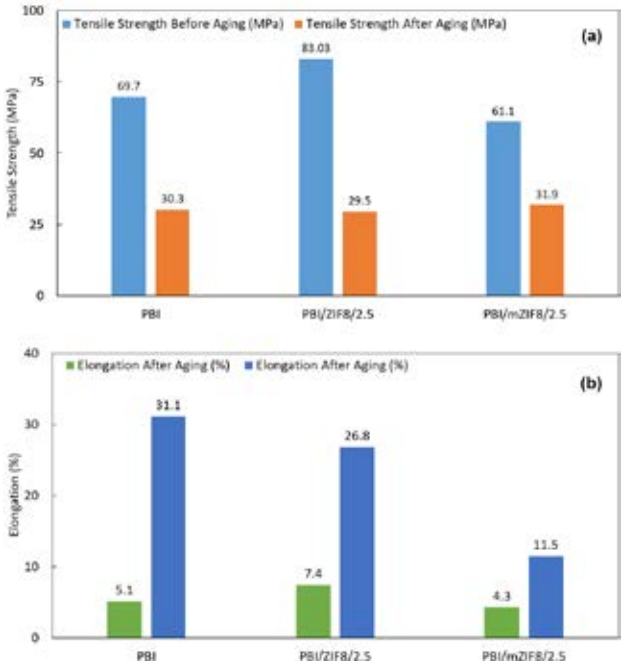

Fig. 4. Mechanical properties of pristine PBI and composite membranes before and after aging test.

5. CONCLUSIONS

In this study, PBI/ZIF8 and PBI/mZIF8 composite membranes were successfully prepared and physically and electrochemically characterized for AEMWE application. The obtained characterization results showed that the PBI-based composite membranes were suitable for the AEMWE system for hydrogen production.

ABSTRACT

Natural disasters often lead to significant disruptions in communication infrastructure, hindering search and rescue operations. In such situations, rapidly deployable and autonomous communication solutions are critical for effective intervention. Unmanned Aerial Vehicles (UAVs) have emerged as a promising technology for establishing temporary communication networks in disaster-stricken areas. Unlike fixed-wing UAVs, rotary-wing UAVs, with their hovering capability and Vertical Takeoff and Landing (VTOL) features, are well-suited to establish stable communication nodes in disaster zones. However, rotary-wing UAVs powered by conventional batteries face challenges in maintaining uninterrupted communication due to limited flight time. This study explores the integration of Proton Exchange Membrane Fuel Cell (PEMFC) technology with rotary-wing UAVs to enhance flight duration and operational efficiency. PEMFC hybrid energy systems significantly extend the flight times of UAVs, ensuring continuous connectivity between first responders, affected populations, and command centers. The proposed system is evaluated through simulation-based performance analysis, considering factors such as energy efficiency, coverage, and communication reliability. The results demonstrate that PEMFC-supported UAVs outperform traditional battery-powered UAVs in terms of flight duration and network reliability. These findings highlight the revolutionary potential of fuel cell-integrated UAV networks for post-disaster communication and search-and-rescue operations.

Keywords: UAV, communication, disaster management, fuel cell, hybrid system

1. INTRODUCTION

Natural disasters are unforeseen and destructive events that pose significant threats to human life, critical infrastructure, and economic stability [1]. Disasters such as earthquakes, hurricanes, floods, and wildfires can severely damage existing telecommunications infrastructure, thereby significantly disrupting search and rescue operations as well as emergency response efforts. In scenarios where traditional communication networks are either damaged or completely disabled, the demand for mobile and rapidly deployable alternative communication systems has been increasing [2]. In this context, UAVs have gained increasing prominence in disaster management and emergency communication in recent years. UAVs, particularly those with extensive coverage capabilities and extended flight endurance, play a crucial role in establishing temporary communication infrastructures, thereby enhancing coordination among field teams and significantly improving the efficiency of rescue operations [3]. However, conventional battery-based energy systems remain a major limiting factor for the prolonged operation of UAVs. Therefore, enhancing UAV operational efficiency through innovative energy solutions has become a critical research area. A lot of studies in the literature have explored the potential of UAVs in maintaining communication networks in disaster scenarios.

Kobayashi et al. developed a "Flying Communication Server" to ensure communication during large-scale disasters. This system enables users to share videos and engage in text-based conversations using their smart devices. Even in the event of a communication infrastructure collapse, this system facilitates information exchange, making it a critical communication tool during disasters [4]. Moreover, research on the ability of UAVs to establish communication networks in emergency situations has demonstrated that multiple UAVs can collaborate to form a communication network. Shibata et al. showed that a large number of UAVs, equipped with wireless communication units, could create an aerial wireless mesh network. This system is specifically designed to facilitate information transmission in isolated areas, playing a crucial role in mitigating communication disruptions during natural disasters [2]. Such a structure is essential in addressing communication breakdowns in disaster scenarios. Another study examined how UAV flight paths can be optimized to improve communication with individuals on the ground. The research highlighted that UAV movement strategies are a significant parameter in enhancing the efficiency of communication networks [5]. This underscores the necessity of optimizing UAV movement for effective communication during natural disasters. The communication capacity of UAVs is particularly vital in emergency situations. Mylin investigated the reliability of small-scale UAV communication links, emphasizing the impact of link quality on UAV operational reliability and mission success [6]. Additionally, Tuna et al. explored how UAVs could establish a communication network in cases where the communication infrastructure collapses during natural disasters. Their study addressed the potential applications of UAVs in emergency communication and the challenges encountered in such scenarios [7]. The communication capabilities of UAVs are not only critical in emergencies but also play a significant role in post-disaster recovery efforts. Abdu Saif et al. assessed the advantages of using UAVs as wireless service providers during post-disaster phases. Their research shows that it can provide rapid information flow [8]. Chen et al. proposed a framework outlining how UAVs could be structured within

emergency communication systems. Their study emphasized the necessity of optimizing UAV energy management strategies to ensure continuous data transmission [9].

Effective communication among UAVs is crucial for the success of search and rescue operations following natural disasters. Since such disasters often destroy existing communication infrastructure, alternative solutions are necessary. UAV-based systems encompass a variety of platforms with different operational advantages [10]. Fixed-wing UAVs are suitable for communication relays due to their wide coverage area and long flight duration. In contrast, rotary-wing UAVs provide local communication support with their Vertical Take-Off and Landing (VTOL) capabilities and ability to hover [1]. While fixed-wing UAVs may be insufficient for creating a stable communication area, rotary-wing UAVs can establish a continuous communication network in challenging terrains. However, the short flight time of rotary-wing UAVs remains the biggest limitation [11].

This study analyzes the effectiveness of PEMFC-supported rotary-wing UAVs in disaster communication systems. Suitable communication protocols for multi-UAV systems operating in disaster areas were examined, and Mobile Ad-Hoc Networks (MANET) was determined to be the most effective and appropriate communication system. Additionally, the impact of fuel cell integration on energy efficiency was evaluated. System performance was tested through simulations conducted under various scenarios. As a result, the collapse of communication infrastructure during natural disasters negatively impacts rescue efforts. PEMFC-enhanced rotary-wing UAVs offer a significant solution to this issue with their long flight times and potential for continuous communication. The use of this proposed system as an effective communication tool in disasters will significantly enhance the success of operations.

2. MATERIALS AND METHODS

The use of UAVs for post-disaster situation assessment and rescue operations is becoming increasingly widespread. In particular, the ability of UAVs to collect and transmit information in emergency situations enhances the effectiveness of rescue teams. The capability of UAVs to autonomously fly, scan specific areas, and perform designated tasks during disaster scenarios accelerates post-disaster data collection processes, enabling rescue teams to respond more rapidly [12]. The advantages of rotary-wing UAVs, such as their ability to hover, flexible maneuverability, wide communication coverage, and extended flight duration with PEMFC technology, make them ideal for use as communication servers in natural disaster scenarios. This system can significantly enhance the success of search and rescue operations by providing uninterrupted communication and facilitating the prompt delivery of aid to victims. Figure 1 illustrates how rotary-wing UAVs can establish communication in a potential natural disaster scenario.

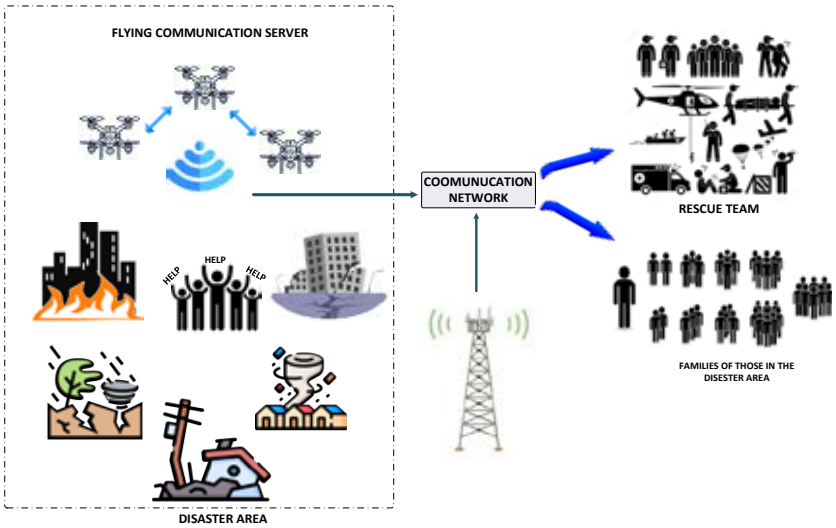

Fig 1. Uninterrupted Communication with Flying Communication Servers in Disaster Scenarios

The visual shows rotary-wing UAVs providing continuous communication between rescue teams and the families of disaster victims in affected areas. Rotary-wing UAVs, utilizing MANET technology, establish a dynamic and flexible communication network without the need for a central infrastructure. This is of critical importance, especially in situations where infrastructure has collapsed or access is restricted. Through MANET, rotary-wing UAVs enable rapid and reliable data transfer, supporting disaster management and emergency response processes.

2.1. Importance of PEMFC/Hybrid UAV Design

In natural disaster situations, communication infrastructure is often severely damaged, making continuous communication critical for the effectiveness of rescue operations [9]. In this context, the use of hybrid UAVs powered by PEMFC plays a significant role in the reconstruction of communication infrastructure post-disaster. The energy efficiency and extended flight durations provided by hybrid systems are crucial for rebuilding communication infrastructure after a disaster. As a critical component of the proposed system, rotary-wing UAVs enhanced with PEMFC technology can stay airborne for longer durations compared to traditional battery-powered systems, thereby ensuring continuous communication. This enables the seamless flow of information between rescue teams, victims' families, and other relevant organizations, strengthening post-disaster coordination. By restoring collapsed communication infrastructure through flying communication servers in the form of rotary-wing UAVs, victims in disaster areas can transmit their help requests, and rescue teams can manage operations more effectively.

2.2. UAV-Supported Mesh Network Technologies for Uninterrupted Communication

The communication techniques used in UAVs vary depending on the mission type and operational requirements. The primary methods include Radio Frequency (RF), Satellite Communication (SatCom), 4G/5G, Line-of-Sight (LOS), Beyond-Line-of-Sight (BLOS), Mesh Networks, and Optical Communication. In disaster-stricken areas where infrastructure is damaged, UAVs can maintain communication through different techniques. Mesh networks establish direct links between UAVs, ensuring uninterrupted communication. Additionally, UAVs can act as aerial base stations to restore mobile network connectivity. UAVs primarily utilize two communication methods: UAV-to-UAV communication enables direct or indirect data transfer between UAVs. In BLOS scenarios, other UAVs serve as relays for data transmission [13]. UAV-to-Ground Station communication involves UAVs establishing connections with ground stations or mobile control points. Mesh networks are classified into three main types: MANET feature dynamic and self-organizing structures. Flying Ad-Hoc Networks (FANET) are specifically designed for UAVs, accommodating high speeds and variable distances. LoRa-Mesh offers long-range communication with low power consumption. MANET-based UAV networks provide flexible and autonomous communication, particularly in infrastructure-less environments. In these systems, where UAVs function as nodes, their mobility and dynamic nature make them critical components in large-scale operations [14]. Consequently, UAVs operating as MANET nodes present significant potential for dynamic, flexible, and infrastructure-independent communication, especially in remote or rapidly changing scenarios.

3. RESULTS AND DISCUSSION

In this study, a MANET-based communication model has been developed to ensure continuous communication among multiple rotary-wing UAVs in natural disaster scenarios. Within the scope of the simulation, the long-term operational capabilities of PEMFC-powered rotary-wing UAVs were examined, and the continuity of network connectivity was analyzed.

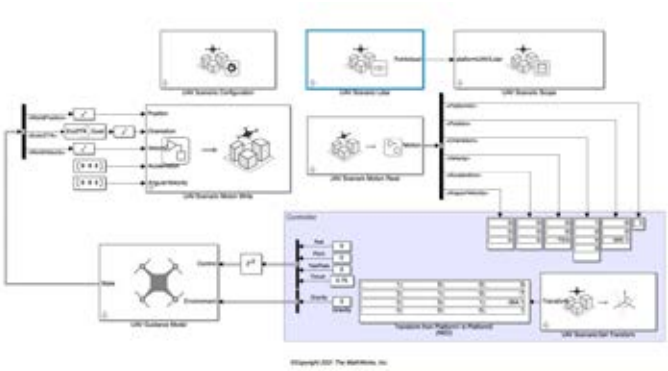

Fig 1. UAV Scenerio model

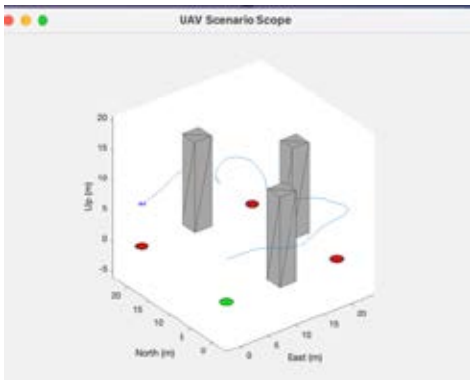

Fig 2. UAV Scenerio Scope

Figure 1 illustrates the rotary-wing UAV control model created in the Simulink environment. The model defines the rotary-wing UAVs' motion dynamics, routing algorithms, and communication protocols. Specifically, a dynamic network topology has been designed to adapt to varying environmental conditions. Figure 2 demonstrates that the rotary-wing UAVs maintain uninterrupted communication between designated points while maneuvering through obstacles in three-dimensional space. The simulation results reveal that the continuity of the connection between nodes is ensured through the MANET protocol.

Table 1 shows the advantages provided by PEMFC-powered rotary-wing UAVs in terms of flight time and energy efficiency. Compared to rotary-wing UAVs powered by traditional battery systems, PEMFC-supported systems achieve longer flight durations. For example, the hybrid quadcopter designed in the previous study, equipped with a 1000 W PEMFC and a 119 Wh Li-Po battery, achieved a flight time of 165 minutes. This enables continuous communication in a

potential disaster scenario and allows for more effective operation in areas without infrastructure. Additionally, the low hydrogen consumption enhances energy efficiency, strengthening operational sustainability.

Table 1. Performance Comparison of PEMFC-Enabled rotary-wing UAVs

Number of Rotating Propellers	PEMFC Rated Power (W)	BatteryType	Battery Power (Wh)	Total Weight (kg)	Flight Endurance (minute)	Hydrogen Consumption (g/m)	Reference
6	1500	Li-po Battery	100	11.5	90	0.644	[15]
4	30	Li-po Battery	77	3.152	11	0.0067	[16]
4	1900	Li-po Battery	55	5.16	121.2	2.37	[17]
4	1000	Li-po Battery	119	6.536	165	0.418	Designed hybrid UAV

4. CONCLUSIONS

Natural disasters cause significant damage to existing communication infrastructure, greatly disrupting search and rescue operations. To address this issue, UAV-based aerial communication networks have emerged as a critical solution for ensuring continuous connectivity in disaster areas. However, the limited flight time of UAVs powered by traditional batteries remains a significant constraint. This study aims to provide uninterrupted communication by utilizing PEMFC-supported rotary-wing UAVs, offering longer flight times and enhanced energy efficiency for disaster communication networks. Additionally, UAV-supported mesh networks, particularly those based on MANET architectures, offer a robust and flexible solution for maintaining connectivity in infrastructureless environments. The proposed PEMFC-supported rotary-wing UAV system presents a promising approach to reducing communication disruptions in disaster scenarios, aiming to enhance the effectiveness of emergency response and recovery efforts.

ABSTRACT
CO2 emissions comes from the energy and transport sectors released into the atmosphere are mostly city-based that causes environmental problems. Decarbonization is one of the main issues to be addressed in preventing environmental problems. In this context, it is necessary to determine the net zero energy city strategies. This study presents the the role of hydrogen energy in net zero city strategies.

Keywords: Net zero cities, Hydrogen, Sustainable urban planning

1. INTRODUCTION

In recent years, cities around the world have been rapidly modernizing and urbanizing, and are also facing several environmental problems. Many issues that affects urban environmental areas such as;

- increase in population,
- increase in energy demand,
- increase in transportation problems.

Urban energy demand increases with rapid population growth, urbanization and industrialization which is responsible for a significant portion of urban energy utilization and greenhouse gas emissions, and is mostly met by non-renewable energy sources. Non-renewable energy sources are still used as primary energy sources in many areas, from industrial activities to transportation, from electricity generation to heating and cooling applications. Also, inefficient use of energy is among the effects of environmental problems. Inefficient use of fossil fuels causes an increase in GHG emissions releases to the environment due to more fossil fuel consumption.

Nowadays, it has become more important than ever to combat various environmental issues such as global warming and climate change. It is stated that total energy-related greenhouse gas emissions released into the atmosphere reached 41.5 billion tons of equivalent carbon dioxide in 2022 [1,2]. In this context, the transition from non-renewable energy economies to renewable energy economies with high sustainability and decarbonization potential comes to the fore. In this regard, the use of renewable energy has become one of the key factors in meeting urban energy demand towards achieving sustainable urban areas. Meeting the ever-increasing energy demand of cities from renewable energy sources is a critical issue for the green and sustainable transformation of cities. Meanwhile, the transition from fossil-based economy to renewable energy economy for achieving carbon-free cities, it is necessary to increase energy efficiency and change energy production and consumption.

The net zero energy city concept has recently been promoted globally [3,4]. The concept of a net zero energy city is that city generates as much as energy as it demands from renewable energy sources [4-6]. Many researchers have published several reports and articles related to net zero energy systems such as at residential buildings, at commercial buildings, for electric mobility, on a community level, on a district level, and on a city-scale level [4,6-15]. The objective of the study is to presents the importance of hydrogen energy in net zero energy city strategies considering the transportation, waste management and energy systems associated with sustainable urban energy planning.

2. NET ZERO CITIES KEY STRATEGIES

Net zero cities key strategies are given below[16,17];
- Sustainable Urban Planning
  - mixed use zoning
  - density control
  - green infrastucture
  - green areas/corridors/roofs/walls

- Energy Systems
  - Transition to renewable energy sources (hydrogen based solar and wind)
  - Decreasing to use fossil fuels and greenhouse gas emissions

- Energy-efficient building and design

- Transportation
  - Promotion of public transportation
  - Creating accessible urban areas
  - Development of cycling and pedestrian zones
  - Renewable transportation

- Waste Management
  - Reduction of using plastics
  - Development of recycling infrastucture
  - Exploration of waste to energy Technologies

2.1. Sustainable Urban Planning

- Hydrogen Infrastructure Integration:
  - Planning hydrogen refueling stations for vehicles.
  - Planning regional energy systems that use hydrogen for heating and cooling in buildings.
  - Creating hydrogen production centers near renewable energy sources and transportation hubs.
- Mixed-Use Development: Designing to encourage low-carbon transportation, such as hydrogen-powered public transportation between residential and commercial areas
- Energy Efficient Buildings: Encouraging new buildings to integrate hydrogen-ready systems for future use.

2.2. Transportation

- Hydrogen-Powered Vehicles: Transition to hydrogen fuel cell vehicles (FCVs) for public transport.
- Use of hydrogen-powered buses, trains, and ferries in public transportation systems.
- Hydrogen Refueling Infrastructure: Establishment of a comprehensive citywide network of hydrogen refueling stations for hydrogen-powered vehicles.

2.3. Energy Systems

- Green Hydrogen Production: Production of green hydrogen using renewable energy sources (solar, wind, hydroelectric) through electrolysis
- Hydrogen for Power Generation: Hydrogen can be stored and used as fuel for power plants or backup generators
- District Heating Systems: Integrating hydrogen into district heating systems to provide low-emission heat to residential and commercial buildings, replacing natural gas or coal.
- Smart Grids and Energy Storage: Use hydrogen as part of an energy storage solution to balance supply and demand in a smart grid.

2.4. Waste Management

- Waste-to-Hydrogen Technologies: Convert organic waste (for example, food waste, agricultural by products, or municipal solid waste) into hydrogen through processes such as gasification, electrolysis, pyrolysis, or biogas conversion.
- Carbon Capture and Utilization (CCU): Combine waste-to-hydrogen processes with carbon capture to ensure that all carbon emissions generated during hydrogen production are captured and stored, further reducing the city's overall carbon footprint.
- Hydrogen in Recycling and Industrial Waste: Hydrogen can also be used in some industrial processes that recycle materials or convert waste into usable products.

4. CONCLUSIONS

Hydrogen can play a critical role in decarbonizing various sectors, including urban planning, transportion, energy systems and waste management.

ABSTRACT
DC-DC converters are critical power conversion systems that regulate voltage and current levels for battery packs in electric vehicles (EVs) powered by fuel cells (FCs). The longevity of fuel cells is heavily influenced by the current drawn by the DC-DC converter. Additionally, the converter topology must be cost-effective, minimize voltage and current stresses on semiconductor devices, offer ease of control, and provide flexible voltage outputs to meet the dynamic demands of the battery pack. This study introduces a single-switch DC-DC power converter designed specifically for fuel cell-based electric vehicles (FCEVs), controlled by an innovative adaptive neuro fuzzy controller (ANFC). The proposed controller ensures no overshot and no oscillations on output, extremely small settling time and steady-state error. Simulation and experimental results for proposed power converter are presented, validating the theoretical findings.

Keywords: Hydrogen Energy, Electric Vehicle, DC-DC Converter, Artificial Intelligent, Adaptive neuro fuzzy controller

1. INTRODUCTION

Fuel cell electric vehicles (FCEVs) have garnered increasing attention in the automotive sector due to their low carbon emissions, reduced air pollution, and the mitigation of risks associated with fossil fuel leakage. However, integrating fuel cells (FCs) directly with a vehicle's battery pack necessitates several modifications. The ability to provide a controllable high charging voltage for the battery pack, maintain low alternating current, and extend the operating life by minimizing the current fluctuations drawn from the fuel cells (FCs) are the basic requirements of the DC/DC converter used in FCEVs. Many electric vehicle (EV) manufacturers still use traditional converter topologies, and these systems often fail to fully meet the above requirements. In addition, the efficiency of the converter is of critical importance on the battery's state of charge and the vehicle's driving range. In addition, cost effectiveness, extending the life of the components by reducing the voltage and current stress on the semiconductor circuit components, and implementing a simpler control mechanism are also very important. In recent years, studies have been conducted on Adaptive Neuro-Fuzzy Inference System (ANFIS) applications for energy management and efficiency optimization in electric vehicles. When these studies are examined, it is seen that they mostly focus on improving DC/DC converters and increasing the overall EV performance. For example, in the study of Thangavel and Kumar, a fuzzy-based interleaved boost converter was designed to meet the energy storage needs of high-capacity batteries for electric vehicle applications and to optimize torque and speed control [1]. In addition, studies have been conducted on ANFIS algorithms in the context of PEM fuel cells. In this context, Khanafari et al. developed an adaptive neuro-fuzzy controller to provide water management in a three-cell PEM fuel cell [2]. Singh et al. investigated the effect of optimized DC/DC converters to maximize power draw through maximum power point tracking (MPPT) in photovoltaic-assisted BLDC motor-based water pumping systems. In their study, they evaluated different DC/DC converter topologies and revealed how these structures contribute to increasing efficiency [3]. In addition, Ibrahim et al. proposed a fuzzy-Ant Colony Optimization (ACO) based control system to provide voltage regulation in EV energy storage systems and used a Cuk converter to integrate energy storage components with the drive system [4]. It is seen that ANFIS based control strategies and MPPT applications are popular in electric vehicles integrated with renewable energy. For example, Touti et al. proposed an innovative control approach to increase energy efficiency by integrating a PEM fuel cell system with a boost DC/DC converter [5]. Such studies provide significant contributions to the development of more efficient energy management systems for electric vehicle charging infrastructures [6-8]. Literature studies show that ANFIS based research in electric vehicle technology has made significant progress in DC/DC converter control. As a result, it is evaluated that these studies play a critical role in the development of advanced energy management strategies to increase the efficiency and performance of electric vehicles.

This study presents a high-gain topology utilizing a single power switch with adaptive neuro fuzzy controller system. The high voltage gain enables the integration of low-voltage, high-power fuel cells, which must be stepped up to 800 VDC or even higher or lower, depending on the electrical specifications of the EV, such as battery pack voltage and auxiliary loads like lighting. The use of a single switch simplifies control implementation and allows for flexible voltage generation to meet the real-time demands of the battery pack. An Adaptive Neuro-Fuzzy-based controller with three inputs and one output effectively regulates the output voltage, achieving the desired setpoint in a very short time without overshoot. The system maintains the desired output voltage with high stability, even in the presence of input voltage fluctuations and output load variations.

2. THE PROPOSED CONVERTER TOPOLOGY AND ADAPTIVE NEURO FUZZY CONTROLLER

2.1. Gain calculation

In the initial stage, the proposed converter circuit and its various operational states are introduced. To analyze the converter effectively, it is essential to evaluate the topology in two distinct modes: the intervals when the power switch is activated (ON state) and deactivated (OFF state). Figure 1 illustrates the design of the power converter. As shown in the figure, the proposed converter features a single power switch, which simplifies the controller design and ensures flexibility in generating the required voltages for the battery pack. The topology of the proposed converter indicates that totally three inductors are used. When the switch is turned on, the current from the input source flows through two parallel branches including the inductors L1 and diode D1 and inductor L2 and diode D3. The voltage on the capacitor C3 strarts to charge the inductor L3 and load is feed through the voltage on capacitor Cbat. For the next time interval, diode D2 is activated and input inductors L1 and L2 strsrt to discharged and capacitor C2 is charged again. Input current passes throughinductor L3 to charge the capacitor Cbat. Brcause of internal feature of an inductor in switching converters, the input current faces to pass in series through all the inductors that makes the current smooth with lowest possible ripple and this specification are crucial since enhances the relability of the system and help to longer longevity of the FC stack. Furthermore, the SL cell boosts the FC voltage and stores it in capacitor C1. In the subsequent stage, a soft-switching voltage enhancer cell is cascaded with the SL cell to reduce voltage stresses on the power switch (S) and further increase the voltage across capacitor C1, which is then transferred to the battery pack. The inclusion of inductor L3 ensures the generation of a smooth, low-ripple current for the battery pack, a critical feature for extending its lifespan. This characteristic is a vital consideration in designing a professional and efficient converter topology.

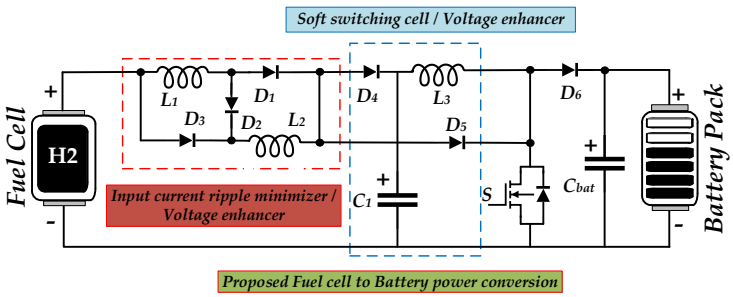

Fig. 1. The proposed FCEV converter topology and its integration with FC stack and battery pack

The operational states of the converter during the time intervals when switch S is activated (ON state) and deactivated (OFF state) are depicted in Figure 2a and Figure 2b, respectively. The current directions are illustrated using distinct colors in these figures. Referring to Figure 2a, the voltages and currents for the inductors and capacitors can be expressed as follows:

$$V_{L1} = L_1.\frac{di_{L1}}{dt} = V_{L2} = L_2.\frac{di_{L2}}{dt} = V_{FC} \quad (1)$$

$$V_{L3} = L_3.\frac{di_{L3}}{dt} = V_{C1} \quad (2)$$

$$V_{Cbat} = V_O \quad (3)$$

In these equations, V_{L1}, V_{L2}, and V_{L3} represent the voltages across the inductors L_1, L_2, and L_3 respectively. V_{Cbat} denotes the voltage across the output capacitor C_{bat}, and V_O represents the voltage across the battery pack.

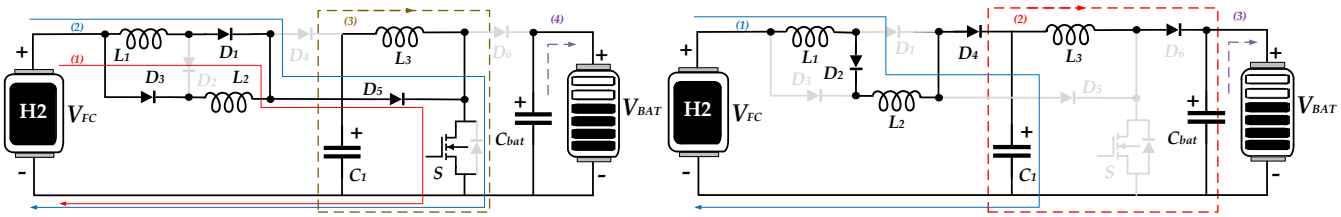

Fig. 2. The state of the circuits components when the switch is (a) activated and (b) deactivated

$$V_{L1} + V_{L2} = L_1.\frac{di_{L1}}{dt} + L_2\frac{di_{L2}}{dt} = V_{FC} - V_{C1} \xrightarrow{L_1=L_2=L_x} L_x\frac{di_{Lx}}{dt} = \frac{V_{FC}-V_{C1}}{2} \quad (4)$$

$$V_{L3} = L_3.\frac{di_{L3}}{dt} = V_{C1} - V_{bat} \rightarrow \frac{di_{L3}}{dt} = \frac{V_{C1}-V_{bat}}{L_3} \quad (5)$$

The gain of the proposed converter can be obtained by second balance rule for inductors. For inductors L_1 and L_2 which are eqaul, one can write $L_1 = L_2 = L_x$ and then:

$$V_{Lx}D + V_{Lx}(1-D) = 0 \rightarrow V_{FC}D + \frac{V_{FC}-V_{C1}}{2}(1-D) = 0 \rightarrow V_{C1} = V_{FC}(\frac{1+D}{1-D}) \quad (6)$$

For inductor L_3:

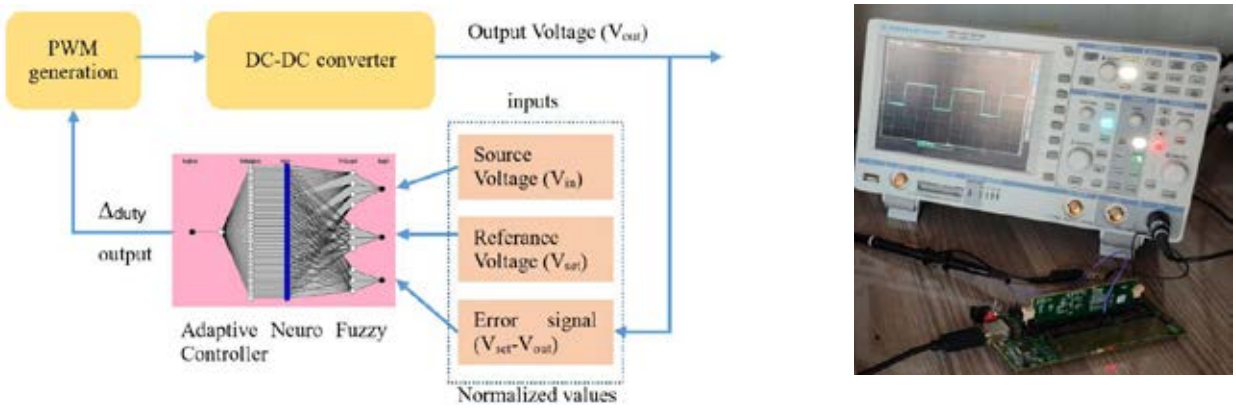
$$V_{L3}D + V_{L3}(1-D) = 0 \rightarrow V_{C1}D + (V_{C1} - V_O)(1-D) = 0 \rightarrow V_O = \frac{V_{C1}}{1-D} \quad (7)$$

The voltage gain M, can be obtained:

$$M = \frac{V_O}{V_{FC}} = \frac{1+D}{(1-D)^2} \quad (8)$$

2.2. Adaptive Neuro Fuzzy Controller

The proposed Adaptive Neuro-Fuzzy-based controller features three inputs Vin (input voltage), Vset (reference voltage), and Error (voltage error signal) and one output, ∆duty (duty cycle adjustment). Figures 3a and 3b present the combined structure of the converter and the controller, illustrating their integration within the system and the generated pulse width modulation (PWM) switching pulses for power switch in practice based on the propsed ANF controller.



a) b)

Figure 3. (a) Proposed Adaptive Neuro-Fuzzy Controller System and DC-DC Converter and (b) generated switches PWM pulse by the DSP-based controller

The proposed Adaptive Neuro-Fuzzy Controller (ANFC) computes the required ∆duty values to achieve the desired output corresponding to the given input parameters. In the PWM block, the computed duty cycle values are used to generate the corresponding PWM signals. For the controller design, 100,000 random values were generated for Vin, V_{set}, and V_{out}. Using (8), both the required duty cycle value for the desired V_{set} and the actual duty cycle corresponding to Vo were calculated. The difference between these two values was used to determine ∆duty. To define the ANFC input membership functions, V_{in} was normalized within the range [0-1] for 22–24 V, while Vset and Vo were normalized within [0-1] for 250–350 V. This process resulted in a total of 400,000 training data points, which were utilized for training a Sugeno-type fuzzy controller. The training of the controller which has 36 rule was conducted in MATLAB 2023b using the grid partition method and a hybrid optimization approach. The Adaptive Neuro-Fuzzy System (ANFS) automatically determined the number and range of membership functions for the input signals. Consequently, the input membership function layer was structured as 4-3-3, consisting of Gaussian membership functions. The training performance achieved an MSE (Mean Squared Error) of 0.0038 after 100 epochs. The resulting model was implemented in Simulink, where it demonstrated high accuracy within the specified operating ranges.

3. RESULTS AND DISCUSSION

The results for the voltages and currents of the proposed converter, obtained using a MATLAB program, are presented in this section. As illustrated in Figure 4a, with a duty ratio of approximately 0.64, the converter is capable of boosting the input voltage from 24 VDC to around 300 VDC, achieving a voltage gain of about 12.65 times. This result validates the

accuracy of the theoretical analysis for the voltage gain calculations and the operational states of the converter depicted in Figure 2. Figure 4b displays the input current from the FC and the current stress on the switch S as sample waveforms. Figure 4c illustrates how the ANFC adjusts the duty cycle as the output voltage (V_O) reaches the 300 V setpoint. As observed, the proposed controller achieves a very short settling time (0.016 sec) with zero overshoot, zero oscillation, and an extremely small steady-state error (0.7 V). This figure also highlights the minimized current fluctuations in the FC input source, as claimed by the proposed converter design. As calculated and observed, for an output power of around 200 W and an input voltage of 24 VDC, the average current drawn from the FC is approximately 8.33 A, which aligns with the theoretical predictions. Additionally, the figure demonstrates that the converter achieves the lowest possible current ripples, ensuring an extended lifespan for the FC, a critical feature for reliable and efficient operation.

4. CONCLUSIONS

In this study, an adaptive neuro fuzzy-based high voltage gain, low input current dc/dc boost converter for hydrogen-powered electric vehicles is proposed. In the design of the controller, the training dataset was generated based on data obtained from the characteristic equation of the system. This dataset was used to train the Adaptive Neuro-Fuzzy System (ANFS), which enables the controller to dynamically adjust its response to varying operating conditions. The ANFS-based approach offers a significant advantage over conventional methods, as it automatically determines the membership functions and rule sets, eliminating the need for extensive manual tuning and reducing the overall design complexity. Unlike traditional PID controllers, which often suffer from dead time, overshoot, and oscillations, the proposed AI-driven controller effectively mitigates these issues. By leveraging adaptive learning and fuzzy inference mechanisms, it achieves a highly stable response with zero overshoot, minimal steady-state error, and an exceptionally short settling time. This ensures not only fast and accurate regulation of the output voltage but also improved robustness against input voltage fluctuations and load variations. The integration of an intelligent control mechanism enhances the overall system performance, efficiency, and reliability, making the proposed controller a highly effective solution for precise and adaptive DC-DC converter regulation.

ABSTRACT

The integration of artificial intelligence into the control and optimization of DC-DC converters presents promising opportunities in improving energy management and efficiency in electric vehicle (EV) sector. This study presents a low-input current and low voltage stress topology for application in fuel cell (FC) to battery charging systems in EVs. A current filter by forming a switched inductor at the input side of the converter quarantees a small ripple for input osurces that enhances the longevity and longlife of the FC stacks. The application of the switched capacitor at the end side of the converter decreases the voltage stress on the main power switch and enhances the mean time to failure rate of the converter that is between the most important featres of a converter. The converter design incorporates a three-layer, three-input artificial neural network structure. The regression values were 0.982 for training, 0.983 for testing, and 0.9827 overall, indicating minimal prediction error and confirming the effective training of the neural network model. The laboratoty test results confirm the correctness of the proposed algorithm and application of the proposed converter.

1. INTRODUCTION

The increasing utilization of hydrogen energy and its production through environmentally sustainable approaches have gained significant attention in recent years as part of efforts to mitigate the greenhouse effect and reduce the carbon footprint. Reaserchers intensively have focused on application of FC and hydrogen energy in Evs. These techniques bring many of advantages like the green and cheap energy, abundance due to presence in the air and helping to stop global warming, and ease and spread of EVs quickly [1,2]. For instance, [3] presents an implementation of a microbial FC. On the other hand, the application of power electronic-based converters and their control mechanisms are inevitable to convert the generated voltage of the FC stack for battery pack chargings in EVs. for fast charging issues, since FC generates a DC voltage, DC-DC converters widely are used to enhance the limited generated voltage by the FC to a high voltage or high current DC voltage for EV battery pack. In recent years, the battery voltage pack has reached up to 800 VDC that is much more than generated voltage by a FC cell. Besides, the control mechanism is another significant issue that should be considered. Controllers which are based on the minimum complexity and being simply implemented are in focal point of attentions. Liu et al. implemented a control method based on genetic algorithms and artificial neural networks to enhance the efficiency of converters [4]. Since maximum power point tracking (MPPT) techniques play a critical role in optimizing the utilization of renewable energy sources, advanced control strategies have also been applied in this domain. For instance, Bharathi et al. introduced an artificial neural network-based approach to optimize power utilization in a solar-powered electric vehicle [5]. Additionally, a neural network-based MPPT technique was proposed to improve the efficiency of photovoltaic power systems, which are highly sensitive to environmental factors [6].
DC-DC converters play a pivotal role in maintaining the optimal energy balance between power sources and the energy storage system of electric vehicles. A comprehensive study on the role of such converters in energy management was presented by Gorji et al. [7]. Akyazı presented a step-up converter controlled through a PI-Fuzzy Logic Controller. The controller parameters were optimized using a Genetic Algorithm to enhance system efficiency [8]. Furthermore, Dhimish and Schofield conducted research on the industrial application of AI-based buck-boost DC-DC converters, demonstrating their potential in enhancing adaptive energy management systems [9]. These findings reinforce the notion that AI-powered control strategies can revolutionize the way power electronics systems are designed, monitored, and optimized. In this study, a DC-DC converter topology is proposed for charging of EVs purposes via a fuel cell based energy system. A 3-layer 3-input artificial neural network structure is used in the design of the DC-DC converter. Theoretical evaluations, simulation results and switching PWM pulses generated via digital signal processors (DSP) microcontroller in a laboratory environment are presented in this study.

2. THE PROPOSED CONVERTER TOPOLOGY AND AI CONTROLLER

2.1. Gain calculation

The proposed converter is presented in figure 1. This figure simply shows that the suggested converter has the capability of conecction of the FC stacks or PV arrays to the battery charging packs of EVs. The illustrated converter includes a switched-inductor-capacitor cell (SL-SC) at the input side and a switched-capacitor (SC) cell at its end side. The application of SL-SC minimizes the current ripple of the input source since both inductors are charging in parallel and discharging in series and capacitor C1 presesnts a fixed voltage to easily can be enhanced by the SC cell. The application of SC cell at the next side cause a significant decrease in voltage stresses across the main power switch and simply enhances the voltage on capacitors C1 and C2. The proposed converter has a significant voltage gain that fits its application to high voltage charging systems.

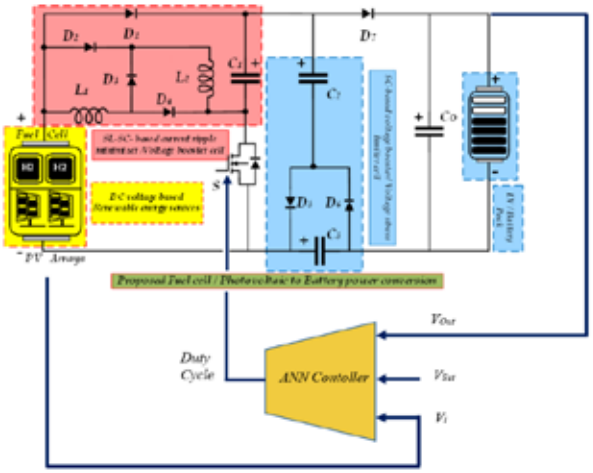

Fig. 1. The proposed FCEV converter topology and its suggested Pseudo AI controller

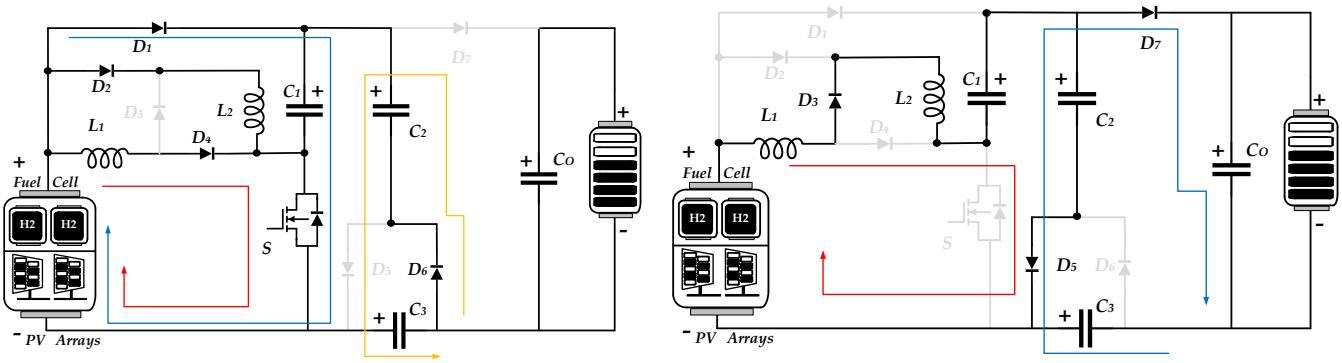
Figures 2a and 2b present the state of the components in the suggested power converter topology for times intervals that the switch S is turned on and off respectively. For the time duration that the main switch is activated, both inductors and capacitor C1 chrged in parallel with input voltage source. The below equations can be written for this state:

$$V_{L1} = L_1.\frac{di_{L1}}{dt} = V_{L2} = L_2.\frac{di_{L2}}{dt} = V_{in} \quad (1)$$

$$V_{C1} = V_{in} \quad (2)$$

$$V_{C2} - V_{C3} = V_{in} \quad (3)$$

$$V_{CO} = V_O \quad (4)$$



(a) (b)

Fig. 2. The state of the circuits components when the switch is (a) activated and (b) deactivated

When the switch is deactivated, the inductors begin discharging into the output capacitor and battery pack. Capacitor C2, which was discharged in the previous time interval, is now recharged, activating diode D5 to charge capacitor C3. As the voltages across capacitors C2 and C3 increase, the output voltage also rises. The following equations can be derived for this operational mode:

$$V_{L1} + V_{L2} - V_{C1} + V_{C2} = V_{in}, \xrightarrow{L_1=L_2=L_x} V_{Lx} = L_x \frac{di_{Lx}}{dt} = \frac{V_{in}+V_{C1}-V_{C2}}{2} \quad (5)$$

$$V_{C2} = V_{CO} - V_{C3} \quad (6)$$

The gain of the proposed converter can be obtained by second balance rule for inductors. For inductors L_1 and L_2 which are eqaul, one can write $L_1 = L_2 = L_x$ and then:

$$V_{Lx}D + V_{Lx}(1-D) = 0 \rightarrow V_{in}D + (\frac{V_{in}+V_{C1}-V_{C2}}{2})(1-D) = 0 \xrightarrow{V_{C1}=V_{in}} V_{C2} = \frac{2.V_{in}}{1-D} \quad (7)$$

From equation (3):

$$V_{C3} = V_{C2} - V_{in} = \frac{2.V_{in}}{1-D} - V_{in} = \frac{1+D}{1-D}V_{in} \quad (8)$$

Based on equations (6,7 and 9), the voltage gain M, can be obtained as below:

$$V_{CO} = V_{C2} + V_{C3} = \frac{2.V_{in}}{1-D} + \frac{1+D}{1-D}V_{in} \rightarrow M = \frac{V_O}{V_{in}} = \frac{3+D}{1-D}V_{in} \quad (9)$$

2.2. Controller features and Designings

In this study, a neural network-based controller is proposed for the control of a DC-DC converter. The proposed controller is designed with 3 inputs, 1 output, and 3 layers. The number of neurons in the layers is determined to be 20:40:10. The input parameters of the controller are V_{in}, V_{set}, and Error signals, while the duty cycle value forms the output parameter. The structure of the controller is shown in Figure 3.

```

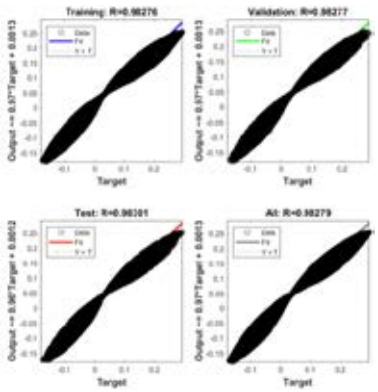
a)



b)

Fig.4. a) Pseudo code of the algorithm developed for creating the training data, b) regression values at the end of the training phase

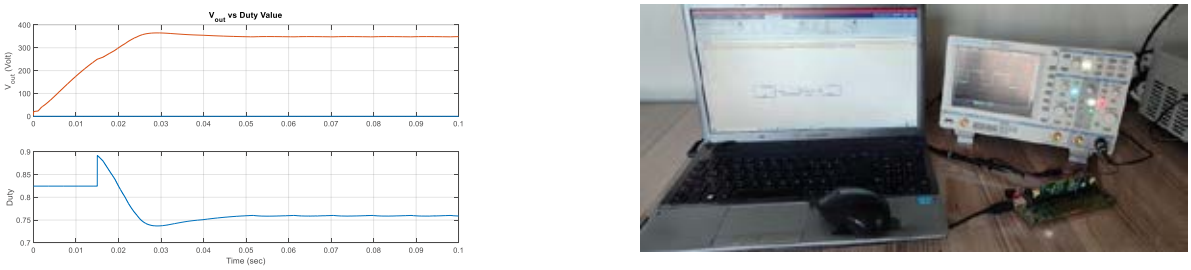
2.2.1.Training and Testing of the Controller

To train the controller, a training dataset consisting of input-output, set value, and duty cycle values needs to be obtained. Unlike previous studies, the training values are not generated randomly but cyclically to include all intermediate values. The data is obtained according to Equation 9. The pseudo-code of the algorithm used to create the dataset is shown in Figure 4a. The V_{in} value is produced between 22 and 24 V, the V_{set} value between 200 and 350 V, and the V_o value between 150 and 350 V. Using these values, the required and instantaneous duty values are calculated, and the difference between them, Err_duty, is obtained. This value is the output of the ANN.

As a result, 1,448,412 data points were generated, consisting of 3×362,103 input values and 362,103 target values. This dataset was shuffled and presented to the artificial neural network, and the training and testing processes were completed in 4 epochs by using Levenberg-Mardquart learning algorithm. The training performance was obtained as 29×10^{-5}. The regression values at the end of the training phase reflect the model's performance in fitting the data. These values indicate the degree of correlation between the predicted outputs and the actual target values. The regression values are shown in Figure 4b.

3. RESULTS AND DISCUSSION

A simulation study was conducted in the MATLAB Simulink environment to test the performance of the controller. The output voltage and corresponding duty cycle variation obtained for a 350 V set value are graphically presented in Figure 5a. As seen, a settling time of 0.05 seconds, low overshoot voltage, very low oscillation, and a very smooth duty cycle variation are achieved. As can be seen from this result, the proposed ANN controller successfully controls the DC-DC converter within the specified ranges. Figure 5b presents the interaction of matlab-compatible digital signal processors (DSP) and proposed AI algorithm to generate the pulse width modulation (PWM) signals to drive the power switch S in practice.



a) b)

Fig.5. (a) Simulated DC voltage output for the battery pack and (b) experimentally generated PWM driving pulses for the switch using the ANN algorithm.

4. CONCLUSIONS

This study introduces a high voltage gain DC-DC boost converter designed to increase the voltage of the fuel cell (FC) stack for battery charging in EVs. Since EVs require high voltage levels, often up to 800 VDC, a high-gain converter is essential to meet load demands. The proposed converter features a single power switch, simplifying both the control process and the complexity of the controller circuit. A DSP microcontroller, compatible with MATLAB, is utilized for implementation. On the control side, an AI-based controller is developed using pseudo codes and the Levenberg-Marquardt learning algorithm. The regression values obtained were 0.982 for training, 0.983 for testing, and 0.9827 overall, indicating minimal prediction error and confirming the effective training of the neural network model.

ABSTRACT
In this study, Fe-Ru alloys have been prepared by electrodeposition process. Cyclic voltammetry measurements confirm the possibility of co-deposition of iron with ruthenium from single bath. Formation of alloy is possible by applying the potential below the reduction value for Fe^{2+}/Fe process. Modification of electrodeposition conditions allows to obtain different composition of electrodeposited thin films. Maximal amount of iron in alloy were close to 30% mass. Morphological study and structural analysis for obtained Fe-Ru alloys were carried. Comparative analysis of catalytic activity in hydrogen evolution reaction in 1 M NaOH were conducted. All of the obtained Fe-Ru coatings are more active materials for water splitting process than electrodeposited Ru thin film. Low overpotential value can be affected by presence of RuFe and Ru_4Fe phases, homogenously distributed in ruthenium metal matrix.
Keywords: Iron, Ruthenium, electrodeposition, hydrogen evolution reaction, noble metals alloys

1. INTRODUCTION

One of the most exciting areas in materials science and electrocatalysis is designing alloys for water splitting. In particular, the synthesis of alloys containing highly active noble metals has become a major research focus. While binary alloys of platinum, palladium, and rhodium are well documented, another platinum group metal—ruthenium remains relatively underexplored. Ru-based alloys most commonly investigated for electrocatalysis include Co–Ru[1-2] and Ni–Ru.[3] Nickel–ruthenium alloys can be electrodeposited from chloride solutions at −0.5 to −1.0 V vs. SCE, with electrochemical tests confirming codeposition below the nickel reduction potential. These high-quality Ni–Ru coatings vary in phase composition (NiRu (100) and (101)) and electroactive surface area as Ni content increases, exhibiting strong water-splitting activity—likely due to their well-developed active surface and NiRu phases [4]. Similarly, Ru–Co alloys are deposited from a 0.75 M Co^{2+} + 0.025 M Ru^{3+} solution at −0.5 to −1.2 V vs. SCE. Deposition of Ru quickly becomes diffusion-controlled (−0.7 V), while Co deposition is enhanced by Ru, leading to Ru–Co films with globular morphology and increasing Co content (22.1/7.4 to 70.2/86.1 wt%) as the potential shifts from −0.6 to −1.0 V. These coatings show superior hydrogen evolution reaction (HER) performance and stability in alkaline media, with Ru–Co@Ti_2AlC formed at −0.6 V requiring an overpotential of just −95 mV to reach −100 mA cm^{-2} in 1 M KOH.[5] Although binary alloys of ruthenium with Ni and Co have been studied, Fe–Ru systems remain unexplored. This gap in the literature serves as the primary motivation for the present study on synthesizing and evaluating Fe–Ru alloys for electrocatalytic applications.

2. MATERIALS AND METHODS

Iron-Ruthenium alloys were electrodeposited from acidic chloride electrolytes. The experiments were conducted at room temperature using reagents of analytical purity. Electrochemical tests were performed with a BioLogic SP-200 potentiostat and EC-LAB software. Cyclic voltammetry and stripping analysis utilized a standard three-electrode measurement cell, with a 0.196 cm^2 carbon-glass working electrode and a platinum coil counter-electrode. The potential was measured against a saturated calomel electrode. The potentiostatic deposition system was similar. Deposition took place on 2.8 cm^2 etched copper plates, with a parallel platinum sheet counter-electrode. A custom-designed electrolytic cell (300 ml volume, 6 cm electrode distance) was used for electrodeposition, with the electrolyte replaced for each experiment. Post-deposition, the alloys were cleaned in deionized water and air-dried. Elemental composition was determined via XRF (Rigaku Rimini) with a Palladium lamp, and phase composition was analyzed by XRD (Rigaku MiniFlex II) using a copper tube (λ = 1.54059), comparing diffractograms to ICDD database cards. SEM images were captured using a Hitachi Su-70 scanning microscope. The water-splitting ability of the Fe-Ru coatings was assessed by chronopotentiometry in a 1 M NaOH solution and Tafel slope estimation in linear range.

3. RESULTS AND DISCUSSION

All the results the electrochemical synthesis of Fe-Ru alloys was preceded by cyclic voltammetry studies. Chloride electrolytes with a Cl- ion concentration of 3 M and pH = 1 were used for research. Due to the significant difference in the reduction potentials of the Ru/Ru^{3+} and Fe/Fe^{2+} redox potentials, electrolytes with a higher concentration of Fe^{2+} ions relative to Ru^{3+} ions (0.5 M Fe^{2+} + 0.01 M Ru^{3+}) were used. The obtained curves for the solution containing only Fe^{2+} ions are shown in Figure 1a).

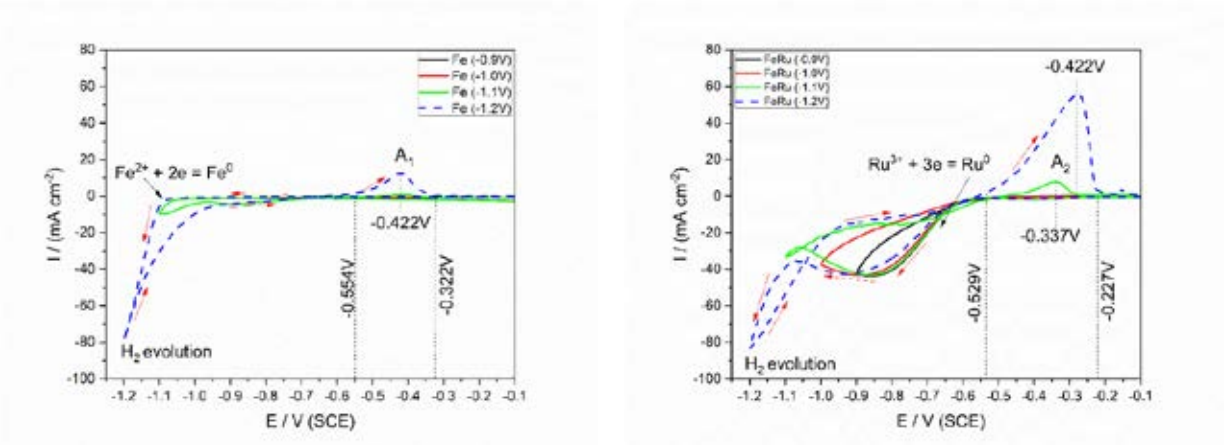

Fig. 1. Cyclic voltammetry registered on GC disc electrode at 40 mVs^{-1} scan rate for electrolytes containing: a) 1 M Fe^{2+}, Cl^- = 3 M, pH = 1 and b) 1 M Fe^{2+} , 0.01 M Ru^{3+}, Cl^- = 3 M, pH = 1 for different vertex potentials.

The use of a glassy carbon electrode was motivated by its ability to determine the reduction potential of Fe^{2+} ions while avoiding hydrogen evolution on the working electrode's surface. An increase in current density and the appearance of hydrogen bubbles were observed only when the glassy carbon surface was covered with a metallic iron deposit. During the cathodic scan, from the OCP potential range to -1.1 V, no change in current density was observed. Only after exceeding -1.15 V did the current density increase, indicating the onset of Fe^{2+} ion reduction to the metallic form. During the scan from -1.1 to -1.2 V, gas bubbles were observed on the electrode surface, likely related to hydrogen ion reduction and water splitting process. Iron, like nickel and cobalt, has relatively high catalytic activity for hydrogen evolution. After exceeding the potential of -0.55 V, further anodic scanning shows a peak corresponding to the dissolution of the metallic phase, with a maximum at -0.42 V. The next step was to compare the cyclic voltammetry curves obtained for the solution containing Fe^{2+}, Ru^{3+} ions, and their mixture at the same ion concentrations. The results are shown in Figure 1b).
As previously discussed in Figure 1a), the reduction reaction of Fe^{2+} ions starts after exceeding a potential of -1.1 V, resulting in the formation of a metallic phase on the electrode surface. This is confirmed by the presence of an anodic peak (A1) in the range of -0.55 V to -0.32 V. The voltammogram for the solution containing only Ru3+ ions showed two cathodic peaks. The first is due to the reduction of ruthenium ions to the metallic form (K1), leading to the appearance of peak K2 at -0.7 V, related to hydrogen ion reduction on the electrode surface. The increase in current density recorded from -1.1 V is due to water decomposition reaction. In the studied system, the anodic scan did not show peaks corresponding to the dissolution of the metallic ruthenium phase. The scan obtained for the solution containing both metals' ions is significantly different from the combined curves for iron and ruthenium. The first noticeable difference is the disappearance of cathodic peak K1 and the shift of the reduction process towards more negative potentials. The first cathodic process starts at -0.64 V and reaches a maximum at about -0.9 V. The recorded current density in this range is much higher than that for the ruthenium or iron only solution. After exceeding -1.1 V, an increase in current density related to water splitting is observed. The anodic scan shows a distinct peak (A2), shifted towards more positive potential values compared to the electrolyte containing only Fe^{2+} ions. The intensity of this peak is much higher in the Fe2+ + Ru3+ system. It is suspected that the presence of metallic Ru on the electrode surface during the scan may decrease the concentration of hydrogen ions in the electrode vicinity, affecting the Fe^{2+} ion reduction potential. Such a potential shift could intensify the alloy deposition process. These findings indicate that there is a possibility to electrodeposit the Fe-Ru alloys from acidic chloride solutions. For this study the different deposition potentials were applied to obtain the Fe-Ru alloys with different chemical composition. The chemical and phase composition of alloys were verified by XRF (left side of the spectra) and XRD analysis, which were presented on Figure 2.

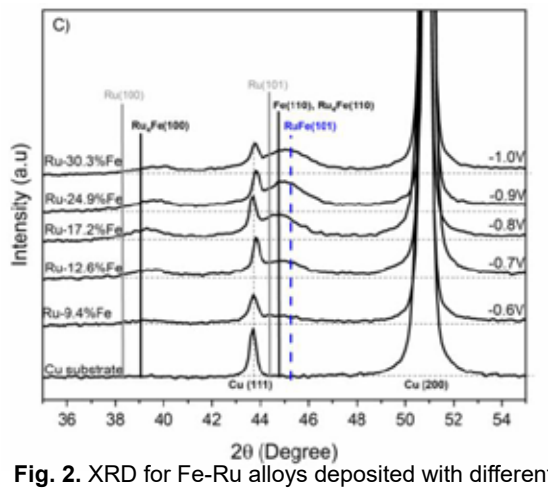

Fig. 2. XRD for Fe-Ru alloys deposited with different deposition potentials: from -0.6V to -1.0V vs SCE. Electrolyte composition: 1.0 M Fe^{2+} + 0.01 M Ru^{3+}.

The XRD patterns for Fe–Ru coatings prepared at different potentials can be explained based on the standard reference data provided by the ICDD database cards. The most prominent reflections at around 43° and 51° (2θ) belong to the copper substrate, in line with ICDD card 00-004-0836 (FCC Cu). These peaks remain unchanged in all samples, which can be taken as a convenient reference point for evolution of the diffractions obtained under different deposition potentials. At more positive deposition potentials (e.g., −0.6 V), the dominant peaks in the 36°–46° 2θ range correspond to ruthenium's HCP structure (ICDD card 00-006-0663), evident from Ru(100) and Ru(101) reflections. The relative intensity of these Ru peaks confirms that the as-deposited films are predominantly Ru-rich (according to XRF measurements). As the potential becomes more negative the alloy incorporates progressively more Fe, which manifests in the slight shift of the peaks or growth of additional reflections. Some samples begin to show weak signals that match ICDD card 00-006-0696 (BCC Fe), especially as the Fe content surpasses about 20 wt % at −0.9 V to −1.0 V. However, the formation of Fe-rich intermetallics is often more apparent than pure BCC Fe. Two HCP intermetallic compounds, RuFe (ICDD card 01-071-8378) and Ru_4Fe (ICDD card 00-040-1147), appear as new or more intense reflections around the same 2θ range occupied by Ru. Their presence indicates that the Fe does not merely substitute into the Ru lattice at random; instead, under certain alloying conditions, it can form ordered phases such as Ru_4Fe or RuFe. RuFe(101) becomes increasingly evident as the alloy shifts from predominantly Ru toward more balanced or even Fe-rich compositions. The morphology of obtained Fe-Ru alloys were also investigated by SEM observations, which are shown in Fig.3.

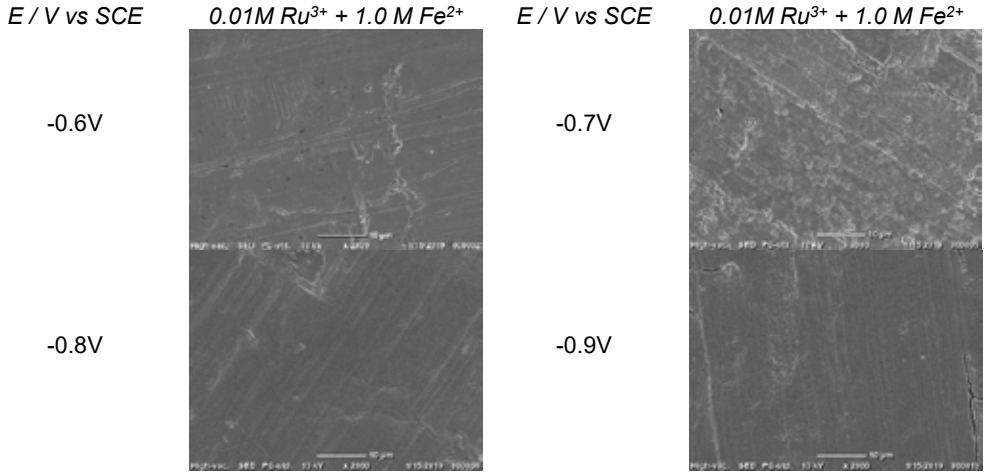

Fig. 3. Scanning Electron Microscopy images for Fe-Ru alloys deposited under different deposition potentials and electrolyte composition.

The SEM images reveal the morphological evolution of the alloys with application of different potentials. It should be noted that the irregularity of the grains is growing with the more negative potential, what can be attributed to significant hydrogen evolution reaction during the synthesis. Moreover, some cracks or voids can be seen for the potential -0.9V. In case of other samples, the surface is free of defects and the scratches from the substrate can be seen. From macroscopical point of view, the alloys are metallic-bright and very uniform, without any visible cracks, defects or discontinuity of the metallic coating. The catalytic activity of the Fe-Ru alloys were tested by two different approaches: by application of the constant current density (-10 mA cm^{-2}) for a time 600 s, to preliminary check of the potential value of hydrogen evolution reaction (Fig 4a) and application different values of the current density in a range between 0.1 and 200 mA cm^{-2}, which allows to determine the linear range of the Tafel slope. Obtained results shows that the alloy $Ru_{86}Fe_{14}$ exhibit the lowest overpotential for hydrogen evolution reaction among Fe-Ru alloys, and almost identical to pure Ru coating. It should be noted that the addition of the Fe into Ru is modifying the mechanism of HER in alkaline solutions, which can be seen as the increasing the value of Tafel slope as a function of the iron concentration in alloy.

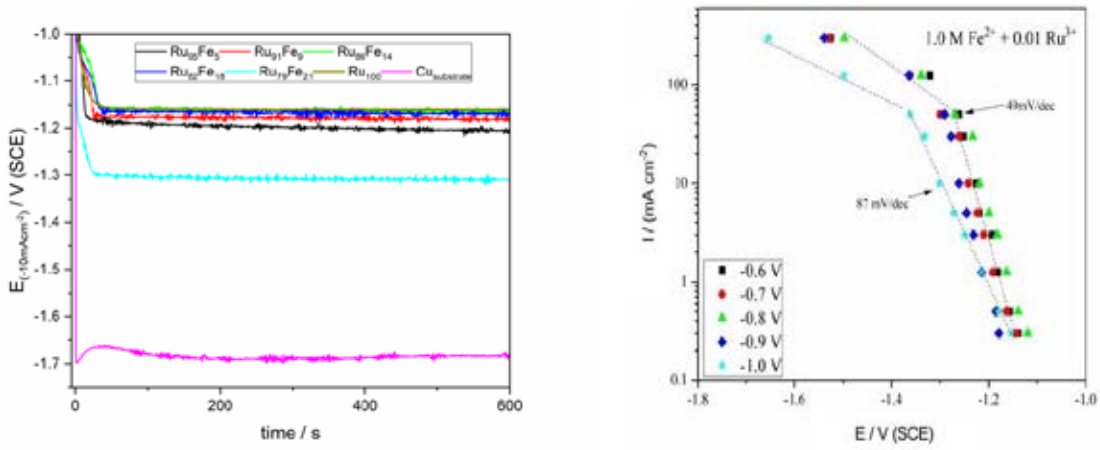

Fig. 6. a) Chronopotentiometric curves registered in 1 M NaOH after application of constant current density: -10 mAcm^{-2} for Fe-Ru alloys deposited with different deposition potentials: from -0.6V to -1.0V vs SCE with used electrolyte 1.0 M Fe^{2+} + 0.01 M Ru^{3+} and b) registered Tafel slopes.

4. CONCLUSIONS

The Fe-Ru binary alloys can be prepared in electrochemical way and successfully used as a cathode material for alkaline water splitting. The chemical composition can be tuned by modification of deposition parameters, and it significantly affect the crystalline structure of alloys. Incorporation of iron into hexagonal structure of Ru led to formation of mixture of Ru and Fe-Ru phases, visible as the shifted peaks on the XRD spectra. Morphology of alloys is uniform and free of voids and defects. Catalytic activity of alloys shows that the alloys with small addition of Fe into Ru (less than 20%) can be as active as pure Ru coatings. The incorporation of iron into alloy is modifying the HER mechanism, what was confirmed by Tafel slope measurements.

ABSTRACT
This research presents a pioneering, state-of-the-art multigeneration system that is specifically designed to tackle carbon dioxide emissions in glass production plants. This innovative system utilizes monoethanolamine absorption to extract carbon dioxide from glass production processes. The hydrogen gas used in the system is created through alkaline electrolysis and is supported by wind power. A portion of the hydrogen produced is used to react with carbon dioxide, producing methanol, while the remaining amount is stored in a storage tank. The system also produces valuable outputs such as electricity, district heating, and hot water. The design of the system incorporates other renewable resources, such as solar energy, to optimize its overall functionality. The system achieved a hydrogen production rate of 0.04491 kg/s and a methanol production rate of 0.1582 kg/s. Additionally, the system boasted an energy efficiency of 75.73% and an exergy efficiency of 36.59%, respectively.

Keywords: Glass industry, Hydrogen, Methanol, Exergy, Carbon Capture.

1. INTRODUCTION
Scientists and engineers work hard to come up with innovative and ground-breaking solutions to the urgent problems of climate change and rising global energy consumption [1]. Glass is used in everything from windows and dinnerware to the flat screens of smartphones. The expansion of infrastructure and the population are driving up demand. But glass is heated to incredibly high temperatures in furnaces. Its production results in 95 million tonnes of CO_2 annually worldwide and 22 million tons in Europe [2]. Sand and energy are requisite components in the production of glass. Historically, energy has been supplied through the combustion of natural gas with air to achieve temperatures sufficient for the transformation of sand into molten glass suitable for molding. However, this process is characterized by high energy consumption and significant pollutant emissions [3]. The predominant source of carbon emissions in glass production is the process of heating the melting furnace to temperatures exceeding 1,000 degrees Celsius, which constitutes an energy-intensive operation [4]. Therefore, carbon capture technology, such as monoethanolamine (MEA) absorption, can be implemented in glass production facilities to mitigate the increase in global CO_2 emissions. The utilization of concentrated CO_2 subsequent to carbon capture is directed towards the synthesis of novel materials and fuels. Through the process of hydrogenation, CO_2 from the atmosphere can be utilized to produce methanol, dimethyl ether, and formic acid. Upon combustion of these fuels, carbon dioxide is released into the atmosphere. This CO_2 can subsequently be absorbed and converted back into fuels, establishing a carbon-neutral cycle.
The primary objective of this research is to address the essential requirements of a modest residential community in Kırklareli, Turkey, by proposing an innovative multigeneration system that produces five beneficial outputs. In addition to providing district heating, hot water, and electricity, the system will also generate critical energy carriers, including hydrogen and methanol. The community's increased energy demands will be met using renewable resources, and the methanol will be synthesized using CO_2 captured from a glass production plant's monoethanolamine absorption technology to enhance sustainability. The study's evaluation encompasses comprehensive energy and exergy analyses, which assess the system's performance in its designated environment.

2. ANALYSIS
The proposed system is analysed thermodynamically to identify the mass flow rates, enthalpies, pressures, and temperatures of flows entering and exiting the system. The exergy destruction rate is determined to locate irreversible losses within each component of the system. The modelling is done using the EES software under specific assumptions, along with the balance equations written for mass, energy, entropy and exergy. The chemical reaction taking place in the methanol reactor is $CO_2 + 3H_2 \rightarrow CH_3OH + H_2O$.
The overall energetic and exergetic efficiencies of the system are defines as

$$\eta_{en,ovr} = \frac{\dot{W}_{net}+\dot{Q}_{HW}+\dot{Q}_{DH}+\dot{m}_{H2}LHV_{H2}+\dot{m}_{CH3OH}LHV_{CH3OH}}{\dot{m}_{flue}h_{flue}+W_{WT}+\dot{Q}_{Solar}} \text{ and } \eta_{ex,ovr} = \frac{\dot{W}_{net}+\dot{Q}_{HW}\left(1-\frac{T_0}{T_S}\right)+\dot{Q}_{DH}\left(1-\frac{T_0}{T_S}\right)+\dot{m}_{H2}ex_{H2}+\dot{m}_{CH3OH}ex_{CH3OH}}{\dot{m}_{flue}ex_{flue}+W_{WT}+\dot{E}x^{Q_{Solar}}}$$

where $\dot{W}_{net}$ is net power produced by the proposed system and is calculated as

$$\dot{W}_{net} = \dot{W}_{HPT} + \dot{W}_{LPT} + \dot{W}_{Exp} + \dot{W}_{GT} - \dot{W}_{Pump1} - \dot{W}_{Pump2} - \dot{W}_{Pump3} - \dot{W}_{Pump4}. - \dot{W}_{Comp1}. - \dot{W}_{Comp2}. - \dot{W}_{Comp3}. - \dot{W}_{BComp}$$

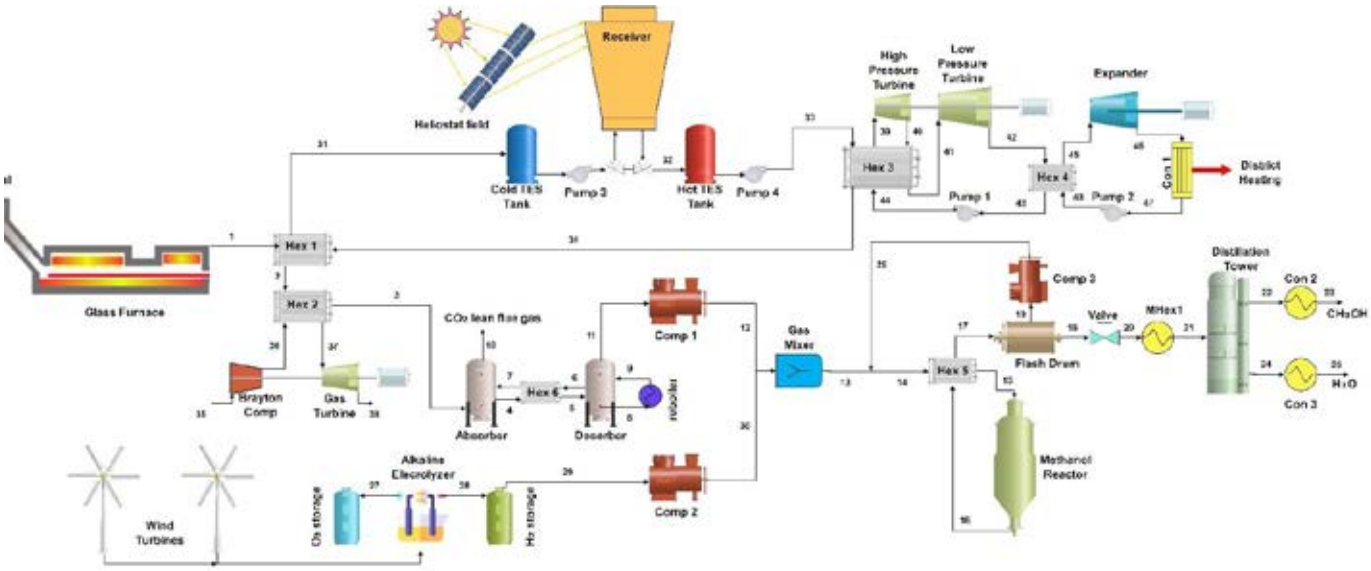

Fig. 1. Schematic view of the integrated system proposed for glass production plants.

3. RESULTS AND DISCUSSION

Consequently, the heat exchanger 3 (Hex 3) exhibits a significant exergy destruction of 1087.8 kW, while the solar thermal system (STS) demonstrates the highest exergy destruction at 1632.2 kW. The exergy destructions of the condenser 1 (Con 1), methanol reactor (Mreac), low-pressure turbine (LPT), and expander (Exp) subsystems are determined to be 738.6, 121.02, 120.72, and 11.34 kW, respectively. It is evident that the STS exhibits the highest exergy destruction, whereas the Exp demonstrates the lowest exergy destruction.

A parametric study was conducted to evaluate the performance of the integrated system, taking into account the first and second laws of thermodynamics. In the study, the change of methanol and hydrogen production rate depending on wind speed in the integrated system and the change of system performance depending on ambient temperature were investigated. Fig. 2 demonstrates that energy efficiency exhibits a slight increase as ambient temperature rises. Conversely, during heating, the overall exergetic efficiency exhibits a downward trend as the ambient temperature increases. This phenomenon is anticipated, considering that a heating system's efficacy diminishes in warmer months when a reduced heating load is required. As the temperature increases from 273 to 303 K, the energy efficiency improves from 75.28 to 75.82%, exergy efficiency increases from 36.59 to 36.56%.

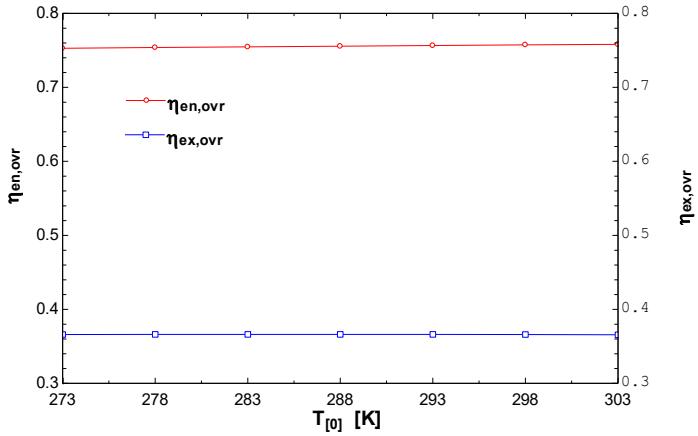

Fig 2. Variation of the ambient temperature with overall efficiencies.

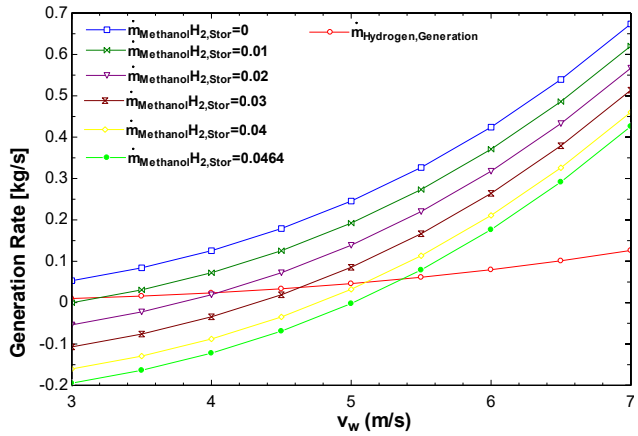

Fig 3. Exchange of supplied wind speed with CH_3OH and H_2.

Fig. 3 depicts the impact of varying wind speed input on methanol and hydrogen production. The wind speed for the selected target region varies between 3 and 7 m/s. The mean annual wind velocity is 5.87 m/s at an elevation of 100 meters. A portion of the produced hydrogen is utilized in methanol production, while the remaining portion is stored in the storage tank. In Fig. 3, parametric studies were conducted for various scenarios, including the utilization of all produced hydrogen in methanol production, as well as scenarios where 0.01, 0.02, 0.03, 0.04, and 0.0464 kg/s of hydrogen are stored in the storage tank, with the remaining portion used in methanol production. The results demonstrate that both the hydrogen production rate and the methanol production rate increase with increasing wind speed.

Furthermore, as the stored hydrogen production rate increases, the amount of hydrogen allocated to methanol production decreases, resulting in a corresponding decrease in the methanol production rate.

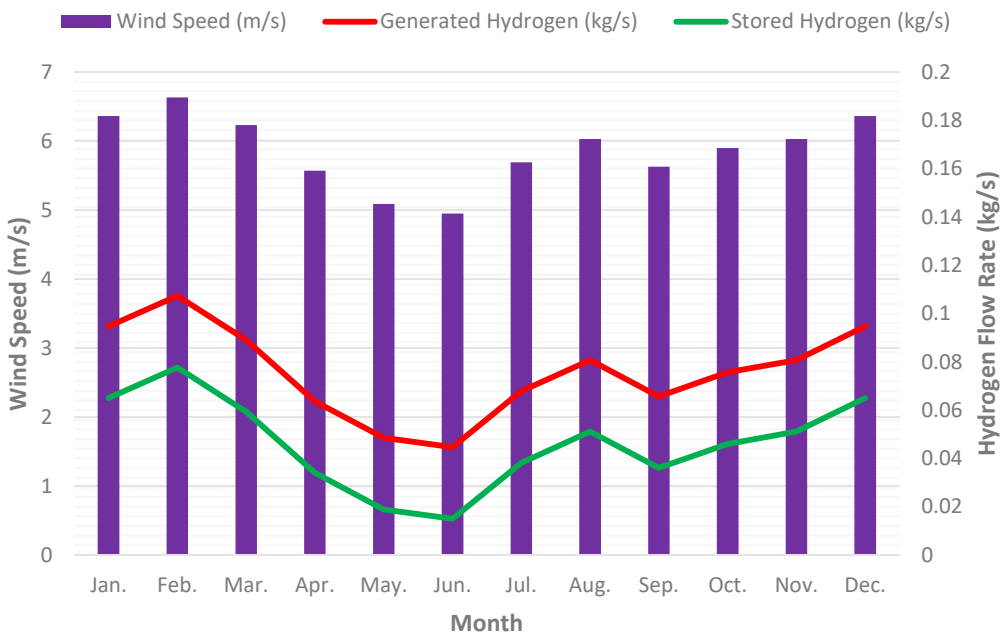

Fig. 4. Variation of wind speed and production rate of produced and stored hydrogen throughout the year.

Fig. 4 demonstrates that the maximum wind speed was observed in February, while the minimum occurred in June. Consequently, the highest rate of hydrogen production, corresponding to the wind speed, was 0.1073 kg/s in February, and the lowest rate was 0.044 kg/s in June. The quantity of hydrogen generated throughout the year is adequate for methanol production in the glass production facility, with excess hydrogen stored in storage tanks.

4. CONCLUSIONS

The primary outcomes derived from the integrated system proposed for glass production facilities are as follows. Firstly, the net power generated under the specified conditions, methanol flow rate, and hydrogen flow rate are calculated as 9541 kW, 0.1582 kg/s, and 0.045 kg/s, respectively. Additionally, the generated hot water flow rate and heating effect are calculated as 0.089 kg/s and 8898 kW. Secondly, the energy efficiency and exergy efficiency of the system are calculated as 75.73% and 36.59%, respectively. These results demonstrate the efficacy of the integrated system proposed for glass production facilities in terms of power generation and energy efficiency.

ABSTRACT
Water management in proton exchange membrane (PEM) fuel cells is crucial for the efficient operation of the system, and the materials used in gas diffusion layers (GDL) play a decisive role in this process. In this study, the use of carbon fabric as an alternative to traditionally preferred carbon paper in GDLs was evaluated. However, precipitation issues were encountered during the preparation of carbon-based coating solutions due to the instability of polytetrafluoroethylene (PTFE) in an alcohol medium. To address this issue, the non-ionic surfactant Tween 40 (TW40) was used at different concentrations (1.5%, 4.5%, 8%, and 16%), and the stability of these solutions was tested. The analysis results showed that the solutions containing 16% TW40 provided the highest stability.
Keywords: PEM Fuel Cells, Carbon Fabric Gas Diffusion Layer, Polytetrafluoroethylene (PTFE) Stabilization

1. INTRODUCTION

Proton exchange membrane (PEM) fuel cells have emerged as a strong alternative for automotive and stationary applications. Their ability to respond to rapid load changes with high power densities has increased interest in their use. However, water management is a critical factor for the efficient operation of the system. Insufficient water reduces ion conductivity in the membrane and catalyst layer (CL) while increasing membrane-CL contact resistance. On the other hand, excessive water accumulation in the membrane-electrode assembly (MEA) limits catalytic areas and hinders reactant transport. In this context, the selection and processing of materials used in gas diffusion layers (GDL) are of great importance[1].

Today, carbon paper is commonly used in GDLs. However, in this study, the use of carbon fabric as an alternative to carbon paper was investigated. The potential advantages of carbon fabric include higher mechanical durability, better gas distribution, and greater flexibility. Therefore, carbon facric is seen as having high potential for enhancing the performance of PEM fuel cells. To evaluate the feasibility of using carbon cloth as a GDL, the stability of carbon-based coating solutions was also examined.

2. MATERIALS AND METHODS

The coating solution was prepared according to the literature [2]. A total of 0.5 g of Vulcan XC-72 carbon was dispersed in 80 mL of isopropyl alcohol solution containing 120 mg of SDS and 30 wt% PEG by sonication for 30 minutes, followed by stirring for 60 minutes. A 34 wt% Teflon emulsion was added dropwise to the mixture and stirred for 15 minutes. However, precipitation occurred upon the addition of PTFE, preventing successful coating. The agglomerated solution is shown in Fig. 1a.

A carbon-free solution was prepared according to the formulation: a solution containing 34 wt% PTFE, 40 mL of isopropyl alcohol, 120 mg of SDS, and 30 wt% PEG was mixed in an ultrasonic bath for 30 minutes. Precipitation occurred in the solution (Fig. 1b). Experimental results indicated that this phenomenon was due to the dispersion conditions of PTFE and its interaction with surfactants.

Fig. 1. a) Aglomerer solutıon

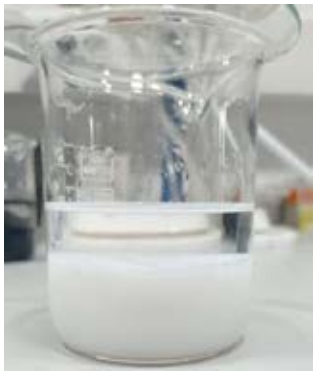

Fig. 1. b) Carbon -free solution

The cause of agglomeration was investigated, and the stability of PTFE in different solvents was examined. PTFE was dispersed in water and alcohol separately and left to stand. After one day, almost no agglomeration was observed in water, whereas in alcohol, PTFE agglomerated and precipitated within hours. It was determined that the PTFE dispersion was stabilized in water using a non-ionic surfactant. To better understand the precipitation issue observed in the alcohol medium and to analyze the composition of the dispersion, Thermogravimetric Analysis (TGA) was performed. This provided a more detailed understanding of the thermal behavior of the PTFE dispersion.

As a result, the type and amount of the non-ionic surfactant could not be precisely determined. Additionally, it was concluded that the precipitation issue arises from the instability of PTFE in alcohol and is related to the fact that the dispersion is stabilized in water.

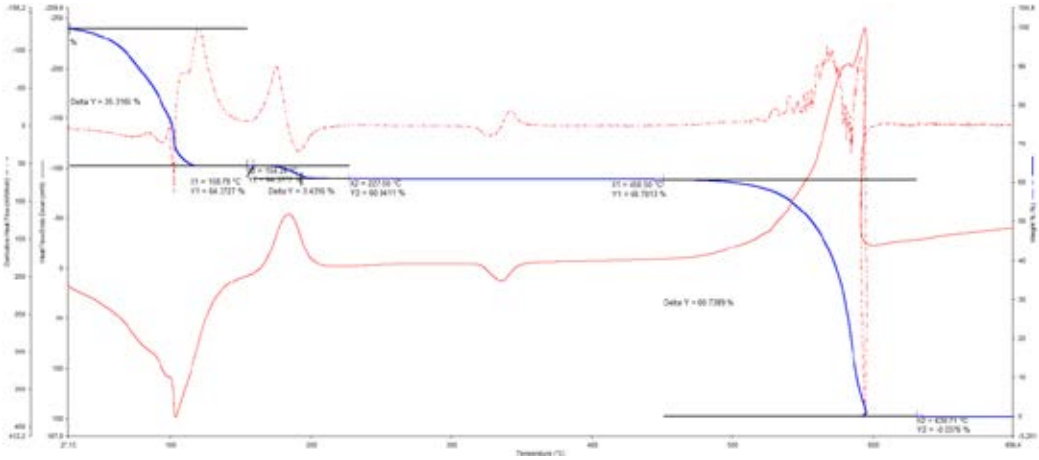

Fig. 2. PTFE's TGA and DTA analysis curve

The literature review on non-ionic surfactants examined their effects on the stabilization of PTFE dispersions and concluded that molecular structure and topology are key determining factors.[3] It was observed that the saturation level of the hydrophobic chain also influences stability, with TW80, which contains an unsaturated hydrophobic chain, providing better stabilization than TW60, which has a saturated hydrophobic chain. Additionally, surfactants with a lower critical micelle concentration (CMC) were found to enhance dispersion stability by forming a higher micelle density.
Based on these findings, Tween 40 was selected due to its suitable hydration balance and stabilization properties. Solutions containing 25 mL of water and 5 mL of PTFE were prepared with Tween 40 at volume ratios of 1.5%, 4.5%, 8%, and 16%. The mixtures were stirred on a magnetic stirrer for 40 minutes and then left to stand overnight. After the resting period, the most distinct phase separation was observed in the solution containing 4.5% TW40, while the most stable structure was exhibited by the solutions containing 8% TW40 and 16% TW40. The visual appearances of the solutions are presented in Fig. 3.

Fig. 3. a) 1,5% TW40

Fig. 3. b) 4,5% TW40

Fig. 3. c) 8% TW40

Fig. 3. d) 16% TW40

Ethanol (5 mL) was added to the solutions, stirred on a magnetic stirrer for 30 minutes, and then left to stand for 1 hour. Observations revealed that no agglomeration occurred in the solutions. This process was repeated twice, with no changes observed in the results. The solutions, with a total of 15 mL of ethanol added, were left to stand overnight, but no morphological changes or phase separation were detected. Subsequently, an additional 10 mL of ethanol was introduced, stirred for 20 minutes on a magnetic stirrer, and allowed to stand for 2 hours. At this stage, no changes were observed in the solutions.

Next, 50 mg of Vulcan XC-72 activated carbon was added to the solutions, which were then subjected to ultrasonic bath mixing for 1 hour. Upon removal from the ultrasonic bath, precipitation was observed in the solution containing 1.5% TW40. The solutions were left to stand overnight, and no phase separation was detected in those containing 4.5% and 8% TW40. The conditions of the carbon-added solutions are presented in Fig. 4.

Fig. 4. a) 1,5% TW40

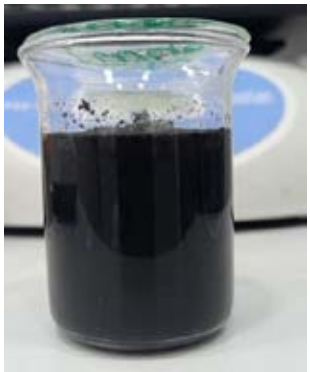

Fig. 4. b) 4,5% TW40

Fig. 4. c) 8% TW40

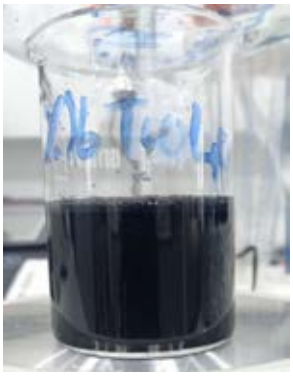

Fig. 4. d) 16% TW40

The coating was also applied to the carbon fabric by spraying and left to dry overnight in an oven at 105°C. The dried fabrics were then sintered at 350°C for 30 minutes. After sintering, the fabrics exhibited hydrophobic behavior, repelling water from their surface. The water interaction behavior of the fabrics is shown in Fig. 5.

Fig. 5. a) 4,5% TW40

Fig. 5. b) 8% TW40

Fig. 5. c) 34% PTFE 16% TW40

34 wt% PTFE, 16 wt% TW40, and 25 mL of distilled water were mixed on a magnetic stirrer for 15 minutes. Ethanol (a total of 25 mL) was then added gradually over 30 minutes while stirring. Subsequently, 50 mg of carbon was slowly introduced and mixed in an ultrasonic bath for 1 hour. A 2 mL coating was applied to the carbon fabric, which was then sintered at 350°C for 30 minutes, resulting in a coating mass of 124.35 mg. This confirmed that a stable solution was achieved. However, the dip-coating method did not yield the desired results, as a homogeneous and sufficient coating amount was not obtained.

CONCLUSION

In this study, the feasibility of using carbon fabric as a gas diffusion layer (GDL) in PEM fuel cells was investigated. It was determined that carbon fabric provides superior mechanical strength, gas distribution, and flexibility compared to carbon paper. However, to be used as a GDL, carbon fabric must be rendered hydrophobic. To achieve this, carbon-based coating solutions were prepared, and their stability was examined.

Due to the instability of PTFE in an alcohol medium, precipitation issues were encountered. To address this, TW40 was employed. The stability of solutions containing different TW40 concentrations was assessed, and solutions with 8% and 16% TW40 exhibited the highest stability. These solutions were used to coat carbon fabric, which was subsequently sintered at 350°C. The sintered fabrics demonstrated hydrophobic properties, repelling water from their surface.

In conclusion, the use of carbon fabric as a GDL is feasible, and TW40 has proven effective in stabilizing PTFE dispersion. This study offers a new perspective on the development and commercialization of PEM fuel cells. However, further research is needed to enhance the application of carbon fabric as a GDL. In particular, exploring different coating techniques and materials may further improve the performance of carbon fabric in fuel cell applications.

ABSTRACT
This study aims to recover and characterize Nafion membrane from used MEAs in PEMFCs through ethanol-based Soxhlet extraction. Recycling Nafion membranes is an economic necessity given their high cost and valuable structure. The recycling potential of ethanol as an environmentally friendly solvent has been evaluated, and the chemical and thermal structure of the recovered material has been examined using ATR-FTIR, UV-Vis spectroscopy, and Thermal Analysis methods. The results reveal that the recycled Nafion exhibits chemical and thermal properties similar to commercial Nafion and may have the potential for reuse in fuel cells. The ethanol-based recycling method presents an economically viable and environmentally friendly alternative for Nafion membranes.

Keywords: Proton exchange membrane, Nafion, Recycling, Soxhlet extraction

1. INTRODUCTION

Fuel cells hold strategic importance among clean energy technologies. Nafion is a fluorinated polymer that plays a central role as a proton exchange membrane (PEM), providing proton conductivity in hydrogen fuel cells [1]. Its chemical structure consists of a combination of a hydrophobic perfluorinated polymer backbone and side chains containing hydrophilic sulfonic acid groups. While Nafion membranes, a critical component of Proton Exchange Membrane Fuel Cells (PEMFCs), offer high performance, their production costs and used membrane waste pose significant problems in terms of economic and environmental sustainability. The high cost of new Nafion membranes makes recycling more economically attractive, while the waste of Nafion, a valuable material, is unacceptable in terms of resource efficiency. In this context, the recovery of used Nafion membranes has the potential to prevent both economic losses and reduce environmental impact. In the literature, it has been shown that Nafion membranes can be recycled by solvent-based methods [2]. In this study, the recovery and characterization of Nafion membranes using ethanol, an environmentally friendly solvent, were experimentally investigated. The aim is to evaluate the economic and environmental suitability of ethanol for Nafion recycling and the reuse potential of the recovered material.

2. MATERIALS AND METHODS

2.1. Materials

Used PEMFC MEA (Fig. 1.), commercial Nafion membrane reference, analytical grade ethanol, cellulose extraction cartridge were used. The extraction process was carried out with a Soxhlet apparatus (Fig. 2.), and a rotary evaporator and centrifuge were used for the separation process. Characterization analyses were performed by ATR-FTIR, UV-Vis spectroscopy, and Thermal Analysis.

Fig. 1. Used Membrane Electrode Assemblies (MEA)

Fig. 2. Soxhlet extractor

Fig. 3. Weighed membranes for efficiency calculation

2.2. Experimental Procedure

Soxhlet extraction method was used to recover the Nafion membrane from the used MEA sample. A weighed MEA sample of 3.6375 grams (Fig. 3.), was placed in a cellulose extraction cartridge and transferred to the Soxhlet apparatus.

270 ml of ethanol was added to the collection flask, and extraction was performed for 14 days. The obtained Nafion-ethanol solution was concentrated with a rotary evaporator and then catalyst separation was performed by centrifugation. The chemical structure of the recovered Nafion sample was analyzed by ATR-FTIR and UV-Vis spectroscopy, and its thermal stability was analyzed by TGA and DSC compared with commercial Nafion reference. In addition, the hydrophobicity of the recovered Nafion solution was evaluated by coating it on a glass slide using an airbrush method.

3. RESULTS AND DISCUSSION

ATR-FTIR spectra (Fig. 4.) (Fig. 5.) revealed that the recycled Nafion sample showed a high degree of similarity to commercial Nafion (Table 1.). The peaks at 1433 cm^{-1}, 1203 cm^{-1}, 1142 cm^{-1}, 1058 cm^{-1}, and 980 cm^{-1} were observed at similar positions and intensities in both samples [3]. This supports that the ethanol-based recycling method provides recovery while preserving the Nafion polymer structure. The Nafion sample coated with airbrush gave the closest results to the commercial reference. Hydrophobicity tests (Fig. 6.) showed that the surface properties of the recovered material were similar to Nafion [4]. Studies with Thermogravimetric Analysis (TGA) and Differential Scanning Calorimetry (DSC) showed that the thermal behavior of the recycled Nafion sample (Fig. 7.) significantly matched the Nafion TGA and DSC graphs in the literature [5]. This compatibility supports that the sample can be reused as a proton conductive membrane material. A Nafion solution dissolved in ethanol was analyzed using UV-Vis spectroscopy, with baseline measurements taken using ethanol as the reference. In the obtained spectrum (Fig. 8.), characteristic peaks corresponding to the recycled Nafion were observed, and these peaks were found to be consistent with the UV-Vis spectra reported in the literature. [6]

4. CONCLUSIONS

This study has shown that the ethanol-based Soxhlet extraction method can be an effective alternative for the economic and environmentally friendly recovery of Nafion membrane from used PEMFC MEAs. The recovered Nafion exhibits similar chemical and thermal properties to commercial Nafion and has the potential for reuse in fuel cells. The use of ethanol as a solvent provides a safer and more environmentally sensitive recycling process, while the recovery of a valuable polymer such as Nafion provides significant advantages in terms of economic and resource efficiency. In future studies, the reuse potential of recycled Nafion membranes should be evaluated more comprehensively with detailed characterization analyses such as proton conductivity, mechanical properties, and fuel cell performance tests.

ABSTRACT
In this study, a silver-deposited carbon fiber electrode (Ag/AC) prepared by the electroless deposition method was investigated for its redox processes and electrocatalytic activities during the oxidation of methanol and sodium borohydride in alkaline solutions. The Ag/AC catalyst was characterized by X-ray diffraction (XRD), energy dispersive X-ray analysis (EDAX), scanning transmission electron microscopy (SEM and TEM), and electrochemical voltammetry. The electrocatalytic performance of the Ag/AC catalyst for the oxidation of methanol and sodium borohydride was evaluated by cyclic voltammetry. The anodic peak current density for sodium borohydride oxidation on the Ag/AC catalyst was found to be three times higher than that for methanol. The peak current density of methanol oxidation decreased with increasing methanol concentration, but the current density of sodium borohydride increased with increasing borohydride concentration. The maximum current density was reached at 10 M sodium borohydride concentration and remained stable. Sodium borohydride oxidation shows the highest activity on Ag/AC electrode in alkaline medium.

Keywords: Methanol and sodium borohydride, silver, alkaline fuel cells

1. INTRODUCTION
Recently, there has been renewed interest in alkaline fuel cells due to the use of non-noble metal catalysts and the potential for low-cost mass production, in contrast to other types of fuel cells [1,2]. In an alkaline fuel cell, the chemical energy of fuels (such as hydrogen, hydrazine, or alcohols) and oxidants (such as oxygen) can be converted directly and efficiently into electricity. This flexibility in fuel choice makes alkaline fuel cells a promising power source for a variety of portable electronic devices [3,4]. A key advantage of alkaline fuel cells is the replacement of platinum or platinum-based electrocatalysts with non-platinum alternatives, positioning alkaline fuel cells as a potentially more affordable technology compared to PEMFCs and DMFCs. It is widely accepted that the oxygen reduction reaction (ORR) is more straightforward in alkaline environments than in acidic conditions, supporting the viability of using less expensive catalysts instead of platinum. Among these non-platinum catalysts, silver nanoparticles stand out as a promising substitute for platinum due to their high catalytic activity for ORR in alkaline media. Silver is known to have the highest electrical conductivity of any element and is about 100 times more affordable than platinum [1]. Various methods, including electroless plating [5,6], chemical reduction [3-9], electrochemical deposition [10], and ion beam assisted deposition [11], have been developed to fabricate silver nanostructures. However, only a few studies have focused on the facile synthesis of silver nanoparticles on carbon substrates, and a more comprehensive understanding of their electrochemical performance in alkaline electrolytes is still needed. The objective of this study is to compare the electrochemical oxidation of methanol and sodium borohydride over Ag/AC catalyst in alkaline solution.

2. MATERIALS AND METHODS
2.1. Synthesis of Vucan XC-72 supported nano-Ag catalyst (Ag/AC)
The potassium hydroxide, methanol and sodium borohydride that are used in this work were analytical grade of Merck origin and were used without further purification. Vulcan XC-72 carbon (S_{BET} = 230 m^2 g^{-1}). was procured from Cabot Corp. All other reagents used were of analytical grade. For the classical preparation method, 1.573 g $AgNO_3$ (MW: 169,88 $g.mol^{-1}$,99.9% purity, Alfa Aesar) were dissolved in 100 mL of ethylene glycol (puriss. p.a.,≥99.5% Fluka). Then, pH of the solution was adjusted to 11 by adding dropwise solution of 1M NaOH in ethylene glycol. Carbon Vulcan XC-72 was thermally treated for 4 h at 600 ^oC under nitrogen and then it was added to the solution (1000 mg) and the mixture was ultrasonically homogenized for 5min and heated until 120 ^oC, then 4 mmol $NaBH_4$ was slowly added to the mixture. The mixture was mixed mechanically for 16h and then suddenly cooled until room temperature. After preparation, catalytic powders were washed with acetone, abundantly rinsed with ultra pure water, and centrifuged with 5000 rpm and then they were dried in a vacuum oven at room temperature.
2.2. Preparation of the working electrode
The catalyst inks were first homogenized within 1-2 hours using a homogenizer. Then the sample of 20µL catalyst ink (16gAg/cm2) was deposited on the glassy carbon surface to ensure the smooth thin film catalyst coating. To fix the catalyst on the glassy carbon surface, 20 µL of diluted 0.01 wt% Nafion solution was deposited on the surface of the catalyst layer.
2.3. Electrochemical measurements
The cyclic voltammetry experiments were conducted in a conventional three-electrode system, with a saturated calomel electrode (SCE) in a Luggin capillary compartment and platinum wire as the reference electrode and the counter

electrode, respectively. The working electrode was prepared by coating the catalyst ink on disk-type graphite, surface area of 1 cm^2. All the potential in this manuscript was relative to that of the SCE reference electrode. All electrochemical experiments were carried out using a CHI 660C potentiostat at room temperature (24±3 °C). Nitrogen was bubbled for 5 min in 30 ml solution before the measurements. The cell was cycled between −1.2 and 1.1V at a 100 mV/s sweep rate.

2.4. Catalyst surface characterization

X-ray diffraction (XRD) analysis was carried out with the use of a Theta–Theta Scintag powder diffractometer equipped with aCuK α source (λ = 1.5406 °A). High-resolution scanning electron microscope (SEM) micrographs of the catalyst powders were recorded with a JEOL JSM 6700F. Catalyst compositions were determined by energy dispersive X-ray spectroscopy (EDS) elemental analysis by means of an X-ray LINK detector with a Pentafet window coupled to a scanning electron microscope (JEOL JSM-6300). Unless otherwise specified, all catalyst compositions presented in the text were those resolved by EDS analysis were performed with a Philips UHV-5600 apparatus with an Al K α emission source.

3. RESULTS AND DISCUSSION

3.1. SEM, EDX and XRD Characterizations of Ag/AC

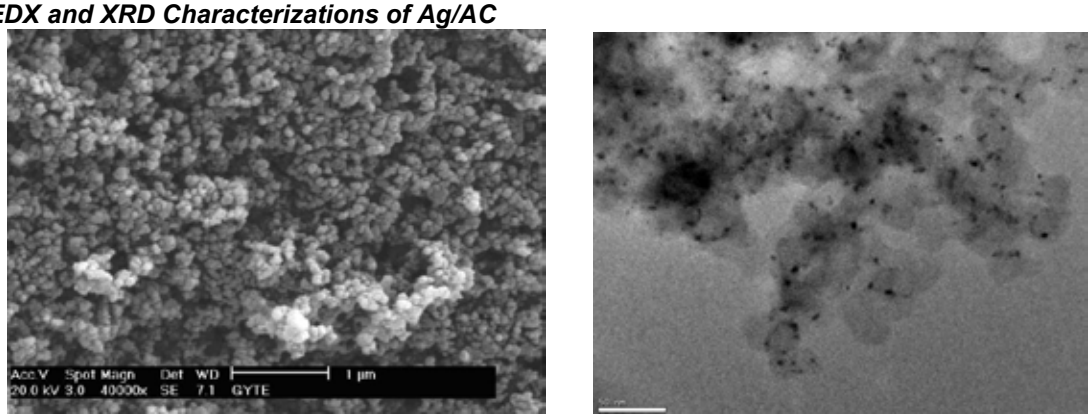

Fig.1. (a) SEM (b) TEM images of Ag/AC

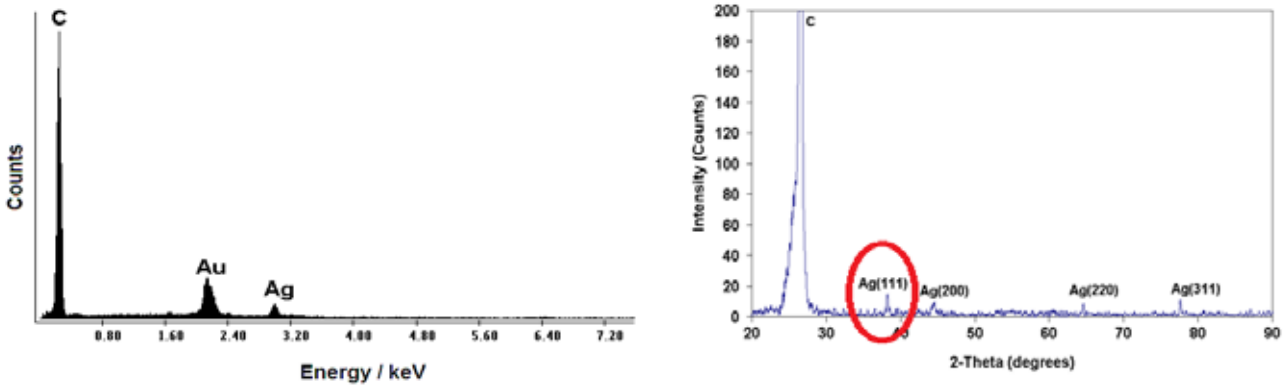
The micrographs presented in Fig. 1 (a) and (b) display the morphology of the electrodeposited Ag obtained by SEM and TEM. It is observed from the Fig 1(b) that the carbon surface was deposited by Ag particles which are highly dispersed, have high multiplicity and they are regular in shape. In Fig. 2a displays the EDX analysis that has confirmed the presence of Ag with intensity. The appearance of the carbon peak was a result of the activated carbon on which Ag nanoparticles were deposited. The gold peak at around 2 keV results from the grid used for the analysis. The EDX analysis has shown strong evidence of homogeneously dispersed Ag nanocrystals at the optimum condition.



(a) (b)

Fig. 2. (a) The EDX analysis (b) The XRD pattern of Ni/CF catalyst at the optimum condition

X-ray diffraction patterns of the anode catalysts employed in this study were shown in Fig. 2b. fcc Ag have distinctive diffractions and hence can be differentiated. The major diffraction peaks of Ag nanoparticles were observed. The VulcanXC-72 show a typical peak of (002) reflection of graphiteat 26.34° . The peaks at 38.18°, 44.52°, 63.08° and 77.58° can be assigned to (111), (200), (220), (311) reflection of fcc phase of Ag. The average particle size of the catalyst was calculated from XRD diffraction peaks using Scherer's equation [46]. Ag particle sizes are calculated according to the diffraction peak of Ag (111) that was found to be in the range of 3.2 nm.

3.2. Electrochemical measurements of VulcanXC supported Ag electrode in 2M KOH

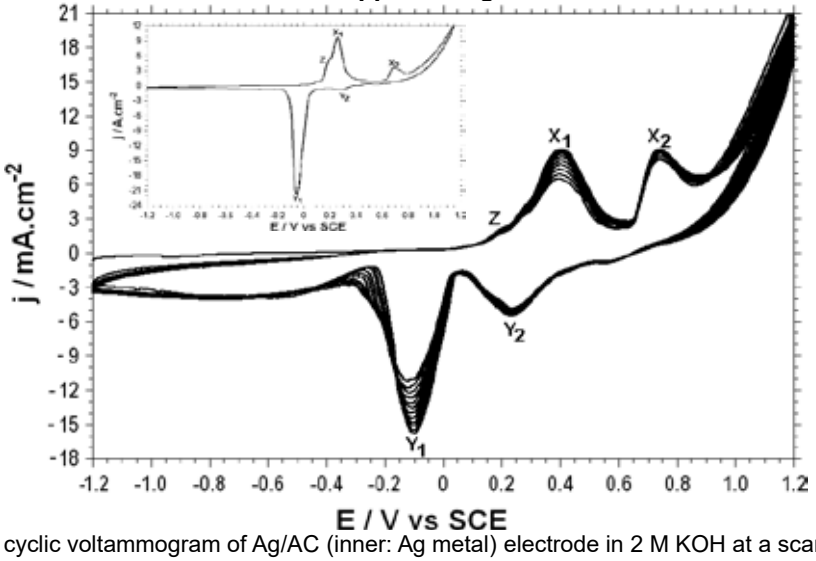


Fig 3. Consecutive cyclic voltammogram of Ag/AC (inner: Ag metal) electrode in 2 M KOH at a scan rate of 100 mVs^{-1}

The overall oxidation process involves a successive formation of Ag_2O and AgO according to the reactions:

$$2Ag + 2OH^- \leftrightarrow Ag_2O + H_2O + 2e^- \quad (1)$$

$$Ag_2O + 2OH^- \leftrightarrow 2AgO + H_2O + 2e^- \quad (2)$$

A competing process to Ag_2O formation is a Ag dissolution according to the reaction

$$Ag + 2OH^- \rightarrow [Ag(OH)_2]^- + e^- \quad (3)$$

The characteristic anodic/cathodic peaks X_1/Y_1 and X_2/Y_2 correspond to the formation/reduction of the Ag_2O and AgO phases. The observed increase of current peaks of the cyclic voltammogram for the latter cycle is caused by the increase of the surface roughness during the first oxidation–reduction cycle. In this case at the potential of prepeak Z several monolayers of Ag(I) hydroxide are formed, and above them a thicker and more porous layer of Ag_2O grows. In inner figure, in the first cycle a pair of redox peaks appearing at 0.4 and -0.11 mV/SCE was assigned to Ag/Ag^+ redox couple and a pair of redox peaks appearing at 0.74 and 0.23 mV/SCE was also assigned Ag^+/Ag^{2+} redox couple, respectively, in alkaline media recorded at a potential sweep rate of 100mVs^{-1}.

3.3. Electrocatalytic Oxidation of Methanol and Sodium Borohydride on VulcanXC supported Ag electrode

Effect of methanol and sodium borohydride concentrations on CVs of Ag/AC with the potential sweep rate of 100 mV/s was investigated and results are presented in Fig. 5 and 6. Methanol concentrations were changed from 1mmol to 10 mmol. It is shown in this figure that the methanol oxidation peak current density decreased with increasing methanol concentration. Thus, the adsorption of the oxidation products at the electrode surface causes the hindrance of further oxidation. Either anodic or cathodic currents decreased with the methanol concentrations between -1.2 to 1.2V vs SCE.

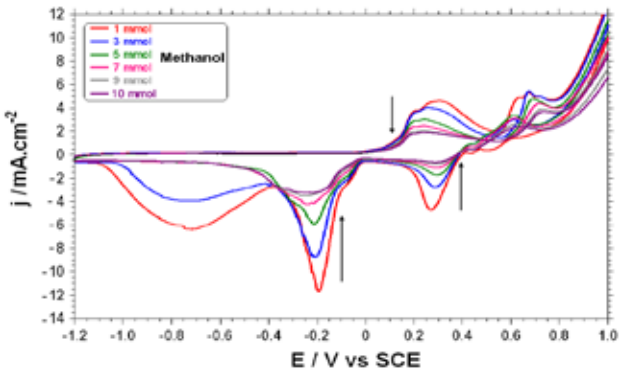

Fig.5. Cyclic voltammogram of methanol oxidation on Ag/AC catalyst in 2M KOH (at 100mVs^{-1} , 298 K)

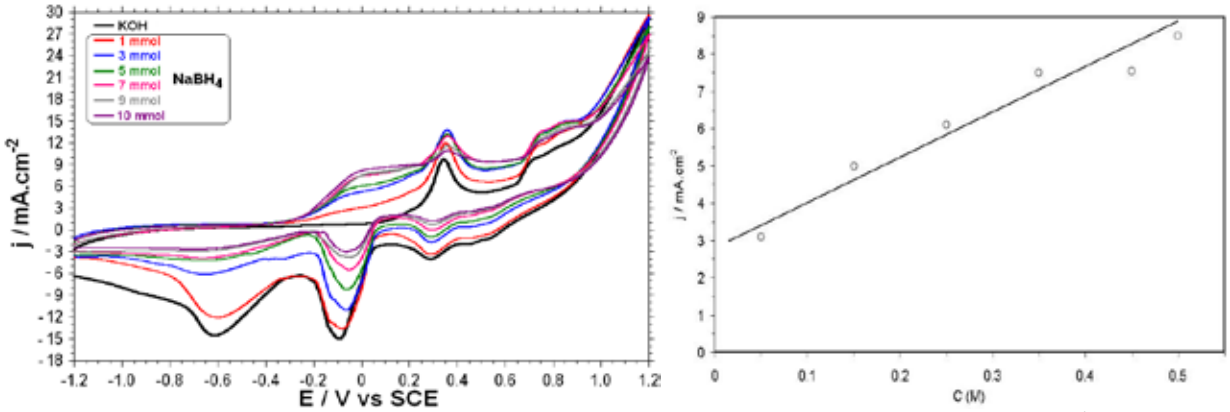

Fig.6. **(a)** Cyclic voltammogram of borohydride oxidation on Ag/AC catalyst in 2M KOH at 100mVs^{-1}, 298 K.
(b) Dependency of the anodic peak current of $NaBH_4$ concentrations

But as seen in Fig.6 the anodic current at 0.4 V in the positive sweep was proportional to the amounts of $NaBH_4$ and any increase in the amounts of $NaBH_4$ caused an almost proportional linear enhancement of the anodic current (inner line). So, electrooxidation of $NaBH_4$ on Ag/AC seems to be certain.

4. CONCLUSIONS

The oxidation reactions for sodium borohydride and methanol are given below

Borohydride $BH_4^- + 8OH^- \rightarrow BO_2^- + 6H_2O + 8e^-$

Methanol $CH_3OH + 2OH^- \rightarrow HCHO + 2H_2O + 2e^-$

$HCHO + 2OH^- \rightarrow HCOOH + H_2O + 2e^-$

$HCOOH + 2OH^- \rightarrow CO_2 + 2H_2O + 2e^-$

The current density of methanol decreased with increasing concentration to 1M and 10M. This result can be attributed to formation of the carbonate at the surface of catalyst [12-13].
The current density of sodium borohydride increased with increasing of borohydride concentrations. Maximum current density was achieved at 10M of the sodium borohydride concentration and remained stable.
The sodium borohydride oxidation shows the highest activity on Ag/AC electrode in alkaline medium.

ABSTRACT

Due to many factors such as increasing industrialization, technological developments and population growth, the world's energy demand is constantly increasing and existing resources are no longer sufficient to meet this need. For this reason, the search for alternative energy sources has accelerated especially in recent years and this has directed countries towards alternative renewable energy sources. Nowadays, countries are forming their strategies, policies and goals regarding the energy sector with a focus on renewable energy and are making serious investments in this field. Due to the current importance of the subject, this study attempts to determine which alternative renewable energy source would be appropriate for certain regions in the hydrogen energy supply chain in Turkey. Six renewable energy alternatives are considered: wind, solar, geothermal, biomass, wave and hydroelectric energy. First of all, the weights of the criteria and sub-criteria used in determining renewable alternative energy sources are calculated using the Fermatean Fuzzy Analytical Hierarchy Process (FF-AHP) method. Then, optimal alternatives among renewable alternative energy sources are determined with the Fermatean Fuzzy Weighted Product Method (FF-WPM). When the results of the study aref analyzed, it is clearly seen that Turkey should focus on hydroelectric and wind energy for Istanbul in its renewable energy investments.

Keywords: Renewable Energy, Hydrogen Supply Chain, Multi-Criteria Decision Making, Fermatean Fuzzy AHP, Fermatean Fuzzy WPM

1. INTRODUCTION

Recently, the rapid increase in the world population causes a constant increase in the amount of energy needed. However, traditional energy sources such as coal, oil and natural gas are limited in nature and are insufficient to meet this increasing energy need. For this reason, countries are turning to renewable alternative energy sources. Today, the three main factors that lead countries to seek alternative energy sources and thus make renewable energy so popular can be defined as follows; Energy security, Economic effects, CO_2 emission reductions [1]. This study aims to determine which energy source would be more appropriate to invest in certain regions in the renewable energy sector in Turkey, based on the increasing importance of renewable energy in the world. Dumrul vd. [2], emphasized that ensuring environmental improvement at national and global levels is a critical issue in order to create an effective energy policy, and they used the (IF-EDAS) method to find the best renewable energy alternative for Turkey and concluded that the best alternative renewable energy source for Turkey is solar energy. According to Özkale vd. [3] examined the total performance scores of renewable energy types obtained through PROMETHEE, one of the Multi-Criteria Decision Making (MCDM) methods for Turkey. As a result, they showed that each type of energy has its own advantages and disadvantages. All criteria are obtained using the PROMETHEE method and according to the general results, hydroelectricity ranked first, followed by solar, wind, biomass and finally geothermal energy. Deveci vd. [4] proposed a new performance metric to eliminate the disadvantages of the existing IVIF-CODAS methods in the literature and applied a multi-criteria decision-making method to rank renewable energy alternatives. As a result, they showed that wind and solar energy stand out with higher evaluation scores than other sources. The main contribution of the study, which is different from the literature where there are similar studies in the literature, is to make a suggestion that enables more reliable investment decisions to be made in the field of renewable energy for each of the determined regions separately. In this study, alternative renewable energy sources are applied separately for the regions and the basis for making investment decisions is strengthened. The important thing for the renewable energy source selection problem is to determine the relevant decision criteria and sub-criteria [5]. FF-AHP is used to weight the criteria and sub-criteria determined for renewable energy alternatives, and FF-WPM method is applied to determine the most suitable alternative energy source for the regions by ranking the renewable energy alternatives. Although there are studies using various methods in determining alternative sources in the field of renewable energy, this study has tried to strengthen the basis for making investment decisions by finding the most suitable alternative energy sources for specific regions.

2. MATERIALS AND METHODS

Fermatean Fuzzy Sets (FFS) can more easily handle uncertain information in the decision-making process [7]. It provides a more flexible solution in determining the uncertainty of information since it covers membership and non-membership

degrees in a wider area compared to intuitionistic and Pythagorean fuzzy sets [6]. In this study, results are obtained in the Fermatean fuzzy environment, which is less used compared to the literature. Using FF-WPM, which is a relatively new approach in the literature for selecting alternative renewable energy sources, Fermatean Fuzzy Set is used as a fuzzy set. FF-AHP solution method is presented to determine the weights of the criteria and sub-criteria.

2.1. FF-AHP Method

Step 1: A hierarchical structure is established by determining the criteria and alternatives.
Step 2: The comparison matrix $P = (p_{ij})_{mxm}$ is created by using expert opinions according to the language terms in Table 1.

$$P = \begin{bmatrix} 1 & p_{12} & \cdots & p_{1m} \\ p_{21} & 1 & \cdots & p_{2m} \\ \vdots & \vdots & \ddots & \vdots \\ p_{m1} & p_{m2} & \cdots & 1 \end{bmatrix} \tag{1}$$

Step 3: The expert opinions are verified to be consistent in each pair of comparison matrices (P). The net numbers are compared with the FFNs given in Table 1 using the Saaty scale. Then, Saaty's classical consistency formula is applied.

Step 4: The FFWG aggregation operator is applied to the aggregated opinions of each expert in accordance with the created comparison matrix.

Table 1. Linguistic scale for FF-AHP.

SI	*Definition*	*FFN*	*SI*	*FFN*
9	Absolutely more importance (AMI)	(0.970, 0.233)	8	(0.929, 0.121)
7	Very high importance (VHI)	(0.900, 0.307)	6	(0.844, 0.107)
5	High importance (HI)	(0.794, 0.083)	4	(0.737, 0.068)
3	Slightly high importance (SHI)	(0.670, 0.091)	2	(0.585, 0.059)
1	Equal importance (EI)	(0.465, 0.082)	1/2	(0.369, 0.062)
1/3	Slightly low importance (SLI)	(0.322, 0.038)	1/4	(0.293, 0.054)
1/5	Low importance (LI)	(0.272, 0.050)	1/6	(0.256,0.048)
1/7	Very low importance (VLI)	(0.243, 0.040)	1/8	(0.233, 0.053)
1/9	Absolutely low importance (ALI)	(0.224, 0.050)		

Step 5: The FFN weights of the criteria and sub-criteria are estimated. The sum of each criterion weight (w) is equal to one.

2.2. FF-WPM Method

For an MCDM problem specified in the Fermatean fuzzy environment, suppose that there are m alternatives, S_i $(i = 1,2,\dots,m)$ and n criteria C_j $(j = 1,2,\dots,n)$ and the criterion weight vector is $w = (w_1, w_2, \dots, w_n)^T$ and $0 \le W_j \le 1$, $j = 1,2,\dots,n$ and $\sum_{j=1}^{n} W_j = 1$.

Step 1: Fermatean fuzzy decision matrix is created.

$$R = (X_{ij})_{mxn} = \begin{pmatrix} u_{11}, v_{11} & u_{12}, v_{12} & \cdots & u_{1n}, v_{1n} \\ u_{21}, v_{21} & u_{22}, v_{22} & \cdots & u_{2n}, v_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ u_{m1}, v_{m1} & u_{m2}, v_{m2} & \cdots & u_{mn}, v_{mn} \end{pmatrix} \tag{2}$$

Here each of the elements $X_{ij} = u_{ij}, v_{ij}$ is an FFN, which means that if the alternative S_i satisfies the attributes C_j the degree will be the value u_{ij} and if the alternative S_i does not satisfy the attributes C_j the degree will be the value v_{ij}.
Step 2: It is to normalize the matrix $\mathrm{R} = (X_{ij})_{mxn}$ by a linear method. The decision matrix R, normalize matris is transformed into the normalized matrix $\bar{R}$. The criteria are classified into a subset of benefit criteria, B and a subset of cost criteria, C. The linear normalization for any $j \in \boldsymbol{B}$ and the linear normalization for any $j \in \boldsymbol{C}$ are defined as follows, respectively:

$$\bar{X}_{ij} = \frac{X_{ij}}{max_i X_{ij}}\ , \tag{3}$$

$$\bar{X}_{ij} = \frac{min_i X_{ij}}{X_{ij}}, \tag{4}$$

Step 3: The total relative importance of alternative *i* according to WPM is denoted as Q_i and is defined as:

$$\bar{Q}_i = \prod_{J=1}^{n} X_{ij}{}^{w_j} \tag{5}$$

Step 4: In the last step, the score functions (SF) for $\bar{Q}_i$ $(i = 1,2, \dots, m)$ are calculated and the final rankings of the alternatives are determined according to the decreasing order of $\bar{Q}_i$ $(i = 1,2, \dots, m)$.

$$SF = (\mu_T^3 - \mathrm{v}_T^3\ ) \tag{6}$$

Table 2. Linguistic terms and FF numbers.

Linguistic terms		FF numbers
E	Extremely Important (E)	0.975 0.10
V	Very Important (V)	0.85 0.20
I	Important (I)	0.70 0.35
M	Moderately Imported (M)	0.55 0.50
S	Slightly Important (S)	0.35 0.70
N	Not Important (N)	0.20 0.85
U	Extremely Unimportant (U)	0.10 0.975

3. RESULTS AND DISCUSSION

In this study, renewable energy alternatives in Turkey's grid-based hydrogen supply chain are investigated in order to evaluate the applicability and effectiveness of the proposed method. For the evaluation, there is a decision-making group consisting of two academics who have been working in the field of energy for many years and an expert working in the energy sector. There are five main criteria and 21 sub-criteria from the literature for the decision-making group to choose renewable energy types. The weight of each criterion in a decision problem is not equal. The importance of the criteria varies depending on the decision maker. As a result, the values assigned to the criteria by each decision maker should be aggregated. At this point, the weights of the 21 criteria are calculated. Each expert evaluates the criteria using the linguistic terms listed in Table 1. The criterion weights are calculated according to the evaluation results. Then, the weighted combined decision matrix is obtained. The normalized decision matrix is created according to Equations 3 and 4. Exponent calculations are made according to Equation 5 and the score function, the results of which are given in Table 4, is calculated according to Equation 6. The results in Table 4 are given for the province of Istanbul in Turkey. In the continuation of the study, results will be obtained according to expert evaluations for Izmir and Ankara.

Table 4. Numerical results obtained by FF-WPM.

Alternatives	FF-WPM		Score	Rank
S_1	0.71222	0.79774	-0.14641	3
S_2	0.71334	0.79833	-0.1458197	2
S_3	0.68802	0.80226	-0.19065	6
S_4	0.70592	0.79883	-0.1579816	5
S_5	0.71119	0.80084	-0.1538957	4
S_6	0.72344	0.79588	-0.125498	1

According to the results, the renewable energy alternatives with the highest score function according to the values in Table 4 are hydroelectric energy in the first place. Then, respectively, solar energy, wind energy, wave, biomass energy and geothermal energy are in the sixth place. It is concluded that the best renewable energy alternative that will affect Turkey's sustainable development is "hydroelectric energy" for Istanbul.

4. CONCLUSIONS

In this study, a hybrid model is proposed to determine which renewable energy sources should be used on a grid basis in Turkey. Renewable energy sources will be integrated into the HSC design in the transportation sector in 2050, which is considered the earliest year in which this potential can be achieved. In the proposed hybrid model, the FF-AHP method is used to calculate the criteria weights and the FF-WPM method is used in energy selection since it can take into account many time-varying criteria such as renewable energy types and priorities. According to the results, the main criterion with the highest importance level is Environmental (0.656 0.108) from Technical, Economic, Social, Environmental and Political main criteria. Among the sub-criteria, Pollutant Emission (C16) sub-criterion has the highest importance with the weight of 0.124. Calculations will be made by increasing the number of experts for other regions of Turkey, and it is of great importance for Turkey to turn to more renewable energy sources and determine suitable resources.

ABSTRACT
This work presents an in-depth investigation of nanocone-shaped Ni–Pt alloy coatings, produced via galvanostatic electrodeposition from chloride-based baths with varying Pt ion concentrations (0.5, 1, 2, 5, and 10 mM). By including NH_4Cl as a crystal growth modifier, lateral growth was selectively inhibited, leading to the formation of sharply defined conical structures. X-ray diffraction (XRD) revealed predominantly Ni(200) reflections, with no distinct Pt-specific peaks, suggesting that Pt is either incorporated into the Ni lattice substitutionally or dispersed as nanoclusters below the detection limit. Energy-dispersive X-ray spectroscopy (EDS) and X-ray fluorescence (XRF) analyses confirmed the uniform distribution of Pt within the cones, while scanning electron microscopy (SEM) imaging showed that all samples exhibited a high density of cone-like structures; however, the addition of Pt slightly changed the cone dimensions by making them marginally shorter and more rounded at higher Pt loadings. The electrocatalytic performance of these Ni–Pt nanocones for hydrogen evolution was assessed by chronopotentiometry and registered overpotentials progressively decreased as Pt content increased: pure Ni coatings stabilized near −1.50 V after 1800 s, while the highest Pt loading (10 mM) achieved a value around −1.05 V, corresponding to an improvement of approximately 450 mV. These findings highlight that the strategic introduction of Pt into Ni nanocones, combined with a tailored electrodeposition process, produces robust alloys with significantly improved HER activity. As a result, Ni–Pt nanoconical electrodes stand out as promising candidates for advanced water-splitting applications in alkaline media.

Keywords: Ni–Pt alloys, electrodeposition, nanocones, catalytic activity, hydrogen evolution reaction

1. INTRODUCTION

Electrochemical synthesis of nanostructured materials has become increasingly important in electrocatalysis due to their high surface area and enhanced catalytic properties. One particularly promising approach involves electrodepositing transition metal nanocones, offering a combination of high surface-to-volume ratio, mechanical stability, and catalytic effectiveness. Various strategies exist for synthesizing nanocones, including template-assisted deposition and direct electrodeposition methods employing crystal modifiers to control crystal growth direction [1].

In electrodeposition, precise optimization of bath parameters is crucial to achieving directional crystallite growth, which favors the formation of conical nanostructures [2]. Nickel-based nanocones, in particular, have attracted significant attention due to their good catalytic activity and corrosion resistance in alkaline media. Modifying these structures with noble metals such as rhodium or platinum can further enhance their electrocatalytic performance .Recent studies demonstrated that decorating Ni cones with a thin Rh layer significantly improved catalytic activity for hydrogen evolution [3] . Similarly, porous Ni–Pt alloys produced via molten salt electrodeposition exhibited high catalytic performance in alkaline HER/OER processes due to the uniform distribution of Pt [4]. Inspired by these findings, we propose synthesizing Ni–Pt alloy nanocones through electrodeposition from aqueous chloride solutions. This approach ensures Pt dispersion throughout the volume, preventing catalytic deactivation due to surface degradation.

2. MATERIALS AND METHODS

Nickel cones were galvanostatically electrodeposited on chemically polished copper substrates (2.8 cm² area). The electrolyte consisted of 200 g/L $NiCl_2$, 100 g/L H_3BO_3, and 40 g/L NH_4Cl as a crystal modifier. Pt ions were introduced into the bath at concentrations of 0.5, 1, 2, 5, and 10 mM as aqueous solutions. Electrodeposition was conducted at 50°C for 20 min at a current density of 20 mA/cm². Platinum foil served as the anode, while copper substrates were used as cathodes.The synthesis were performed with a BioLogic SP-200 potentiostat and EC-LAB software. Post-deposition, the alloys were cleaned in deionized water and air-dried. Elemental composition was determined via XRF (Rigaku Rimini) with a Palladium lamp, and phase composition was analyzed by XRD (Rigaku MiniFlex II) using a copper tube (λ = 1.54059), comparing diffractograms to ICDD database cards. SEM images were captured using a Hitachi Su-70 scanning microscope. The water-splitting ability of the nanoconical Ni-Pt coatings was tested by chronopotentiometry in a 1 M NaOH solution and Tafel slope estimation in linear range.

3. RESULTS AND DISCUSSION

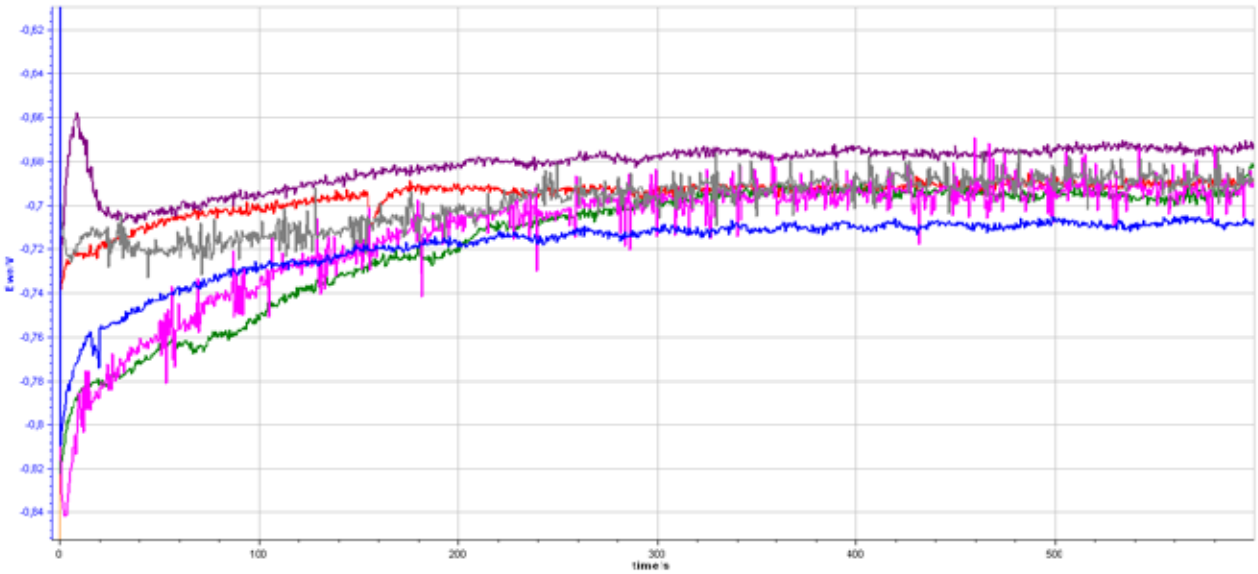

Fig.1. a) Chronopotentiometric curves registered in Ni and Ni-Pt solutions after application of constant current density: -10 mAcm^{-2}.

It can be seen that the addition of the Pt into Ni electrolyte is not significantly modyfing the registered potential value of deposition of alloy. The blank Ni solution (blue line) reach the stable potential value of -0,73 V after 200 seconds. Each addition of Pt ions (0.5, 1, 2, 5, and 10 mM) were slightly decreasing the registered value to – 0.68 V, which is related to the lower deposition overpotential. It can be also noted that, based on the previously performed research, the selected system is able to provide highly-structured nanoconical morphology, which is significantly increasing the surface area of sample, and it can also shift the registered potential value towards more positive regime. Samples after deposition were cleaned, dried and measured their mass, which allow to determine the average thickness of obtained layers, which oscillated between 2-5 um. The crystallographical analysis of obtained Ni and Ni-Pt nanoconical layers were presented on Figure 2.

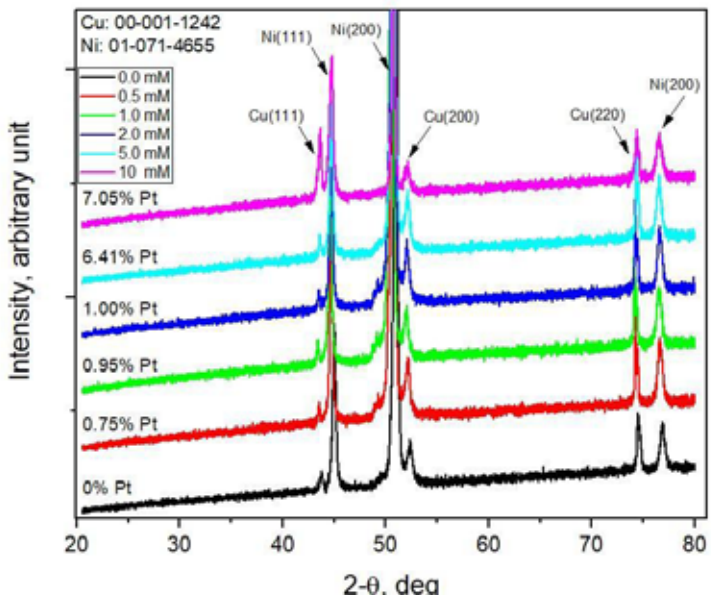

Fig. 2. XRD spectra obtained for Ni nanoconical structures with different addition of the Pt ions in electrolyte. Scan range: 20-80 degrees, scan speed: 0.5 deg/min.

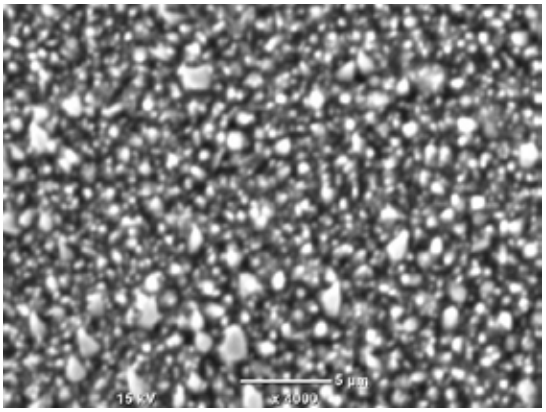
The presented X-ray diffraction (XRD) patterns, the predominant reflections originate from nickel, with the Ni(200) peak standing out as the most intense and well-defined feature, suggesting a strong out-of-plane crystallographic orientation in the deposited Ni-based films. The relatively weaker Ni(111) reflection is also discernible, but the intensity ratio indicates that the film growth conditions favor the (200) texture. Notably, the copper substrate contributes characteristic Cu(111) and Cu(200) peaks, which remain visible through the thin Ni–Pt alloy layers, underscoring the nanometric thickness of these coatings. Although platinum was added to the electrodeposition bath, its concentration in the resulting Ni–Pt alloy films appears to be minimal—so low that no additional diffraction peaks attributable to distinct Pt-rich phases are discernible within this diffractogram. X-ray fluorescence (XRF) and energy-dispersive X-ray spectroscopy (EDS) measurements confirm the presence of Pt at varying concentrations that parallel the nominal bath compositions, yet the crystallographic signatures remain overwhelmingly dominated by Ni reflections. These findings collectively suggest that Pt, while incorporated in small amounts, does not disrupt the

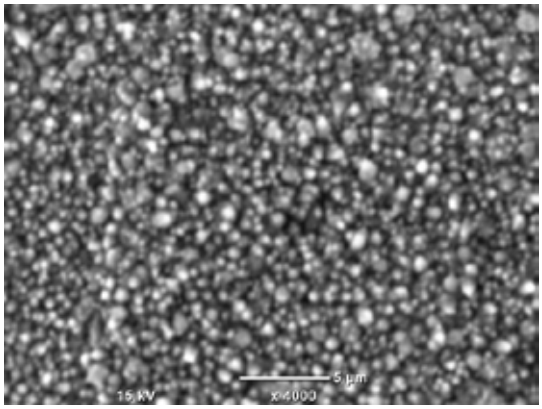
primary fcc Ni lattice to the extent of generating new detectable Bragg peaks, nor does it significantly shift the existing nickel reflections. Instead, the Pt likely enters substitutional sites within the Ni matrix or resides in highly dispersed clusters below the detection threshold for this diffractogram. Morphology of layers are presented on Table 1.

Table 1. Nickel nanostructures obtained by electrodeposition with different addition of Pt ions in electrolyte. Magnification: 4000X

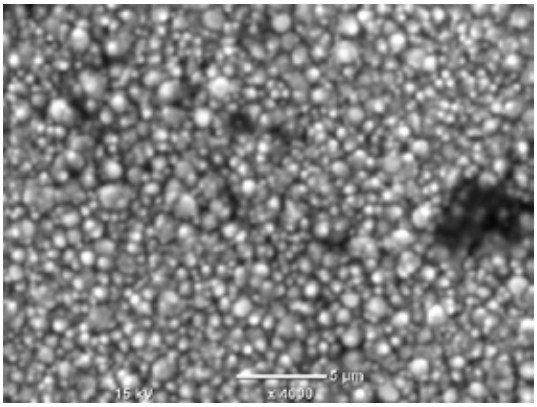
Nickel Nanoconical structures



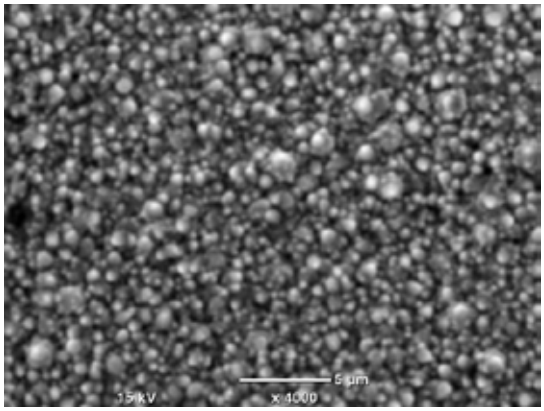
Ni - Pt Nanoconical structures – 0.95% Pt



Ni - Pt Nanoconical structures – 6.41 % Pt



Ni - Pt Nanoconical structures – 7.05% Pt



In the SEM images, all samples show a high density of tiny, cone-like structures that cover the surface. This distinctive “nanoconic” shape arises partly because a crystal growth modifier (NH_4Cl) is added to the plating solution, which selectively slows down growth in the horizontal direction. As a result, the material tends to build upward more readily, creating the pointed structures. In the pure nickel sample, these cones have fairly uniform heights and diameters and are spread evenly across the surface. When a small amount of platinum (around 0.95 wt%) is introduced, the general conical appearance is still there, but there is a slight increase in variation of cone size, indicating that even a minor Pt addition can alter local growth conditions. As more platinum is added (6.41 wt% and 7.05 wt%), you still see a dense layer of cones, yet some changes are noticeable: the cones look a bit shorter, and their tips appear more rounded. This is a sign that higher Pt content—and the way it interacts with the nickel—affects how the surface layers form, likely by changing the balance of surface energies and growth rates. These chemical and surface modification should led to modification of the catalytic activity of layers in hydrogen evolution reaction.

In the chronopotentiometric tests for hydrogen evolution in 1 M NaOH at a constant current density of −10 mA cm^{-2}, the overpotential is clearly reduced with increasing platinum content in the Ni–Pt nanoconical electrodes. For example, the pure Ni sample (blue curve) stabilizes at approximately −1.50 V after 1800 s, whereas the electrode containing 0.5 mM Pt (green) reaches around −1.40 V. Progressively higher Pt concentrations shift the potential to even less negative values: the 1 mM Pt sample (red) plateaus near −1.35 V, the 2 mM Pt sample (purple) around −1.30 V, and the 5 mM Pt sample (pink) roughly −1.20 V. Notably, the 10 mM Pt electrode (silver) exhibits a final potential close to −1.05 V, representing nearly a 450 mV improvement compared to pure Ni. This progressive decrease in overpotential confirms the beneficial role of Pt alloying in enhancing the catalytic activity of Ni-based nanostructures for the hydrogen evolution reaction.

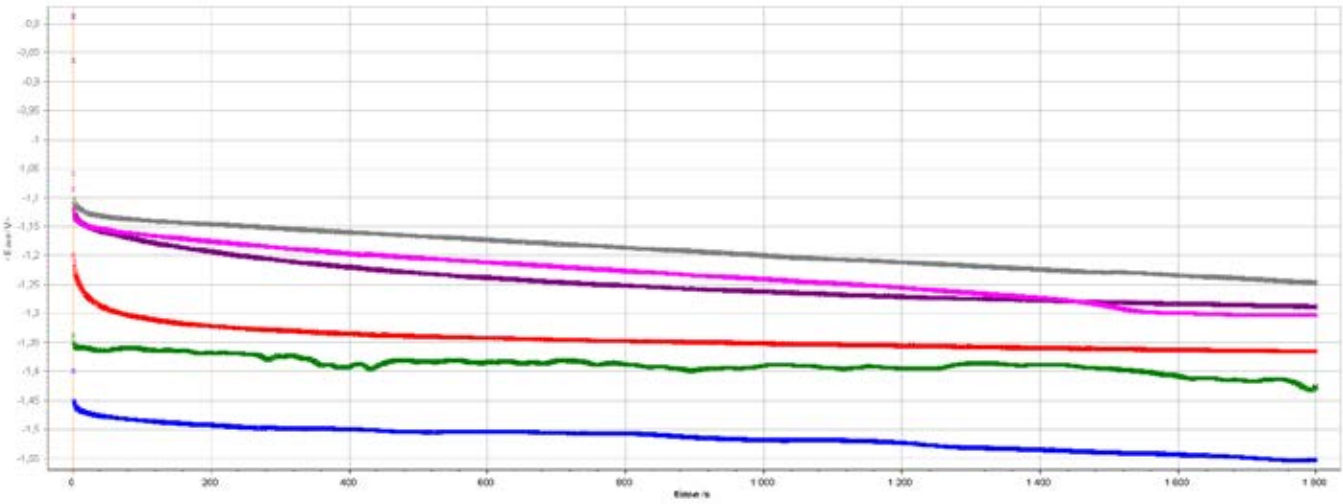


Fig. 3. Chronopotentiometric curves registered in 1 M NaOH after application of constant current density: -10 $mAcm^{-2}$ for Ni-Pt nanoconical alloys deposited with different chemical composition of electrolyte. Polarization time: 1800s.

4. CONCLUSIONS

In summary, this work demonstrates that even small amounts of platinum introduced into nickel during electrodeposition can produce nanocone-shaped Ni–Pt alloys with substantially enhanced electrocatalytic performance toward the hydrogen evolution reaction (HER). Detailed SEM analysis showed that these nanoconic structures—facilitated by the use of NH_4Cl as a crystal growth modifier—were consistently formed across all samples, with minor variations in cone height and apex sharpness correlating with Pt concentration. XRD measurements confirmed that no additional Pt-specific peaks emerged, suggesting that platinum either occupies substitutional sites in the Ni lattice or forms very fine clusters below the detection threshold.

Electrochemical evaluation in 1 M NaOH revealed a clear trend of decreasing overpotential as the platinum content increased. Pure Ni nanocones (blue curve) stabilized near −1.50 V after 1800 s, whereas the 0.5 mM Pt sample (green) improved to around −1.40 V. Increasing Pt loadings further reduced the overpotential, with the 1 mM Pt deposit reaching approximately −1.35 V, the 2 mM Pt deposit −1.30 V, and the 5 mM Pt deposit −1.20 V. Most notably, the electrode containing 10 mM Pt (silver curve) stabilized around −1.05 V, representing a significant 450 mV enhancement compared to pure Ni. These findings highlight how uniform Pt incorporation into the Ni matrix can substantially lower the activation energy for the HER, while preserving the high-surface-area benefits of the nanoconic morphology. Consequently, Ni–Pt nanoconical alloys appear to be promising electrocatalyst candidates for water-splitting technologies, owing to their improved activity and structural stability in alkaline conditions.

ABSTRACT

This article presents a novel method for producing blue hydrogen by extracting methane from gas hydrate deposits through CO_2 injection and converting it into hydrogen via steam methane reforming (SMR). Gas hydrates, which store methane in crystalline water structures, hold immense unused energy potential but carry environmental risks due to methane leakage that can naturally happen. The proposed CO_2 injection technique to gas hydrate deposits provides controlled methane extraction while simultaneously using CO_2 formed by SMR process, reducing overall greenhouse gas emission.

Once extracted, methane undergoes SMR to generate hydrogen, with CO_2 as a byproduct. Instead of releasing into the atmosphere, CO_2 is captured and injected into hydrate formations, creating a circular process that lowers overall emissions. Economic analysis indicates that this approach could be cost-competitive with current hydrogen production methods. Additionally, environmental assessments suggest a significantly reduced carbon footprint compared to conventional techniques, though challenges such as potential methane leaks and hydrate stability require attention.

Field trials, including projects in Japan, demonstrate the viability of CO_2 injection for methane recovery. This integrated approach offers a scalable and sustainable solution for blue hydrogen production, supporting energy security and climate goals, particularly in gas-hydrate-rich regions like the Black Sea.

1. INTRODUCTION

Natural gas hydrates offer a promising pathway for producing low-carbon hydrogen. This study explores an innovative approach to blue hydrogen production by extracting methane from gas hydrate reservoirs using CO_2 injection and then converting the recovered methane into hydrogen and CO_2 through steam methane reforming (SMR). The feasibility of this integrated method is assessed using modeling and simulation, with a particular focus on Asia's gas hydrate reserves [1].

Gas hydrates are crystalline compounds that trap methane molecules within a water-based lattice structure. These deposits, found in vast quantities worldwide, represent a substantial untapped energy resource [2]. However, methane leakage from these reservoirs significantly contributes to greenhouse gas emissions. Since methane has a global warming potential approximately 25 times greater than CO_2 over a 100-year period [3], uncontrolled release could intensify climate change. The proposed CO_2 injection method not only enables efficient methane extraction but also mitigates environmental risks by preventing uncontrolled methane emissions [4]. Studies have shown that CO_2 can replace methane within hydrate structures, making this a viable method for sustainable energy production. Japan's pilot projects in the Nankai Trough have validated this technique, encouraging further research into its application for large-scale blue hydrogen production.

2. MATERIALS AND METHODS

2.1. Gas Hydrate Reservoirs: Characteristics and Extraction Methods

Gas hydrates form in high-pressure, low-temperature environments, such as deep-sea sediments and permafrost regions. It is estimated that global methane reserves trapped within these hydrates range from 500 to 10,000 gigatons of carbon, surpassing the combined known fossil fuel reserves [2]. In terms of energy potential, methane hydrates hold approximately 100 times more energy than all existing oil and gas reserves, positioning them as a crucial resource for future energy security [5].

The extraction of methane from hydrate formations can be achieved through several methods:

- *Depressurization:* Lowering the reservoir pressure to trigger methane dissociation from the hydrate structure.
- *Thermal Stimulation:* Injecting heated fluids, such as steam or warm water, to destabilize the hydrates and release methane gas.
- *Chemical Injection:* Using substances like methanol or glycol to modify reservoir conditions and induce methane release, although this method is costly.
- *CO_2 Injection:* Replacing methane with CO_2 within the hydrate lattice, allowing for controlled methane extraction and the simultaneous formation of more stable CO_2 hydrates [4].

Pilot studies indicate that CO_2 injection is particularly effective for methane displacement in gas hydrate structures within deep-sea environments, where maintaining stability is critical. This dual-purpose approach enhances methane recovery

while reducing overall greenhouse gas emissions. Gas hydrate-containing sediments are complex systems in which methane production is influenced by pressure and temperature changes [6]. Advanced numerical models confirm that CO_2 injection enhances methane recovery while minimizing environmental risks [1]. These insights are crucial for developing sustainable extraction techniques.

2.2. Steam Methane Reforming (SMR) for Hydrogen Production

The extracted methane undergoes SMR, which is the most commonly used process for large-scale hydrogen production. SMR involves two key reactions [7]:

Primary Reforming Reaction (Endothermic):

$$CH_4 + H_2O \rightarrow CO + 3H_2 \ \Delta\mathrm{H} = +206\ \mathrm{kJ/mol} \quad (1)$$

Water-Gas Shift Reaction (Exothermic):

$$CO + H_2O \rightarrow CO_2 + H_2 \ \Delta\mathrm{H} = -41\ \mathrm{kJ/mol} \quad (2)$$

Overall Net Reaction (Endothermic):

$$CH_4 + 2H_2O \rightarrow CO_2 + 4H_2 \ \Delta\mathrm{H} = +165\ \mathrm{kJ/mol} \quad (3)$$

This process occurs in a reformer unit, where methane reacts with steam at 700–1000°C over a nickel-based catalyst. The reaction produces a synthesis gas (syngas) containing hydrogen, carbon monoxide, and carbon dioxide [4]. The water-gas shift reaction further increases hydrogen yield by converting CO into CO_2 and additional hydrogen. The produced hydrogen is separated from carbon dioxide using physical methods such as Pressure Swing Adsorption (PSA) or membrane separation techniques.

2.3. Integration of SMR and CO_2 Injection

By integrating methane recovery with SMR, a closed-loop process is established, where CO_2 from hydrogen production is captured and injected into hydrate reservoirs, reducing net carbon emissions as shown in Fig. 1. This closed-loop approach offers a promising pathway to sustainable blue hydrogen production while addressing key challenges in methane extraction from abundant natural resources and effective carbon management [8].
The key advantages of this combined system include:

- *On-site Hydrogen Production:* Reducing transportation costs and emissions by converting methane to hydrogen at extraction sites.
- *Carbon Sequestration:* Capturing and storing CO_2 within hydrate reservoirs mitigates climate impact.
- *Energy Optimization:* Waste heat from the SMR process can be repurposed to facilitate hydrate dissociation, improving overall efficiency.

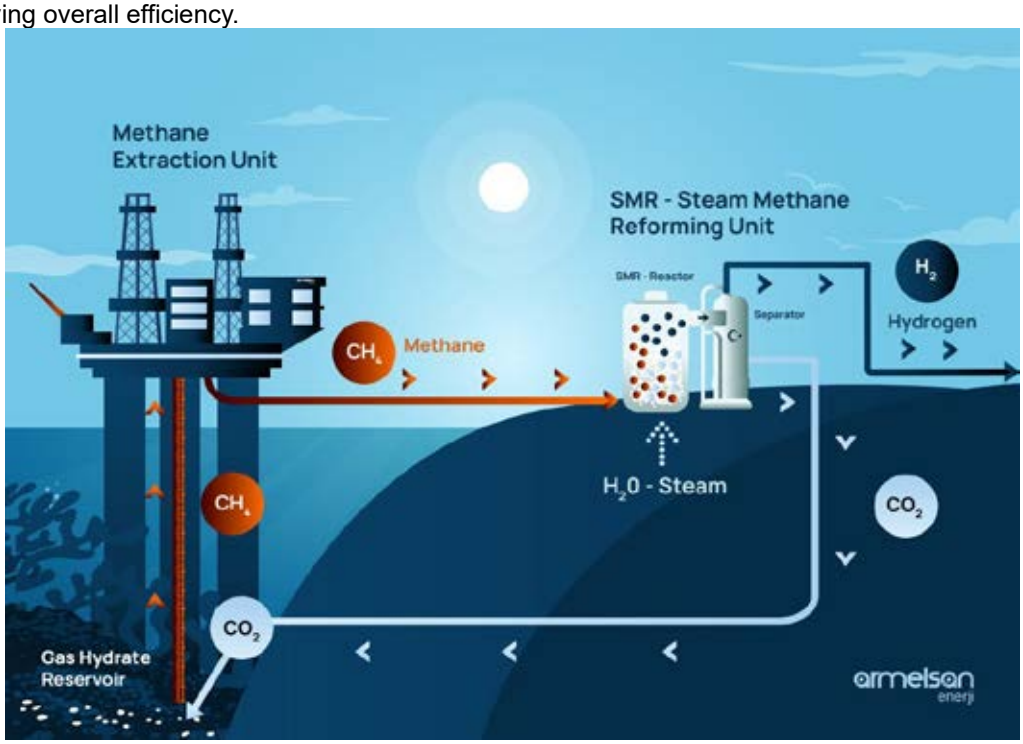

Fig.1. Schematic illustration of integrated system of SMR process with CO_2 injection

3. RESULTS AND DISCUSSION

3.1. Environmental Impact Assessment

Utilizing methane hydrates for hydrogen production presents a viable solution for reducing the greenhouse effect of methane emissions. Life-cycle assessments indicate that blue hydrogen derived from gas hydrates has a significantly lower carbon footprint compared to conventional hydrogen production methods [8]. However, certain environmental challenges must be addressed, including:

- *Potential Methane Leakage:* Advanced monitoring systems are necessary to detect and prevent unintended methane emissions.
- *Hydrate Stability Concerns:* Ensuring that CO_2 injection maintains reservoir integrity is crucial.
- *Marine Ecosystem Impact:* Minimizing disruption to marine environments remains a key focus for sustainable deployment.

3.2. Economic Viability and Market Potential

Economic models suggest that blue hydrogen from gas hydrates could be cost-competitive with existing hydrogen production methods [9]. The estimated breakeven price of $2.016 per kg hydrogen indicates that this approach can be a viable alternative, particularly in regions rich in hydrate deposits. With increasing global demand for low-carbon hydrogen in industries such as transportation and steel production, this method holds significant commercial potential.

3.3. Case Studies and Field Trials

Countries such as Japan, South Korea, and Canada have conducted successful pilot projects demonstrating methane extraction via CO_2 injection [5]. Japan's Nankai Trough experiment showcased the feasibility of replacing methane with CO_2 in hydrate structures, providing valuable data for future large-scale implementation. Ongoing trials aim to refine CO_2 injection strategies and improve the methane-to-hydrogen conversion efficiency.

3.4. Future Research Directions

Advancements in methane extraction through CO_2 injection and hydrogen production technologies such as plasma-assisted methane conversion and advanced catalysts continue to enhance overall process efficiency. Research areas include:

- *Cost Reduction:* Developing more efficient catalysts for the SMR process and refining extraction techniques using CO_2 injection.
- *Environmental Safety Measures:* Strengthening monitoring and control technologies to mitigate methane leaks.
- *Renewable Energy Integration:* Combining hydrogen production with offshore wind or solar power to improve sustainability.

4. CONCLUSIONS

The integration of methane extraction via CO_2 injection and SMR represents a groundbreaking approach to sustainable hydrogen production. By leveraging gas hydrate reserves, this method not only provides an alternative energy source but also significantly reduces uncontrolled methane emissions that could contribute to global warming, with the captured CO_2 from hydrogen production being injected into gas hydrate formations, thereby creating a circular carbon management system.

This closed-loop approach minimizes environmental impact, optimizes energy efficiency, and offers a scalable solution for future blue hydrogen production. As global efforts to transition toward low-carbon energy intensify, continued research and development will be critical in refining this method and unlocking its full potential. The adoption of this innovative process could play a crucial role in achieving long-term energy security and climate resilience. With its gas hydrate deposits in the Black Sea, Türkiye has significant potential to prevent methane emissions that contribute to global warming and produce blue hydrogen through this new integrated process.

ABSTRACT
Fly ash (FA), a by-product of coal combustion in power plants, poses a significant global environmental challenge due to its large-scale production. Rich in metal oxides such as SiO_2, Al_2O_3, and Fe_2O_3, FA offers potential as a catalyst for ammonia decomposition to produce CO_x-free hydrogen. However, its low surface area (< 1 m^2 g^{-1}) limits catalytic performance. In this study, FA was modified by calcination at various temperatures (550, 700, and 1000 °C), HCl treatment, and HCl treatment followed by calcination at 500 °C. The most active catalyst, obtained by HCl treatment followed by calcination at 500 °C achieved 86.0% ammonia conversion at a reaction temperature of 700 °C and a space velocity of 30,000 mL NH_3 h^{-1} g_{cat}^{-1}, exhibiting significantly higher performance compared to the other FA-based catalysts. The enhanced performance on this catalyst was attributed to its enhanced surface area (18.5 m^2 g^{-1}), effective removal of Cl and S impurities, and the formation of relatively small Fe crystallites (23.8 nm). This study demonstrates an environment-friendly and efficient approach to store CO_x-free hydrogen in ammonia.

1. INTRODUCTION
Hydrogen stands out as an energy carrier due to its exceptionally high gravimetric energy density. However, its practical application is hindered by its low volumetric energy density, which poses challenges for storage, transport, and utilization. A promising option for hydrogen storage is its chemical storage in compounds such as methane, methanol, formic acid, or ammonia, which helps mitigate the challenges associated with its low volumetric energy density. Among hydrogen carriers, ammonia stands out because of its carbon-free nature, high hydrogen density both gravimetrically and volumetrically, nonflammability, and compatibility with existing infrastructure [1]. These advantages make ammonia an excellent candidate for CO_x-free hydrogen storage and transportation.
The thermal decomposition of ammonia has been widely studied using Ru-, Ni-, Co-, and Fe-based catalysts [2]. Among them, Ru-based catalysts exhibit the highest activity, however, their practical application is hindered by the high cost and scarcity of ruthenium. Additionally, many high-performance ammonia decomposition catalysts require complex synthesis procedures, leading to increased costs and reproducibility challenges. Therefore, the development of a low-cost, stable, and efficient catalyst that can be synthesized through simple and scalable methods is essential for hydrogen production from ammonia.
In this context, coal fly ash (FA), an abundant industrial waste, represents a significant opportunity as an iron-based catalyst for ammonia decomposition to produce hydrogen [3]. FA is a readily available and cost-free, containing considerable quantities of catalytically active Fe_2O_3 (between 5-15 wt%) [4]. Furthermore, the SiO_2 and Al_2O_3 present in FA can serve as effective support materials, while trace elements such as K, Ba, and Ca can serve as promoters, potentially further enhancing catalytic performance [3]. Despite these advantages, the direct catalytic application of FA is hindered by its significantly low surface area (< 1 m^2 g^{-1}), requiring modification strategies such as acid treatment or thermal calcination to enhance its textural properties and catalytic activity.
This study is the first to systematically evaluate FA as an ammonia decomposition catalyst. Here, FA was modified via acid treatment and calcination at different temperatures to significantly enhance its catalytic performance for ammonia decomposition. This research not only provides an innovative approach to hydrogen storage and utilization but also presents substantial environmental and economic advantages through the valorization of a globally abundant waste material.

2. MATERIALS AND METHODS
FA from Tuncbilek Power Plant (Kutahya, Turkey) was calcined at 550, 700, and 1000 °C for 3 hours with a ramp rate of 10 °C min^{-1}, yielding FA-C550, FA-C700, and FA-C1000. For modified fly ash (MFA) synthesis, FA was treated with 6 M HCl, digested in a Milestone Microwave Digestion System (SK-10) at 220 °C, and precipitated with aqueous ammonia to pH ~8. The product was washed, dried, and calcined at 500 °C with a ramp rate of 10 °C min^{-1}, producing MFA-C500. Samples were thoroughly characterized using X-ray diffraction (XRD), X-ray fluorescence spectroscopy (XRF), Fourier transform infrared (FTIR) spectroscopy, thermogravimetric analysis (TGA), temperature-programmed reduction (TPR), and scanning electron microscopy coupled with energy-dispersive X-ray spectroscopy (SEM/EDX), Brunauer-Emmett-

Teller (BET) pore volume and surface area analysis, transmission electron microcopy (TEM), temperature programmed reduction (TPR), and X-ray photoelectron spectroscopy (XPS).
Catalytic performance was evaluated in a ½-inch quartz tube once-through flow reactor, using 200 mg of catalyst for each run. Before catalytic testing, catalysts were reduced in pure hydrogen (H_2, 99.99%, Air Liquide) at 700 °C. Ammonia (NH_3, 99.99%, Linde) was introduced at a gas hourly space velocity (GHSV) of 30,000 mL NH_3 h^{-1} g_{cat}^{-1}, for an induction period of approximately 30 h at 700 °C. Following the induction, the reaction temperature was varied between 480 and 510 °C under differential conversion conditions (not exceeding 8.0%) to obtain the Arrhenius plots. The outlet gas composition was monitored using a Hiden QGA quadrupole gas analyzer pre-calibrated for H_2, N_2, and NH_3.

3. RESULTS AND DISCUSSION

The composition of the as-received FA was determined by XRF analysis, revealing that the primary constituents of FA are SiO_2 (56.8 wt%), Al_2O_3 (21.1 wt%), and Fe_2O_3 (9.9 wt%). XRD analysis confirmed the presence of a mixture of crystalline phases in FA, with peaks corresponding mainly to quartz (SiO_2), mullite ($3Al_2O_3{\cdot}2SiO_2$), hematite (α-Fe_2O_3), and a lower amount of FeO(OH). Calcination at various temperatures (550, 700, and 1000 °C) did not cause significant changes in the crystalline structure compared to untreated FA. However, the XRD pattern of acid modified samples, MFA and MFCA-C500, presented an increase in amorphous character upon modification. Furthermore, acid modification significantly increased the surface area of FA (<1 m^2 g^{-1}) to 37.7 m^2 g^{-1} (in MFA), but it also introduced typical catalyst poison such as Cl. Subsequent calcination at 500 °C (MFA-C500) effectively eliminated these impurities, as confirmed by EDX analysis, although this was accompanied by a decrease in the surface area to 18.5 m^2 g^{-1}.
Next, calcined and HCl-modified FA samples were reduced in pure H_2 flow to convert the Fe_2O_3 content into the active metallic Fe phase. XRD and XPS analysis of reduced catalysts and H_2-TPR analysis of fresh samples confirmed that Fe_2O_3 present in FA, calcined FA samples, and MFA is successfully reduced to metallic Fe at 700 °C in pure H_2 [3]. The average Fe crystallite sizes determined from the XRD patterns of the reduced catalysts using the Scherrer equation were 32.2, 29.0, 25.2, 24.4, 37.6, and 23.8 nm, for FA-R, FA-C550-R, FA-C700-R, FA-C1000-R, MFA-R, and MFA-C500-R, respectively. Noncalcined reduced catalysts (FA-R and MFA-R) exhibited larger crystallites, while the acid-modified, calcined, and reduced catalyst (MFA-C500-R) showed the smallest crystallite size of 23.8 nm. The surface-averaged nanoparticle size from TEM images was 24.0 nm, consistent with the Scherrer equation result.
When testing the ammonia decomposition performances of these reduced catalysts, the apparent activation energies for FA-R, FA-C550-R, FA-C700-R, FA-C1000-R, MFA-R, and MFA-C500-R were determined as 93.9, 95.8, 93.2, 73.6, 103.7, and 104.7 kJ mol^{-1}, respectively (Figure 1). While calcination at 550, 700, and 1000 °C resulted in comparable catalytic performance, acid modification followed by calcination (MFA-C500-R) significantly enhanced NH_3 decomposition activity (Figure 1 and 2).

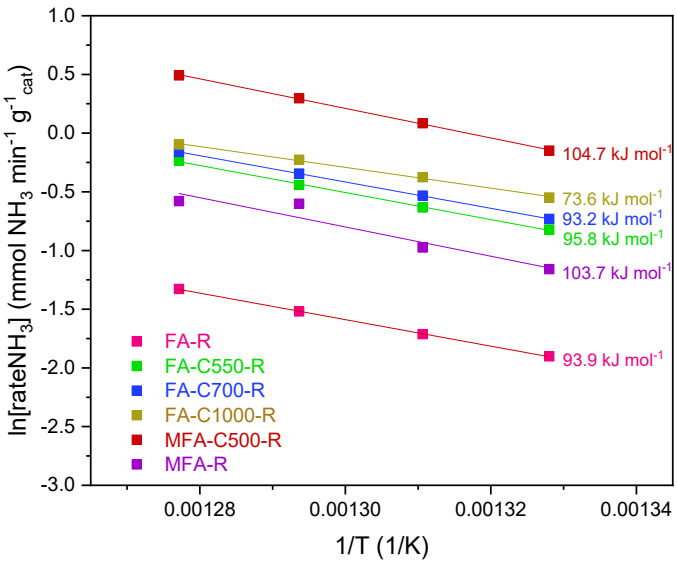

Fig. 1. Arrhenius plots for FA-based catalysts.

At a space velocity of 30,000 mL NH_3 h^{-1} g_{cat}^{-1} and a reaction temperature of 700 °C, the ammonia conversions of FA-R, FA-C550-R, FA-C700-R, FA-C1000-R, MFA-R, and MFA-C500-R were measured as 50.9, 70.4, 73.6, 71.0, 56.1, and 86.0 %, respectively (Figure 2). These results demonstrate that the HCl-modified and calcined fly ash catalyst (MFA-C500-R) exhibited the highest activity, followed by FA-C1000-R, FA-C700-R, and FA-C500-R, which showed similar performances. The non-calcined and directly reduced catalysts (MFA-R and FA-R) provided the lowest activity (Figure 2). This performance trend aligns with the Fe crystallite sizes of each catalyst: the highest-performing catalyst possessed

the smallest Fe crystallites, while the least-performing catalysts exhibited larger Fe crystallites. Data clearly indicate the crucial role of calcination, as catalysts prepared from non-calcined FA exhibited larger Fe crystallites and thus lower catalytic activities. Characterization results revealed that directly reducing FA and MFA without calcination left behind sintering agents (S and Cl impurities), which contributed to increased Fe crystallite sizes and lower catalytic performance. Overall, the highest catalytic performance in our sample pool was achieved with the HCl-modified, calcined, and reduced catalyst (MFA-C500-R), which provided 86.0% NH_3 conversion at 700 °C with a space velocity of 30,000 mL NH_3 h^{-1} g_{cat}^{-1} [3]. This performance was comparable to, or even superior to, that of several conventionally prepared Fe-based ammonia decomposition catalysts reported in the literature.

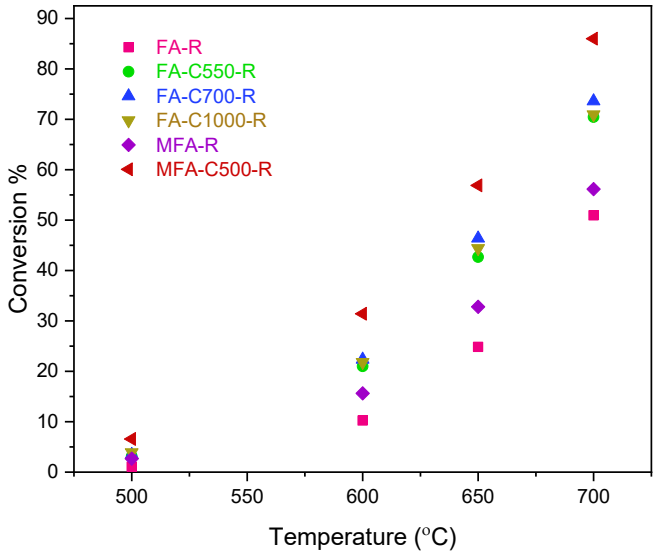

Fig. 2. The catalytic activity measured at different temperatures at a space velocity of 30,000 mL NH_3 h^{-1} g_{cat}^{-1} for FA-based catalysts.

Further investigations on MFA-C500-R were conducted at varying temperatures (400–700 °C) and space velocities (3,000–75,000 mL NH_3 h^{-1} g_{cat}^{-1}). (Figure 3). Its stability was tested for 140 hours on stream, demonstrating excellent long-term performance after an initial 30-hour induction period (Figure 4). XRD analysis of spent catalysts indicated the nitridation of Fe sites, leading to the formation of iron nitride (Fe_xN_y) species, which was also confirmed by XPS analysis. SEM images showed that spent MFA-R contained the largest Fe_xN_y moieties, explaining its low catalytic performance. In contrast, both XRD and SEM analyses of the spent MFA-C500-R catalyst revealed that the calcination step performed on the modified catalyst resulted in smaller Fe_xN_y crystallite sizes. This enhanced dispersion is attributed to the significantly increased surface area of MFA-C500 (18.5 m^2 g^{-1}), approximately 23 times higher than untreated FA, and the removal of sintering agents such as sulfur and chlorine impurities [3].

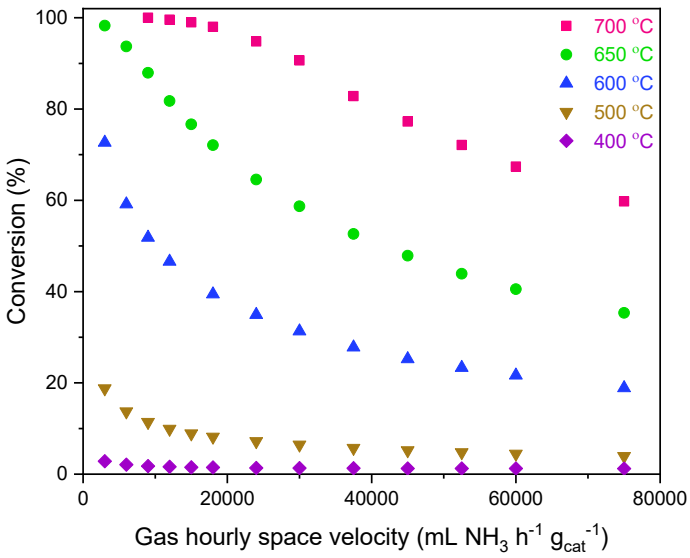

Fig. 3. The catalytic activity of MFA-C500-R at different reaction conditions.

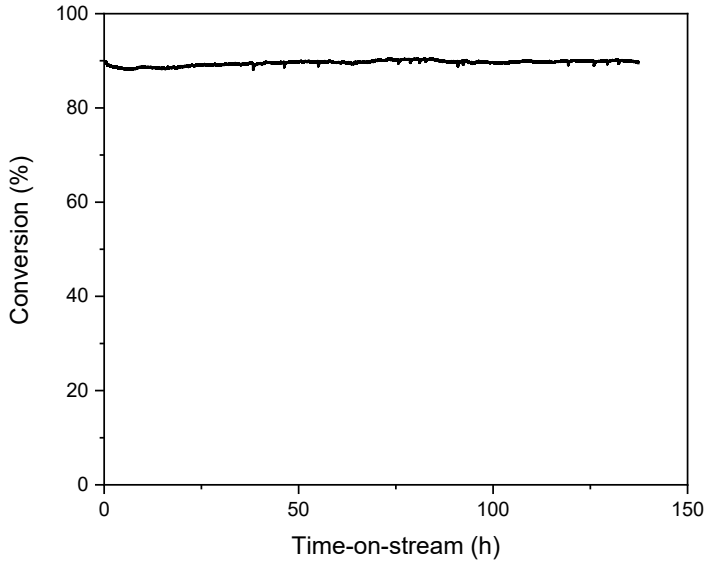

Fig. 4. The catalytic stability test of MFA-C500-R conducted at 700 °C with a space velocity of 30,000 mL NH_3 h^{-1} g_{cat}^{-1}, excluding the initial 30-hour induction period from the graph.

4. CONCLUSIONS

This study demonstrates the successful transformation of FA into an efficient alumina- and silica-supported iron-based catalyst for ammonia decomposition. The combined acid modification and calcination treatments significantly improved the surface area of FA, removed catalyst poisons such as chlorine and sulfur, and reduced Fe crystallite sizes, ultimately enhancing the catalytic performance. Among the prepared catalysts, the HCl-modified, calcined, and reduced sample (MFA-C500-R) exhibited the highest activity, achieving 86.0% ammonia conversion at 700 °C and at a space velocity of 30,000 mL NH_3 h^{-1} g_{cat}^{-1} with remarkable stability over a 140-hour operation period. Detailed characterization of the spent catalysts confirmed the formation of highly dispersed Fe_xN_y species, which contributed notably to the catalyst's excellent performance. These findings highlight the sustainable potential of utilizing low-cost, abundant FA as an efficient catalyst for hydrogen production, demonstrating a promising approach to transforming industrial waste into value-added materials.

ACKNOWLEDGEMENT

The authors gratefully acknowledge Prof. Dr. Alper Uzun for his valuable mentorship and Assoc. Prof. Uğur Ünal from Koç University for acquiring TEM images. The use of TEM facilities at Koç University Nanofabrication and Nanocharacterization Center for Scientific and Technological Advanced Research (n2STAR) is gratefully acknowledged. The authors also thank Dr. Barış Yağcı from Koç University Surface Science and Technology Center (KUYTAM) for his support with SEM/EDX and XPS measurements. This work is supported by Koç University Tüpraş Energy Center (KUTEM). The authors express their gratitude to Tunçbilek Power Plant in Kütahya, Türkiye for providing the FA sample.

ABSTRACT
Today, both environmental concerns and the necessity to find solutions to the world's ever-increasing energy needs force people to find new and clean energy sources and develop environmentally friendly energy conversion systems. In this respect, the 21st century is the period in which 'hydrogen' is used as 'New Energy Technologies' and 'fuel cell' systems are adopted. For this purpose, the change in hydrogen and oxygen consumption in the fuel cell against time was ınvestigated, ranging from 0.86 V to 2.44 V, with the model being repeated each time. The results show that the optimum configuration was found to 2.44 V and 6.88 W of power with the hydrogen flow rate of 0.2 ml/min and the oxygen flow rate of 0.4 ml/min in the polymer electrolyte membrane fuel cell (PEMFC). Our future research in this area will focus on separation of water according to the volume of hydrogen and oxygen gases, as well as determining the efficiency of the solar module and PEM electrolizor.

1. INTRODUCTION
The process of global urbanization has brought about the rapid economic expansion of all countries in the world. With the continuous the world's energy consumption, and the rapid economic development entailes serious emissions of carbon dioxide [1]. The problem of planet heats up caused by the ongoing emission of greenhouse gases has become a threat to survival and development of humanity, which become a global concern. From the 1960s, environmental degradation have pushed up worldwide, governments aim has been to achieve sustainable economic growth with low-carbon emissions and less energy consumption. The renewable energy generation technologies have shaped the future power grid. Amongst these technologies, wind energy, photovoltaic (PV) power generation technologies, which offer advantages such as superior natural resource endowment, constantly increasing development and readily available, are more mature and more productive than other renewable energy generation generation technologies [2]. According to statistics, the world's renewable energy capacity additions expanded with almost 50% in 2023, reaching almost 510 gigawatts (GW), with photovoltaic capacity accounted for three-quarters of renewable energy added globally. China commissioned more solar PV in 2023 as the entire world did a year before, while China’s wind additions also grew by 66% year-on-year. Alongside China's extraordinary acceleration, the USA, EU, and Brazil also hit all-time highs increases in their renewable energy capacity [3]. To become prevalent PV power generation, which is expected to become the largest source of global electricity production, two major problems have to be solved. One of the problems is the instability of PV power generation which will a massively affect electrical grid. In order to prevent this impact, the grid will not accept unstable electricity, which will cause a waste of power. The second problem is the energy storage challenges. Physical energy storage, electrochemical energy storage, and electromagnetic energy storage technologies, which used in energy storage, will not be able to meet the needs of large energy storage and the empowerment of clean energy in the future. Therefore, many energy storage options, such as pumped hydropower storage, hydrogen storage, compressed air, and batteries, etc. are still at the development stage. Compared with them, hydrogen storage has the characteristics of high energy density, large and easy storage capacity, lower conversion efficiency, and transmission [4]. Hydrogen gas (H_2) produced through water electrolysis using renewable energy sources such as solar, wind or hydroelectric energy can be used in areas such as transport as well as electricity supply for fuel cell vehicles.
The purpose of this work is to develop a model of a hybrid system using PV, Electrolyser, Fuel Cell and Battery for transport applications. The first step is to construct the circuit simulator and then adding all the elements that is necessary for this system such as a PV system, Electrolyser, Fuel Cell and Battery. Next, the complete model will be simulated to ensure the circuit will operate as expected. Our goal is to find the optimum design of a new photovoltaic-electrolyser-fuel cell-battery hybrid system that we model for vehicles.

2. MATERIALS AND METHODS
2.1. Photovoltaic Panel
Photovoltaic solar panels (Figure 3. (a)) are made of semiconductor materials and convert sunlight falling on them directly into electrical energy. Increasing the efficiency of photovoltaic systems is a critical step to maximize the amount of electricity obtained from solar energy. Hybrid energy systems have been developed to increase the efficiency of photovoltaic systems. These systems are integrated with photovoltaic cells along with other renewable energy sources or energy storage systems, achieving higher efficiency.

2.2. Electrolyser

Electrolyzers play a critical role in the production of hydrogen from renewable energy sources. The working principle of electrolyzers is based on the process of separating water into hydrogen (H_2) and oxygen (O_2) gases by applying an electric current between the electrodes. Proton Exchange Membrane (PEM) electrolyzers (Figure 3. (b)) separate water into hydrogen and oxygen using a proton exchange membrane, which is an acidic electrolyte. These electrolyzers are more compact, fast-responding and efficient systems. Increasing the efficiency of electrolyzers is of critical importance in reducing energy consumption, reducing costs and increasing hydrogen production capacity.

2.3. Fuel Cell

The function of a fuel cell is to convert the energy of the fuel reaction into electrical energy. A fuel cell can be modeled as a controlled current source. In this study, the H_2/O_2/Air fuel cell (Fig. 3 (c)) was used. The Fuel Cell is a single cell Proton Exchange Membrane Fuel Cell (PEMFC) for H_2/O_2, hydrogen and oxygen operation. By operating the fuel cell with pure Oxygen instead of Atmospheric Oxygen (Air), it has achieved much higher performance with better results. This Proton Exchange Membrane (PEM) fuel cell produces electricity using hydrogen and oxygen gas. Its by-products are water and heat. When using Fuel Cell H_2/O_2/Air, you also hav the option of operating the cell in air-breathing mode simply by removing the stopper. When operating with atmospheric oxygen, the power of the cell is somewhat lower than when operating with pure oxygen.

(a) (b) (c)

Fig. 3. (a) Photovoltaic Panel **(b)** Electrolyser **(c)** H_2/O_2/Air fuel cell

2.4. Electrochemical measurements

For electrochemical tests, a PEM electrolyzer was used for hydrogen and oxygen production. This cell with a surface area of 3.0 cm^2 was used in electrolyzer mode for hydrogen production. Water reacts in the electrolyzer under the influence of electrical energy according to the following formula:

$$2H_2O \text{ <---> } 2H_2 + O_2 \quad (1)$$

This process takes place in the MEA (membrane electrode assembly). The MEA consists of a cathode, an anode, and a special polymer membrane (PEM) that is permeable to protons but a barrier to electrons. Electrolyzer works according to the PEM principle. The produced gases were stored in storage tanks. The energy stored in the gases in chemical form was converted back into electrical energy in the fuel cell.

Fuel Cell H_2/O_2/Air is a single-cell Proton Exchange Membrane Fuel Cell (PEMFC) for hydrogen and oxygen operation. This Proton Exchange Membrane (PEM) fuel cell produces electricity by using hydrogen and oxygen gas. This cell with a surface area of 3.0 cm^2 was used in fuel cell mode for electric production.

3. RESULTS AND DISCUSSION

General view of the studied system is shown in Figure 4.

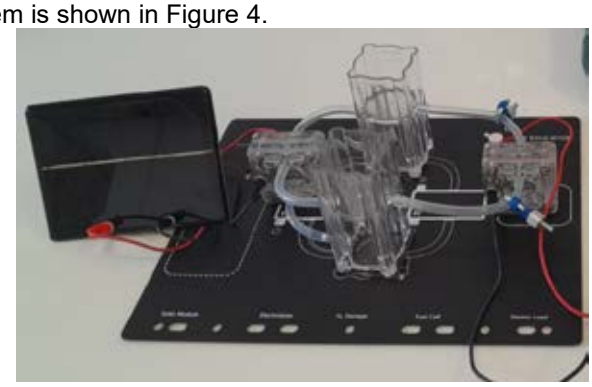

Fig.4. General view of studied system.

We oparete the PEMFC system approximately 10 minutes until the system reaches a stable state, after that *hydrogen and* oxygen *fed into* the *system* and the energy parameters of the system are investigated. The load is applied in steps of 2.82 A. Both hydrogen and oxygen flow rates have been allowed to vary from 0.1-1.0 mL·min⁻¹ gradually increased. In this context, a load-following control strategy is used. Additionally, the time evolution of hydrogen and oxygen consumption rates over a range of currents drawn through the cell has been examined.

Table 1. Hydrogen and oxygen flow rates

Component	H_2 Flow Rate (mL.min^{-1})	O_2 Flow Rate (mL.min^{-1})	Voltage of a Cell (V)
PEMFC	0,2	0,4	2,44
PEMFC	0,4	0,6	2,33
PEMFC	0,6	0,8	1,82
PEMFC	0,8	1,0	0,86

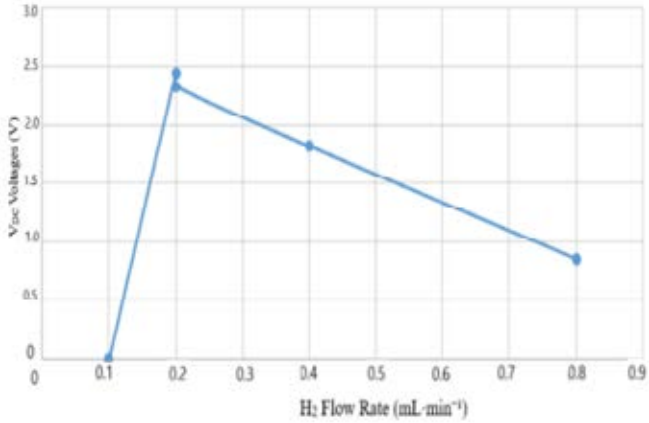

Fig. 5. Voltage versus hydrogen flow rate.

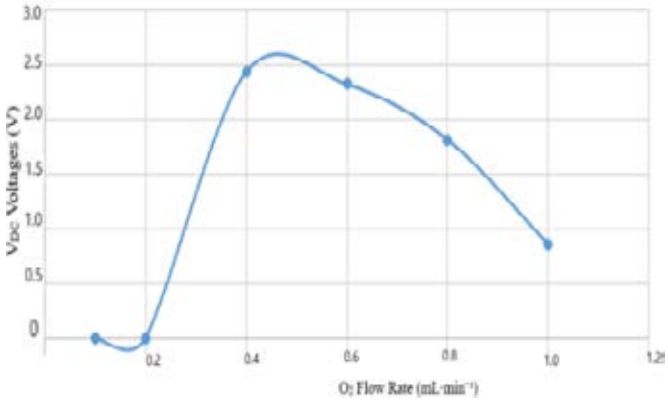

Fig. 6. Voltage versus oxygen flow rate.

As shown in Figure 5, with increase in hydrogen flow rate from 0.1 mL·min⁻¹ to 1.0 mL·min⁻¹, the voltage increases and then rapidly decreases from 0.2 mL·min⁻¹ flow rate. Figure 6 shows that with increase in oxygen flow rate from 0.2 mL·min⁻¹ to 1.2 mL·min⁻¹, the voltage increases rapidly for up to 0.4 mL·min⁻¹, then decreases rapidly. Figure 11 also presents the voltage depending on the flow rate of oxygen and hydrogen.

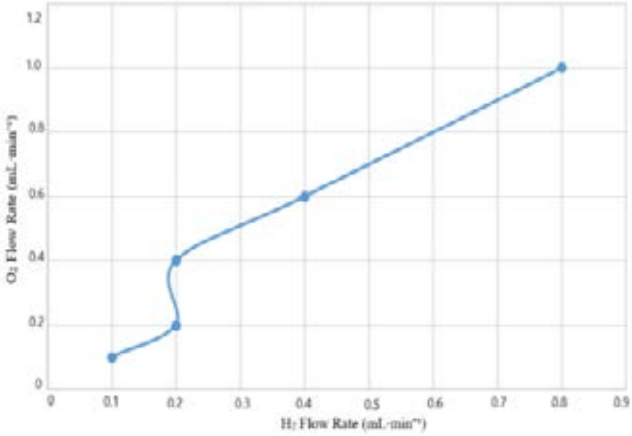

Fig.7. H_2 and O_2 flow rates against time

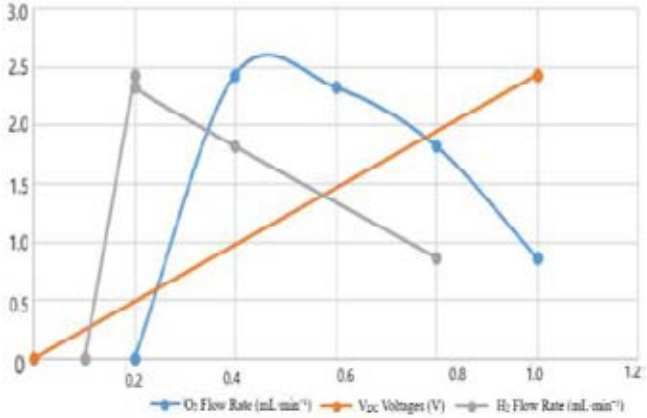

Fig.8. Voltage versus hydrogen and oxygen flow rates.

From Figure 7, it can be seen that there was no electricity production below the flow rate of 0.2 mL·min⁻¹ for hydrogen gas and 0.4 mL·min⁻¹ for oxygen gas. The fuel flow variation profile is shown in Table 1 to note the variation of the parameters of interest within the PEMFC and battery.

The available voltage and power from the fuel cell is a main limiting factor in the development of the system. Figure 8 shows the characteristic curve of the power and voltage relationship. When Figure 9 is examined, it is seen that the fuel cell power density increases with increasing voltage density. Figure shows the cell output range from 2.40 W and 6.88 W. The most efficient voltage and cell output are 2.44 V and 6.88 W, respectively, when the hydrogen flow rate is fixed at 0.2 mL·min⁻¹, and the oxygen flow rate is fixed at mL·min⁻¹ of PEMFC cell.

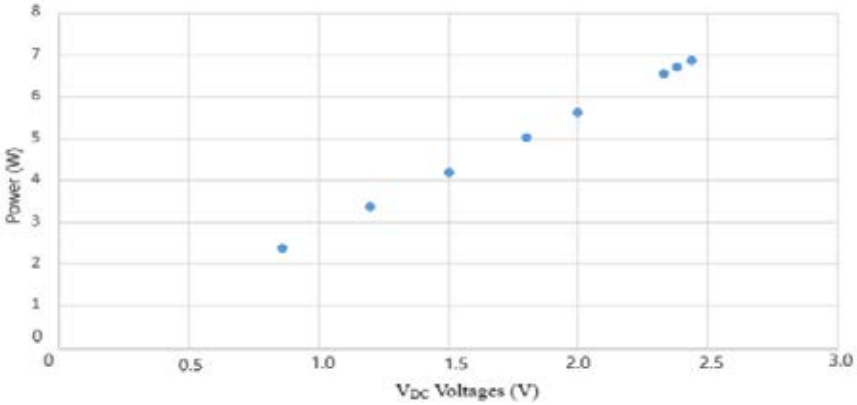

Fig.9. Experimental W-V characteristic of PEMFC cell.

4. CONCLUSIONS

This paper presents the optimum power configuration in a new generation hybrid system for fuel cell electric vehicles. The obtained results show that H2 and O2 gases were the only products from the electrolyzer with their volume ratio close to 2:1, and the efficiency was determined to be nearly 100% during water electrolysis. For this purpose, the change in hydrogen and oxygen consumption in the fuel cell against time was ınvestigated, ranging from 0.86 V to 2.44 V, with the model being repeated each time. The results show that the optimum configuration was found to 2.44 V and 6.88 W of power with the hydrogen flow rate of 0.2 ml/min and the oxygen flow rate of 0.4 ml/min in the polymer electrolyte membrane fuel cell (PEMFC).

This paper demonstrates also the effectiveness of the proposed hybrid PV/Fuel cell system. By installing this system the total cost of the installed system showed that the system can deliver energy with an acceptable cost.

Our future research in this area will focus on separation of water according to the volume of hydrogen and oxygen gases, as well as determining the efficiency of the solar module and PEM electrolizor.

A new product will be developed that will compete with the hybrid system, which is one of the elements of electric vehicle technology.

ABSTRACT

Addressing climate change demands a shift from fossil-based energy to sustainable alternatives, with solid oxide electrolysis cells (SOECs) emerging as a critical technology in this transition. Functioning at elevated temperatures, SOECs transform H_2O and CO_2 into hydrogen and syngas, delivering exceptional efficiency in converting renewable energy into chemical energy carriers. Nevertheless, challenges at the nanoscale and material deterioration hinder the performance of traditional techniques. Machine learning (ML) offers a powerful approach to overcome these obstacles by forecasting SOEC efficiency, simulating degradation processes, and refining operational parameters. This research outlines the core principles of SOEC systems and explores the incorporation of ML, specifically examining the contributions of Extreme Learning Machine (ELM) and Extreme Gradient Boosting (XGBoost) to performance estimation and system enhancement. The results indicate that ML significantly boosts the practical viability of SOECs for industrial use, though it also reveals limitations such as insufficient data availability and difficulties in interpreting model outcomes.

Keywords: Solid Oxide Electrolysis Cells, Machine Learning, Hydrogen Generation, Efficiency Enhancement

1.INTRODUCTION

Mitigating the devastating impacts of climate change has rendered the transition of our energy systems from fossil fuels to renewable resources an urgent imperative. Although wind and solar power possess the capacity to meet global energy demands, their intermittent nature necessitates advanced energy storage and conversion technologies.SOECs, operating within a temperature range of 600–1000°C, efficiently convert H_2O and CO_2 into hydrogen and synthesis gas. Over the past 15 years, advancements have yielded a 2.5-fold increase in efficiency, a 100-fold extension in operational lifespan, and a 100-fold expansion in gas production. However, challenges such as nanoscale intricacies, electrode wear, and material degradation continue to render conventional physical modeling approaches—such as finite element analysis—inadequate and impede commercial scalability [1,2]. While the literature includes efforts to enhance SOEC performance, the comparative analysis of advanced machine ML techniques, such as ELM and XGBoost, alongside their integration with Genetic Algorithms (GA), remains underexplored. Traditional methods are hampered by high computational demands and limited generalizability, whereas this study addresses this gap by systematically comparing ELM and XGBoost, proposing an innovative approach integrated with GA. Using ELM, the current-voltage relationship was modeled with an accuracy of 0.999, underscoring ML's capability to unravel complex processes. This data-driven framework analyzes hydrogen production, temperature variations, and electrode resilience in SOECs, unveiling their potential for optimization at an industrial scale. Consequently, we propose a roadmap to enhance the efficiency and durability of SOEC technology in the realms of performance forecasting and system improvement [3].

2.SOEC AND ML LEARNING

2.1. Fundamentals of SOEC Technology

Modeling approaches for SOECs are categorized into two main types: physical models and ML-based methods. Physical models rely on electrochemical equations and material properties, yet their effectiveness is constrained by a lack of data for novel materials. In contrast, ML-driven techniques such as ELM and XGBoost leverage experimental data to deliver adaptable predictions. In this study, these methods were evaluated using a dataset of 322 current-voltage I-V measurements collected at 800°C, provided by Zhang et al. (2017), supplemented by an additional experimental dataset of 355 data points (encompassing ohmic resistance, current density, and hydrogen production rate measurements). A k-fold cross-validation experimental design was employed, with models trained using Python-based scikit-learn and XGBoost libraries to compare the performance of ELM and XGBoost [1,3,4,6]. Comparative results revealed that XGBoost outperformed ELM (Rcc > 0.999), Random Forest (RF), and Support Vector Regression (SVR) in terms of accuracy ($R^2 > 0.95$). While physical models excel when parameters are well-defined, ELM's single-stage training offers superior speed compared to XGBoost's iterative processes, the computational burden of RF and SVR, and the demands of physical simulations. However, ELM's generalization capacity is limited, whereas XGBoost excels with large datasets and intricate relationships, enhanced by hyperparameter optimization. In terms of interpretability, XGBoost's SHAP and PDP analyses provide an edge over ELM's less transparent structure and the limitations of other methods. Regarding

scalability, ML models readily adapt to new data, while physical models require recalibration. In predictive applications, XGBoost combined with Genetic Algorithms identifies optimal operating conditions (e.g., 1.174 L/(h·cm²) H_2 production at 1.61 A/cm²), guiding performance improvements. PDP analysis indicates increased hydrogen production under conditions of 850°C and 1.5 V, while ML predicts wear trends, aiding the development of robust electrode designs. Additionally, ELM and XGBoost forecast SOEC behavior under varying gas compositions, enhancing compatibility with renewable energy grids. At an industrial scale, these models can improve energy efficiency and reduce degradation rates, thereby extending the commercial lifespan of SOECs [1,4].

2.2. Machine Learning and Modeling Techniques

ML is integrated into SOEC technology due to its ability to predict the behavior of complex systems by learning from data, offering an advantage over physical models by analyzing system performance without requiring extensive material data or computationally intensive processes. In this study, two primary ML approaches—ELM and XGBoost stand out for modeling SOECs. ELM excels in rapidly modeling the current-voltage (I-V) relationships of SOECs; Zhang and colleagues (2017) trained ELM using 322 I-V data points collected at 800°C, achieving a fit exceeding 0.999, which enabled the prediction of system efficiency based on gas mixture ratios (H_2O, CO_2) and demonstrated the superiority of co-electrolysis over other processes. Conversely, XGBoost proves more effective in predicting SOEC performance with complex datasets; a model trained on a 355-point dataset (including measurements of ohmic resistance, current density, and hydrogen production rate) using the XGBoost library in Python delivered high accuracy for parameters such as ohmic resistance (R^2 = 0.9620), current density (R^2 = 0.9536), and hydrogen production rate (R^2 = 0.9677). SHAP analysis identified the dominant influences of active surface area, voltage, and temperature on performance, and when coupled with GA, the model achieved an optimal hydrogen production rate of 1.174 L/(h·cm²). Model training was conducted using a k-fold cross-validation experimental design implemented through the scikit-learn and XGBoost libraries [4-7].

2.3. Comparison of ML Methods and Predictive Applications

ML methods employed to predict SOEC performance offer distinct strengths: ELM is effective with small datasets due to its rapid learning and low computational demand, though its generalization ability is constrained, whereas XGBoost excels in analyzing large datasets and intricate relationships, achieving higher accuracy through hyperparameter tuning. In contrast, alternative methods such as RF and SVR yield lower R^2 values compared to XGBoost. In this study, a comparison of ELM and XGBoost was conducted using the Zhang et al. (2017) dataset (322 I-V points) and an additional 355-point dataset, implemented in Python with the scikit-learn and XGBoost libraries, and validated through k-fold cross-validation. In predictive applications, ML-based models guide the identification of optimal operating conditions for SOECs; for instance, XGBoost combined with PDP analysis demonstrated an increase in hydrogen production under conditions exceeding 850°C and 1.5 V. At an industrial scale, these models can enhance energy efficiency and reduce wear rates, thereby extending the commercial lifespan of SOECs [4-7].

3. DISCUSSION AND RESULT

Although SOEC technology holds the potential to revolutionize renewable energy conversion, challenges such as long-term durability and cost-effectiveness persist. The integration of ML offers solutions to these issues while simultaneously raising new questions. ELM's streamlined architecture provides an advantage in rapid prototyping, whereas XGBoost's complexity is essential for in-depth analyses. The success of these models hinges on the quality and volume of data, underscoring the importance of experimental studies. Kamkeng and Wang (2022) emphasized the role of dynamic simulations in modeling the structural degradation of SOECs, yet the combination of such approaches with ML remains underexplored. In this study, ELM and XGBoost models were trained using the Zhang et al. (2017) dataset (322 I-V points) and an additional 355-point dataset, tested with k-fold cross-validation in Python using the scikit-learn and XGBoost libraries, revealing their potential for performance prediction and optimization [1,2,4,5]. Looking ahead, a hybrid integration of ML and physical models could pave the way for breakthroughs in durability and performance enhancement. Innovative designs, such as proton-conducting SOECs (H-SOECs), promise high efficiency at lower temperatures when supported by ML.Solid oxide electrolysis cells stand out as a critical technology in achieving a carbon-neutral energy future by converting renewable energy into chemical fuels. ML plays a transformative role in advancing these systems, serving as a powerful tool to maximize their potential. ML methods such as ELM and XGBoost provide effective solutions for predicting SOEC performance, modeling degradation, and enhancing efficiency through optimization. Building on insights from works like Hauch et al. (2020), Zhang et al. (2017), and Kamkeng and Wang (2022), the synergy of ML with SOECs demonstrates the capacity to shape the future of renewable energy systems. In this study, ELM and XGBoost models, trained on the 322 I-V data points from Zhang et al. (2017) and an additional 355-point dataset using Python's scikit-learn and XGBoost libraries with k-fold cross-validation, showcased distinct strengths: ELM excelled with fast, straightforward predictions on smaller datasets, while XGBoost outperformed in unraveling complex relationships and improving industrial applicability [1,4,6]. These approaches pushed the boundaries of SOEC technology in areas such as performance forecasting and material resilience. Future research could focus on integrating ML with physical models

to align them with real-world conditions, bolster data infrastructure, and support novel material designs, thereby reinforcing the role of SOECs in sustainable energy systems.

4. CONCLUSION

This study highlights the revolutionary potential of ML in elevating SOECs as a key enabler of renewable energy conversion, tackling persistent challenges like long-term durability and cost-effectiveness while laying the groundwork for a carbon-neutral energy landscape. The incorporation of ELM and XGBoost has proven vital in surpassing the constraints of conventional physical modeling, delivering swift, data-driven insights into SOEC performance and degradation patterns. ELM's proficiency in capturing current-voltage relationships with exceptional precision (Rcc > 0.999) and XGBoost's adeptness at navigating complex datasets ($R^2 > 0.95$) showcase their synergistic advantages—speed and simplicity versus robustness and scalability—outperforming alternatives such as Random Forest and Support Vector Regression. Predictive applications, including achieving an optimal hydrogen production rate of 1.174 L/(h·cm²) at 1.61 A/cm² and confirming enhanced yields at 850°C and 1.5 V through PDP analysis, underline ML's ability to refine industrial-scale operations. Nonetheless, hurdles remain: the models' dependence on high-quality data underscores the value of robust experimental frameworks, and while interpretability is improved by tools like SHAP, it still requires refinement. Moving forward, blending ML with physical models and investigating cutting-edge designs like proton-conducting SOECs (H-SOECs) present compelling opportunities to boost efficiency at reduced temperatures and prolong operational longevity. By addressing these gaps, this research establishes a stepping stone for SOECs to realize their transformative promise, steering sustainable energy systems toward greater resilience and feasibility.

ABSTRACT
Today, both developed and developing countries are transitioning to 'new energy technologies', which are clean energy systems like solar-powered, electric and fuel cell (FC) vehicles for future transport planning. In our country, significant studies have been conducted in this direction and the goverment is working to encourage the use of electric vehicles. The aim of this study is to develop a new photovoltaic-fuel cell hybrid battery system as an alternative to existing hybrid battery systems. It is planned to produce twice as much electricity as other fuel cells thorough electrolysis reactions.
In this study, the fuel cell current and voltage produced with the best electrolyte solution concentration to produce hydrogen discharge were tested and the effect of temperature on fuel cell performance was investigated. In the PV-Electrolyzer-Fuel Cell test based on the change of the concentration of the KOH solution, it was determined that the output power increased with the increase of the concentration. The efficiency also increased slightly as the output power increased. It was observed that the cell voltage increased with the increase of the temperature. At the same time, the power density also increased. The optimum result was determined as 1.5 M concentration and 60 °C temperature.

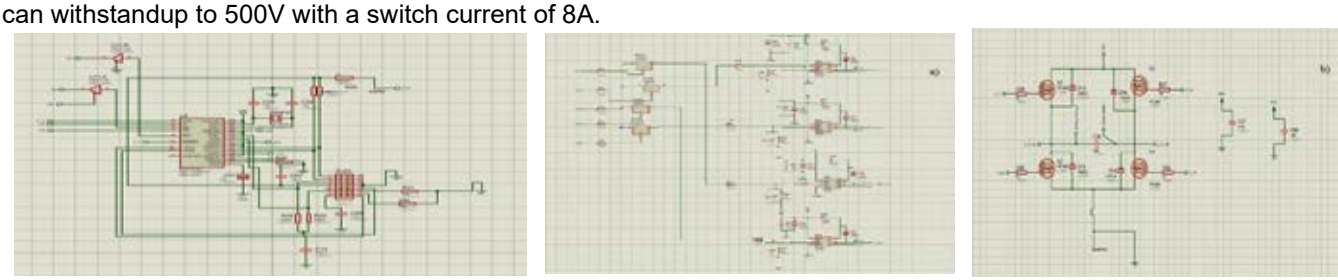
1. INTRODUCTION
Globally, the solar hydrogen and fuel cell attracted more attention as alternative energy sources in 1990s. Solar energy is the most promising source, since the fabrication with a lowercost photovoltaic (PV) devices becomes a reality [1]. However, a solar energy generation does not promise permanent output power due to intermittent weather conditions. PV plant is integrated with other power sources such as hydrogen generator, fuel cell (FC), or battery back-up [2]. The widespread use of hydrogen fuel cell is due to its high-efficiency, faster and more flexible loadresponse, modular production characteristics e.g. change in tone. Unlike batteries, FCs also do not require any special charging. Several types of fuel cells exist, but they all are composed of an anode, cathode and electrolyte membrane that enables the movement of the hydrogen ion (Proton) between the two sides in fuel cells. At the anode (fuel electrode), a catalyst separates the hydrogen molecules into protons and electrons. The ions migrate from the anode to the cathode through the electrolyte. At the same time, electrons move from the anode to the cathode through an external electric circuit, creating direct current (DC) electricity. In cathode another catalyst causes ions, electrons and oxygen (O_2) that reacts to produce water [3]. Proton exchange membrane fuel cells (PEMFC) seem to be the most commonly used type for vehicles, being characterized by low-temperature conditions, high power density, fast start-up process, and rapid response to load changes [4-8]. Our goal is to find the optimum design of a new photovoltaic-electrolyser-fuel cell-battery hybrid system that we model for vehicles.

2. MATERIALS AND METHODS
2.1. Solar Power
Solar panel is used as the primary energy source, fuel cell is used as a backup source in order to meet the electrical load. PV solar panels (Fig. 3. (c)) are composed of by semiconductor materials and they directly convert the sunlight falls onto them to electrical energy. To extract maximum power from solar panel depends on the amount of incident solar radiation on its top. So, a panel needs to be tilted in such an angle that maximum sunlight fall above surface vertically. In this study, the light source is mounted at a perpendicular angle (90° angle) to the solar panel. After turning on the lamp, we wait at least one minute to prevent errors caused due to fluctuations in temperature. An open circuit voltage ($r = \infty$) is used and generated lower resistance sequentially.
2.2. Electronic Control Components
The electrical control componentst of a fuel cell such as inverter, pump and motors, electrical connectors etc. are critical components to ensure the reliable and efficient operation of the fuel cell. In this study, an Electronic Control Interface (ECI) is designed to provide gradual increase in flow rates and to control the power flow.
2.2.1. Design of signal conditioner: To develop this system, Microchip 32mx series has been chosen to construct the electronic control system. It has a 32mx795f512l series mcu 80MHz 32-bit processor, 16 ch Analog-to-Digital Converter (ADC) and 4 Pulse-Width-Modulation (PWM) channels. The signal conditioner can be connected to the PC by USB via a serial port bluetooth. Thus, during the development of the control algorithm, all types software updates, debugging and data exchange can be done through this channel. The signal conditioner will also provide electrical isolation (galvanic) between the processor and the PC by the wireless connection (Fig. 1. (a)).
2.2.2. Motor Drive Circuit: The PFC-3phMotor card operates using the 6PWM channels. DC motor driver circuit (Fig. 1.

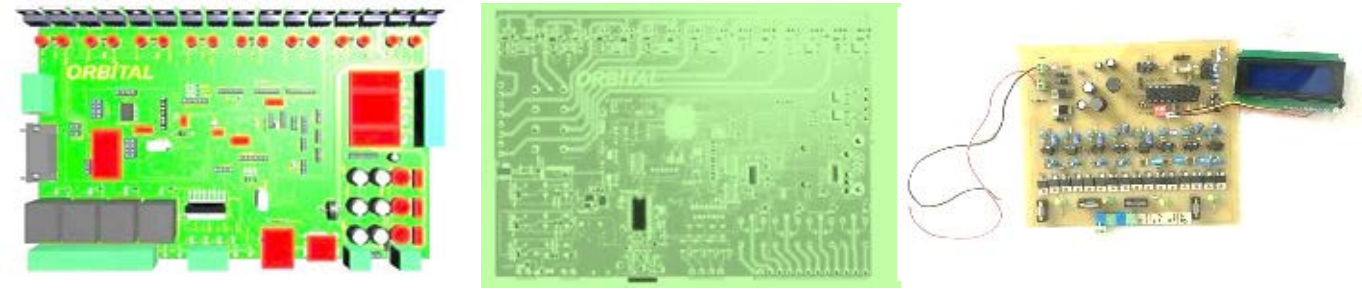
(b)) consists of three MOSFETs forming an H-bridge (Fig.1. (c)) as shown in fig.4. MOSFET technology ensures simpler and more efficient drive circuits with significant economic benefits compared to bipolar devices. This MOSFETs circuit can withstandup to 500V with a switch current of 8A.



(a) (b) (c)

Fig. 1. (a) Ethernet connection circuit. (b) Motor drive circuit, (c) H-Bridge

2.2.3. Electronic Control Interface (ECI): Electronic control interface optimizes the power durability and energy efficiency of the system. ECI includes concentration/humidity/temperature sensors, semiconductor switches, output devices and other electronic units. In this study, the fuel and oxidant flow is recorded sensors with different temperature and concentration and sampled with Analog Digital Converters (ADC) in the digital signal processors (DSP). A new type of computer motherboard has also been developed. System operating characteristics are logged to an SD card using a real-time clock (RTC) module. The motherboard as shown in Figure 5 mainly consists of two modbus/485 communication terminals, one rs232 communication port, and a voice allert system. This motherboard can be connected a touch screen up to 15.1 inches and enable connection to future integrated circuits via ethernet connection.



(a) ***(b)*** ***(c)***

Fig. 2. Sketches of working setup of motherboard a) top-view, b) bottom view, c) design.

2.3. Electrolyser and Fuel Cell

The function of a fuel cell is to convert the energy of the fuel reaction into electrical energy. A fuel cell can be modeled as a controlled current source. In this study, the electrolyser (Fig. 3. (a)) and the H_2/O_2/Air fuel cell (Fig. 3 (b)) was used. The Fuel Cell is a single cell Proton Exchange Membrane Fuel Cell (PEMFC) for H_2/O_2, hydrogen and oxygen operation. By operating the fuel cell with pure Oxygen instead of Atmospheric Oxygen (Air), it has achieved much higher performance with better results. This Proton Exchange Membrane (PEM) fuel cell produces electricity using hydrogen and oxygen gas. Its by-products are water and heat.

(a) (b) (c)

Fig. 3. (a) Electrolyser (b) H_2/O_2/Air fuel cell (c) Solar power.

2.4. Electrochemical measurements

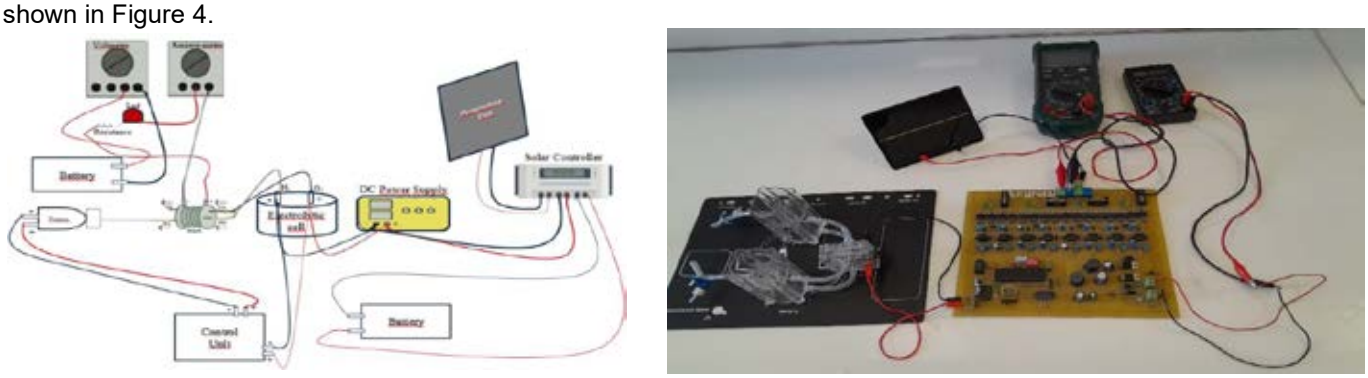
For electrochemical tests, a PEM electrolyzer was used for hydrogen and oxygen production. This cell with a surface area of 3.0 cm^2 was used in electrolyzer mode for hydrogen production. Water reacts in the electrolyzer under the influence of electrical energy according to the following formula:

$$2H_2O \text{ <---> } 2H_2 + O_2 \quad (1)$$

This process takes place in the MEA (membrane electrode assembly). The MEA consists of a cathode, an anode, and a special polymer membrane (PEM) that is permeable to protons but a barrier to electrons. Electrolyzer works according to the PEM principle. The produced gases were stored in storage tanks. The energy stored in the gases in chemical form was converted back into electrical energy in the fuel cell.

3. RESULTS AND DISCUSSION

The model of Photovoltaic-Electrolyser-Fuel Cell and Battery hybrid system and circuit diagram of the studied system is shown in Figure 4.



(a) (b)

Fig.4. (a) Modeling of photovoltaic-electrolyser-fuel cell-battery hybrid system. (b)Circuit diagram of the studied system**.**

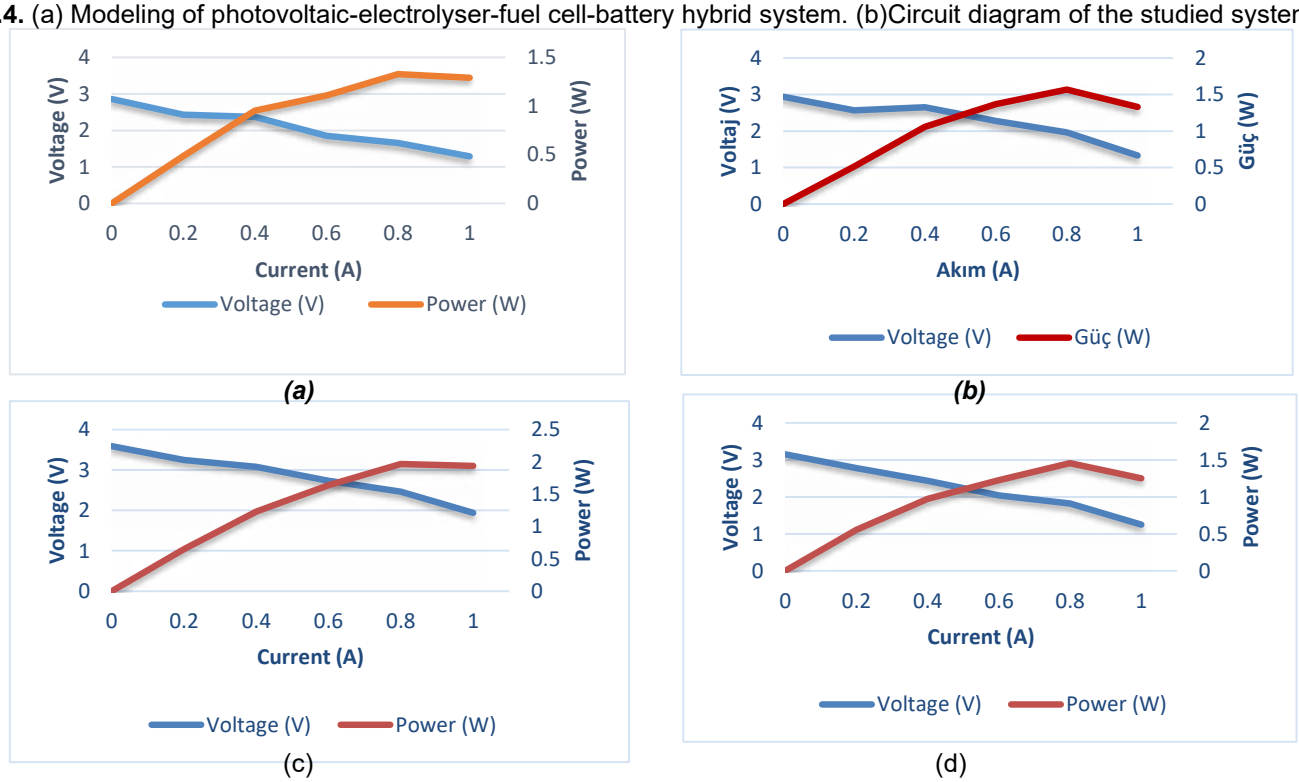


Fig 5. Relationship between current, voltage and output power of PV-electrolyzer-fuel cell and battery hybrid system at (a) 0.50 M, (b) 1,00 M, (c) 1,50 M and (d) 2,00 M KOH solution concentration

In Fig 5. (a), the highest output power of 1.66 V and 1.3280 W at a current of 0.80 A in 0.50 M KOH solution concentration was obtained. In Figure 5. **(b),** the highest output power of 1.96 V and 1.5680 W at a current of 0.80 A in 1.00 M KOH solution concentration was obtained. In Figure 5. (c), the highest output power of 2.46 V and 1.9680 W at a current of 0.80 A in 1.50 M KOH solution concentration was obtained. In Figure 5. (d), the highest output power of 1.82 V and 1.4560 W at a current of 0.80 A in 2.00 M KOH solution concentration was obtained.

In Fig. 6, the relationship between the output power and efficiency of the PV-Electrolyzer-Fuel Cell system was analyzed for a variation of KOH solution concentrations. Here, it is expected that the output power and system efficiency will increase proportionally with increasing current load. The output power is 1.3280 W at 0.5 M KOH solution concentration, 1.5680 W at 1.0 M KOH solution concentration, 1.9680W at 1.5 M KOH solution concentration and 1.9586 W at 2 M KOH solution concentration. The system efficiency is highest at 1.968 W output power in 1.5 M KOH solution and 2.3940 W

at 1.5 M KOH solution.

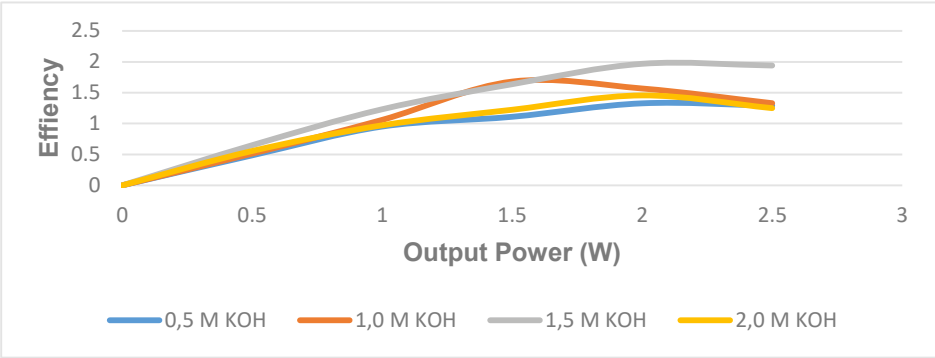

Fig. 6. Output power and efficiency of pfotvoltaic-electrolyzer-fuel cell-battery hybrid system on KOH solution concentration change

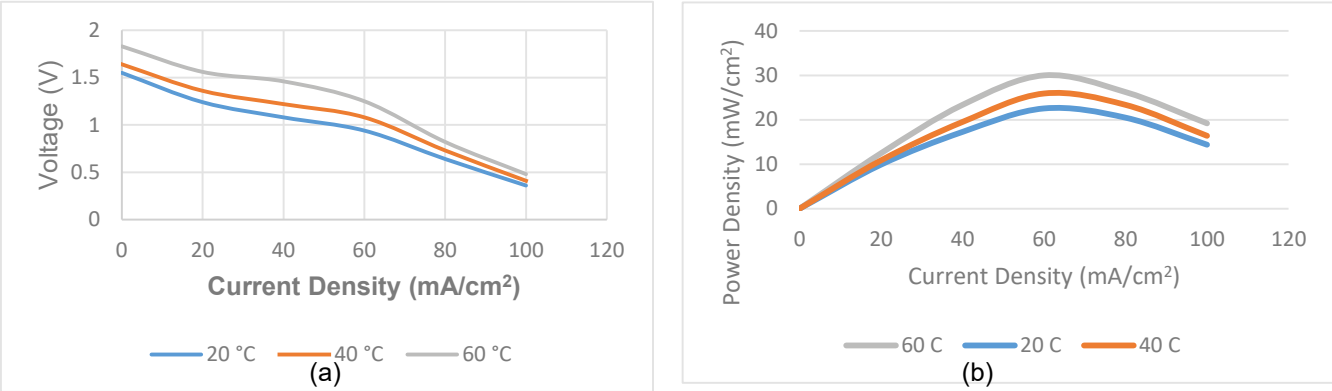

Fig 7. (a) Current density-voltage curve (b) current density-power density curve of PV-Electrolyzer-Fuel Cell system at varying temperatures

Operating temperature is an important parameter to prevent performance losses in the fuel cell. However, increasing the operating temperature is important to determine the optimum cell operating temperature. Measurements were taken at 20, 40 and 60 °C to investigate the effect of temperature on fuel cell performance. It was observed that the cell voltage increased with increasing temperature. At the same time, the power density also increased.

4. CONCLUSIONS

This paper presents the modelling of PV panel, electrolyser fuel cell and battery hybrid system. In the PV-Electrolyzer-Fuel Cell test based on the change of the concentration of the KOH solution, it was determined that the output power increased with increasing concentration. The efficiency increased slightly as the output power increased. The highest power was obtained at 1.5 M. At 2 M concentration, there was a decrease in output power and efficiency. It was observed that the cell voltage increased with increasing temperature. At the same time, the power density also increased. The best result was obtained at 60 °C. The optimum result was obtained at 1.5 M and 60 °C.

ACKNOWLEDGEMENT

ABSTRACT
Proton exchange membrane water electrolyzers (PEMWE) show promise for clean hydrogen production, yet operational conditions and materials selection significantly influence their performance. This study investigates PEMWE performance across various operational parameters. Nafion 115 and Aquivion membranes were evaluated using different catalyst loadings (3-4 mg/cm² IrO_2 anode, 0.4 mg/cm² Pt cathode), various temperatures (50-80°C), and water flow rates (50-100 ml/min). Electrochemical analysis demonstrated substantial performance differences under varying conditions. The test results revealed that at 80°C with a 100 ml/min flow rate, Aquivion membrane-based cells generated approximately 280.26 mA·cm⁻² current density, substantially exceeding the 111.12 mA·cm⁻² achieved with Nafion 115 under identical conditions. Higher catalyst loading further improved system performance. These results highlight the importance of membrane type, operating temperature, flow rate, and catalyst configuration for maximizing PEMWE performance in electrochemical hydrogen production applications.

1. INTRODUCTION

In response to escalating global energy demands and environmental concerns, renewable energy sources integrated with hydrogen technology offer promising sustainable alternatives to fossil fuels. Water electrolysis powered by renewable energy represents an environmentally sustainable approach to green hydrogen production without CO_2 emissions [1]. Among modern electrolyzer technologies, PEMWEs have gained industrial significance due to their ability to handle fluctuating power inputs [2]. PEMWEs function within modest thermal regimes (30-80°C) yet sustain significant current densities (2 $A.cm^{-2}$), yielding gases of exceptional purity (99.99%), and utilize solid polymer electrolyte membranes designed explicitly for proton conduction, making them well-suited for applications ranging from hydrogen refueling stations to renewable energy storage systems [3].

Performance optimization in PEMWEs remains a critical research frontier. Recent research has established vital benchmarks for catalyst integration and performance optimization. Studies have identified optimal Ir loading ranges of 0.204-0.304 mgIr/cm² in PEMWEs, minimizing voltage losses while enhancing conductivity [4]. Other studies have demonstrated that optimal PEMWE performance can be achieved at high working voltages with reduced catalyst loading (0.5 $mg.cm^{-2}$) with 10 wt% ionomer content [5]. Additionally, simplified electrode fabrication methods have achieved high performance (2.39 $A.cm^{-2}$ at 1.9 V) with minimal cathode loading (18.4 µg/cm²), though durability tests indicated a need for further optimization [6]. On the other hand, temperature effects on PEMWE performance were investigated [7]. They operated PEMWEs at 75, 80, and 85°C, demonstrating increased current density with rising temperature under identical membrane electrode assembly (MEA) conditions. Electrochemical analysis confirmed that enhanced ionic conductivity significantly contributed to this performance improvement. Additionally, higher operating temperatures decreased activation potential, exponentially improving performance through increased exchange current density [8].

In this study, PEMWE performance was investigated across multiple operational parameters. The effects of temperature, water flow rate, membrane type, and catalyst loading were examined using Nafion 115 and Aquivion membranes. Electrochemical measurements were performed to determine the relationship between these variables and system performance.

2. MATERIALS AND METHODS

In this study, electrodes were fabricated individually, with the anode catalyst ink air-sprayed onto a gas diffusion layer (GDL) maintained at 60°C. Two different IrO_2 loadings were prepared: i) a 3 $mg.cm^{-2}$ loading using an ink composition of 18 mg IrO_2, 60 µL Nafion solution (ASP-Nafion 10 wt%), 1.2 mL ethanol, and 240 mL deionized water (18 µS conductivity), and ii) a 4 $mg.cm^{-2}$ loading using 24 mg IrO_2, 80 µL Nafion solution, 1.2 mL ethanol, and 240 mL deionized water. For cathode preparation, loading 0.4 $mg.cm^{-2}$ Pt (20% Pt on Vulcan XC-72R, Fuel cell store) was utilized, with the spraying process also conducted at 60°C. All ink formulations underwent sonication for 15 minutes to ensure proper dispersion; experimental parameter values can be seen in 0.

Table 1. Experimental parameters

Parameter	Unit	Min.	Max.
Anode loading	*mg.cm^{-2}*	*3.0*	*4.0*
Cathode loading	*mg.cm^{-2}*	*0.4*	*0.4*
Flow rate	*mL.min^{-1}*	*50*	*100*
Temperature	*℃*	*50*	*80*
Torque	*N.m*	*2.0*	*2.0*

The electrodes were integrated with Nafion 115 and Aquivion E98-09S membranes. Furthermore, the membrane pre-treatment process was customized for the membrane. For Nafion 115, membranes were cut to 5 cm² active area and subjected to a sequential treatment protocol [9]. The entire Nafion pre-treatment process spanned 6 hours. The Aquivion membrane underwent an identical sequence with extended treatment durations of 1.5 hours per step to ensure thorough cleaning. Following pre-treatment, the anode and cathode catalyst inks were sprayed onto the membranes (Airbrush kit, Timbertech store). The MEA hot-pressing parameters were optimized for each membrane type: Nafion 115 was pressed at 2 bar and 120°C for 2 min. At the same time, Aquivion required more aggressive conditions of 5 MPa at 155°C for 2 min to ensure optimal MEA contact and integration.

The PEMWE cell was designed with an integrated MEA. Two titanium (Ti) mesh gas diffusion layers coated with Pt, measuring 2 mil and 10 mil in thickness, were employed as anode GDLs along with carbon paper (Toray Paper 120) to optimize water distribution across the active area. A serpentine flow field was machined into the graphite bipolar plate at the cathode side, while copper current collectors facilitated electrical contact. Teflon gaskets were used throughout the assembly to ensure leak-free operation. The complete setup was fastened between two end plates using screw connections tightened to 2.5 N·m torque. The electrochemical assessment was conducted utilizing an Autolab potentiostat-galvanostat fitted with 10A current booster.. Figure 1 shows the PEMWE single-cell test setup.

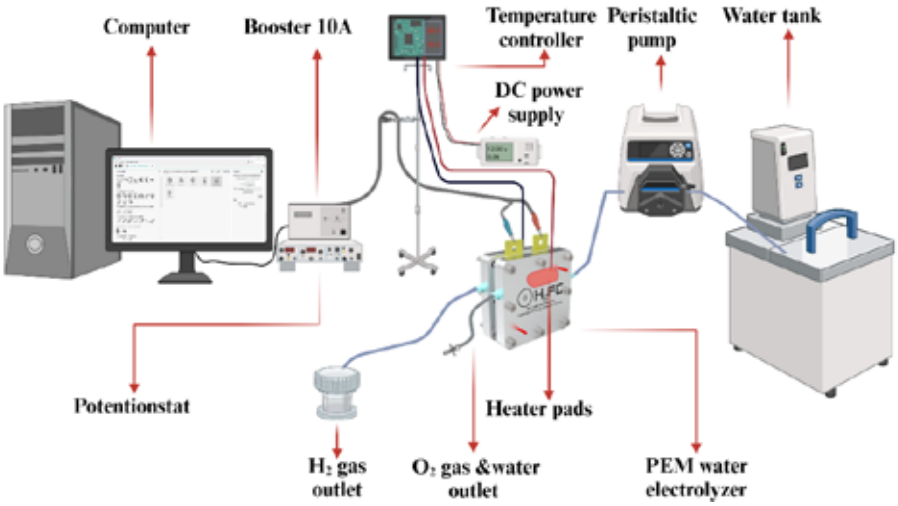

Fig. 1. Experimental setup of PEMWE single cell

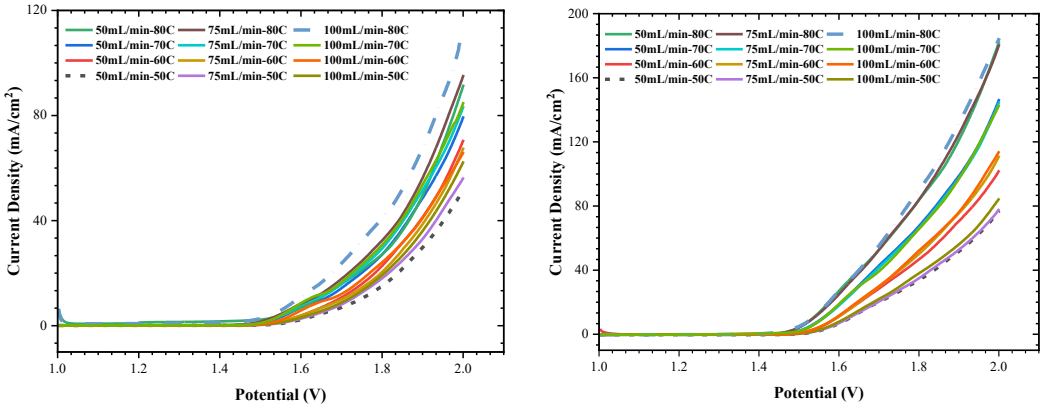
The linear sweep voltammetry (LSV) was performed utilizing a scan rate of 1 mV with step increments of 2.44 mV. Each measurement step lasted 5 seconds, and a 10A high stability booster was activated throughout the procedure [10].

3. RESULTS AND DISCUSSION

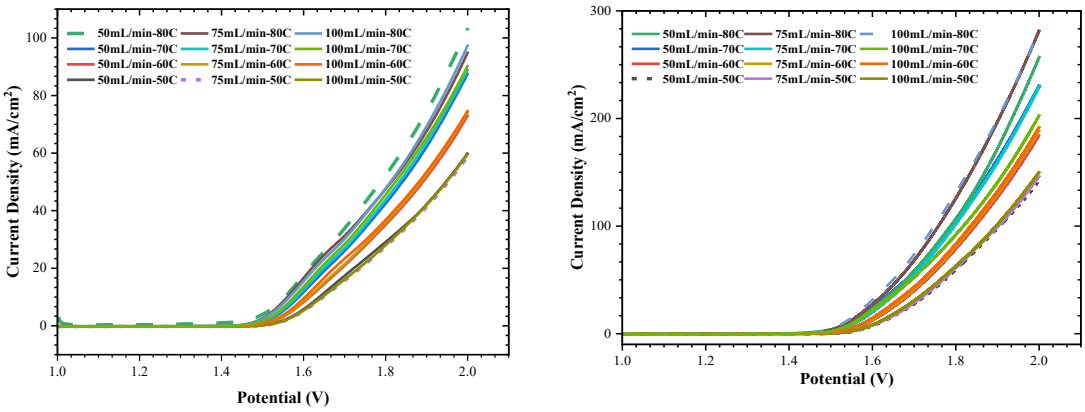
Figure 2 demonstrates the performance of an electrochemical cell employing the Nafion 115 membrane under varying operational conditions. With a 3 mg/cm² IrO_2 anode and 0.4 mg/cm² cathode catalyst loading. Figure 2. a shows that maximum current density (111.12 mA.cm^{-2} at 2V) was achieved at 80°C with 100 ml/min water flow. The 100 ml/min flow rate at 80°C delivered superior performance compared to lower flow rates (75 ml/min yielded 95.45 mA cm^{-2} and 50 ml/min produced 91.75 mA.cm^{-2}) at the same temperature. Furthermore, this configuration dramatically outperformed the system when operated at a lower temperature of 50°C with 50 ml/min flow, which generated only 51.92 mA.cm^{-2}. As seen in Figure 2.b, increasing the IrO_2 anode loading to 4 mg/cm² significantly enhanced performance, yielding 184.68 mA.cm^{-2} at 80°C with 100 ml/min flow, demonstrating the critical impact of catalyst loading and operational parameters on electrochemical cell efficiency.



(a) (b)

Fig. 2. LSV of Nafion 115 with 0.4mg$_{Pt}$ cathode, and Anode loadings (a) 3 mg$_{IrO2}$/cm^2,(b) 4 mg$_{IrO2}$/cm^2

The electrochemical performance of Aquivion membrane-based cells, as seen in Figure 3. Figure 3.a shows that with 3 mg/cm² IrO_2 anode loading and 0.4 mg/cm² cathode catalyst, the PEMWE system achieved a maximum current density of 103.43 mA cm⁻² at 80°C with 50 ml/min flow rate. However, when operated at a lower temperature (50°C) with 75 ml/min flow, performance declined significantly to approximately 57.63 mA/cm² at 2V. Furthermore, Figure 3.b reveals that under conditions of 80°C with a 100 ml/min flow rate, same catalyst configuration produced higher current density around 280.26 mA cm⁻². In contrast, operation at reduced temperature and flow rate (50°C, 50 ml/min) resulted in a substantially lower performance of around 143.59 mA/cm² at 2V.



(a) (b)

Fig. 3. LSV of Nafion 115 with 0.4mg$_{Pt}$ cathode, and Anode loadings (a) 3 mg$_{IrO2}$/cm^2,(b) 4 mg$_{IrO2}$/cm^2

4. CONCLUSIONS

PEMWE experimental analysis demonstrated that optimal performance occurs at 80°C with 100 ml/min flow rate, with Aquivion membranes around 280.26 mA·cm⁻² outperforming Nafion 115 around 111.12 mA·cm⁻². Increasing IrO_2 anode loading from 3 to 4 mg/cm² further enhanced performance, confirming that membrane selection, temperature, and catalyst loading significantly impact PEMWE performance.

ABSTRACT
Green hydrogen production via water electrolysis is emerging as a key technology for reaching net zero CO2 emissions targets due to its ability to generate high-purity hydrogen with minimal environmental impact. In this study, the effect of Co doping on Pt-based electrocatalysts supported on biopolymer-based carbon aerogels (cellulose-CA) using supercritical deposition (SCD) on HER activity and stability was investigated. Pt and Co precursors were deposited onto cellulose-CA via SCD and subsequently reduced via two distinct routes (ex-situ thermal and chemical) under N_2 and H_2 flow at 1 bar and 200°C. Physical characterizations, including ICP-MS, TEM, XRD, XPS, and Raman spectroscopy, confirmed the successful incorporation of Co and Pt via SCD on cellulose-CA. The Co-doped electrocatalysts had similar overpotentials at 20 mA/cm² compared to the non-Co-doped electrocatalysts, despite having half the Pt loading. In particular, Pt-Co-Cellulose-CA reduced thermally had the lowest overpotential (64 mV). Moreover, it had the lowest potential shift (4 mV) after the stress test (1000 cycles at a scan rate of 100 mV/s). These results highlighted the potential of Co doping to enhance the activity and stability of low-Pt electrocatalysts, thereby advancing green hydrogen production via water electrolysis.

Keywords: Hydrogen evolution reaction, Low Pt-loading electrocatalysts, Co doping, Supercritical deposition, Carbon aerogels

1. INTRODUCTION

Green hydrogen is a promising energy carrier due to its remarkable gravimetric energy density (142 MJ/kg, upper heating value) and zero carbon dioxide emissions. Among different types of electrolyzers, alkaline electrolyzers and proton exchange membrane (PEM) electrolyzers have the highest technology readiness level (TRL) with PEM electrolyzers showing the important advantage of a fast response to changing power levels, rendering them the optimal choice to be coupled with dynamic energy sources like renewables [1]. Hydrogen is produced in the cathode part via hydrogen evolution reaction (HER). Platinum (Pt) is the main state-art catalyst for HER due to its optimal Gibbs free energy for adsorbed hydrogen molecules on its active sites [2]. The high costs and limited availability of Pt have motivated researchers to explore various strategies for the development of electrocatalysts with reduced Pt content. The catalyst support plays a crucial role in enhancing the dispersion, utilization and stability of Pt nanoparticles (PtNps). Carbon black, the commercial support, offers advantages due to its electrical conductivity, chemical inertness, and low cost [3]. However, it suffers from stability concerns due to detachment, dissolution, and agglomeration of PtNps [4]. Carbon aerogels (CAs) as catalyst supports have recently gained attention due to their multiscale porosity and high specific surface area. Additionally, their multiscale porosity provides anchoring sites for PtNps and facilitates efficient transport of reactants and products [5]. Various CAs with multiscale pore structures derived from biopolymer sources (e.g., cellulose, alginate, and chitosan) have been reported. Alongside their multiscale porosity and high surface area, they are considered a green alternative due to their recyclability [6]. Supercritical deposition (SCD) is particularly attractive deposition method because it avoids using additional agents that could block Pt active sites and reduce their activity. SCD is especially suitable for impregnating Pt into CAs, as it minimizes the risk of collapsing mesopores and micropores [7]. Furthermore, SCD allows precise control over Pt loading and particle size without requiring additional organic solvents. SCD can be done in different routes (in-situ/ex-situe thermal/chemical) [8]. Each route leads to PtNPs with different physicochemical properties that may affect the HER activity and stability. Another effective method to improve the HER activity and stability of PtNps is doping with other metals such as Ni, Cu, Co and P [9]. For example, it has been reported that doping Co affected the electronic structure of Pt in such a way that enhanced the HER activity and stability [10]. In this study, the aim is to investigate the effect of doping Co on Pt-biopolymer-based CA via two routes of SCD on HER activity and stability. The biopolymer-based aerogels (cellulose-CA) was employed as support. Two SCD despotion methods (ex-situ chemical and thermal routes) were used to investigate the effect of reduction method on the physical and chamical properties of PtNps. Improving PtNps activity and stability aligns with the primary goal of reducing noble metal loading in PEM electrolyzers.

2. MATERIALS AND METHODS

2.1. Materials

Microcrystalline cellulose type II was purchased from JRS Pharma GmbH & Co. KG and abcr GmbH Ger & INT. (1,5-

Cyclooctadiene) dimethyl platinum (II) (Pt(cod)Me_2) and cobalt (III) acetylacetonate, with purities of 97% and 98%, respectively, were purchased from Sigma-Aldrich. All gases used in this work (N_2, H_2, and CO_2) had a purity of 99.998% and were purchased from Ali Gaz. Nafion® 117 solution, with a 5% concentration, was sourced from Ion Solutions Inc. Sulfuric acid (95-98% concentration) was used as required. Sodium hydroxide was purchased from Merck KGaA. Ethanol (EtOH) with ≥99.8% purity and acetic acid with ≥99% purity were purchased from Carl Roth GmbH & Co. KG.All chemicals were used without further purification. Deionized water with a resistance of 18.2 MΩ was used in all experiments.

2.2. Aerogel and Electrocatalyst Preparation

Hydrogel particles were formed using a dripping method in an aqueous solution to synthesize cellulose aerogels, followed by thorough washing. Subsequently, a solvent exchange from water to ethanol (EtOH) was carried out to obtain alcogel particles. These alcogel particles were then subjected to supercritical drying to produce aerogel particles. The aerogel particles were carbonized under N_2 flow at 800°C for one hour to form carbon aerogel particles. A total of 20 mg of Pt(cod)Me_2 and Co(acac)$_3$, either separately or together (10 mg of each), was placed inside a custom-made high-pressure stainless-steel vessel (57 mL volume) along with 200 mg of cellulose-CA and pressurized with CO_2 to 20 MPa at 70°C for 24 hours. After deposition, the adsorbed precursors were thermally and chemically reduced under N_2 and H_2 flow (100 cm³ min⁻¹) for 4 hours at 200°C, respectively.

2.3. Pyhisicochemical Charaterizations

Several characterization techniques were employed to examine the properties of the synthesized electrocatalysts. Pt loadings for all samples were quantified using an Agilent 7700x ICP-MS instrument. X-ray diffraction (XRD) analysis was conducted using a Bruker D8 Advance Diffractometer equipped with a Cu Kα source, covering a 2θ range of 10° to 90°. X-ray photoelectron spectroscopy (XPS) was utilized for surface chemistry analysis, employing a Thermo-Scientific K-Alpha spectrometer with an Al anode (Al Kα = 1468.3 eV). A Renishaw InVia Raman Microscope with a 532 nm laser was used to analyze the structural characteristics of both the unloaded and Pt-loaded supports. Scanning transmission electron microscopy (STEM) was employed to investigate morphology, Pt particle size (based on a count of 100 particles), and dispersion.

2.3. Electrochemical Charaterizations

Electrochemical characterization of the samples was performed using a conventional three-electrode electrochemical cell connected to a potentiostat (Pine Instrument Company Model AFCBP1). The working electrode, provided by Pine Instruments, was a glassy carbon disk with an internal diameter of 0.1963 cm². An Ag/AgCl reference electrode was filled with a saturated KCl solution and a Pt wire counter electrode. The chosen electrolyte was a 0.5 M H_2SO_4 solution. An electrocatalyst ink was prepared by dispersing 8 mg of the electrocatalyst in 1 mL of isopropanol, 3 mL of distilled water, and 50 µL of a 5 wt% Nafion solution from Ion Solutions Inc. The mixture was sonicated in an ultrasonic water bath (Ultra-Turrax® T25) for one hour before deposition. Subsequently, 10 µL of the prepared ink was deposited onto the glassy carbon disk and allowed to air dry at ambient temperature and pressure overnight. Linear sweeping voltammetry (LSV) was conducted at a scan rate of 2 mV/s, and all reported potentials were corrected using Eq. 1.

$$E_{RHE} = E_{Ag/AgCl} + E^{\theta}_{Ag/AgCl} + 0.059pH \quad (1)$$

3. RESULTS AND DISCUSSION

3.1. Physical characterizations

The physical characterization of the synthesized electrocatalysts revealed significant effects of both the reduction method and Co doping. During the SCD process, the solubility of the Co(acac)$_3$ precursor was confirmed through the color change of the supercritical solution to green within the first 1–2 hours (Fig. 1a). After 24 hours, scCO_2 became colorless, indicating that Co(acac)$_3$ had been successfully adsorbed onto the cellulose-CA substrate, as shown in Fig. 1b. The effective deposition of both Pt and Co was subsequently confirmed by ICP-MS analysis (Table 1), which showed a Pt loading of approximately 5.5 wt% for the Pt-Cellulose-CA electrocatalysts, while the Co-doped electrocatalysts contained around 2.5 wt% Pt along with 0.6 wt% Co. Furthermore, Raman spectroscopy analysis of the cellulose-CA structure, assessed by the ID/IG ratio (indicative of defects relative to graphitic content), remained consistent at approximately 1.24 across all synthesized electrocatalysts, demonstrating that metal deposition did not significantly alter the structure of the cellulose-CA support.

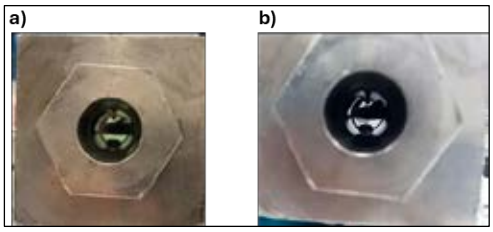

Fig. 1. Deposition of Pt and Co on cellulose-CA via SCD (a) after 1-2 hours and (b) 24 hours

.

The size of PtNPs was found to be influenced by the reduction route. Although the low Pt loading and small particle size hindered the detection of clear Pt peaks in XRD analysis, a more pronounced peak at 2θ = 39.1°, corresponding to Pt [111], was observed in the Pt-Cellulose-CA H_2 compared to Pt-Cellulose-CA N_2, as shown in Fig. 2a. TEM analysis (Fig. 2b-c) corroborated these findings, revealing that the average Pt nanoparticle sizes were 1.1 nm for Pt-Cellulose-CA N_2 and 2.2 nm for Pt-Cellulose-CA H_2, with a notably improved nanoparticle distribution in the thermally reduced electrocatalyst. Additionally, XPS results indicated that both Pt^0 and Pt^{2+} peaks shifted to higher binding energies in the N_2-reduced electroctalyst, as shown in Fig. 2d. This shift was consistent with the small nanoparticle size effect, where smaller Pt nanoparticles exhibit higher binding energies.

Table 1. summary of the physical characterizations of the synthesized electrocatalysts

Electrocatalyts	ICP-MS Pt loading [wt%]	ICP-MS Co loading [wt%]	TEM Np size [nm]	XPS Pt^0 bind energy [eV]	XPS Pt^0 fraction [atomic %]	Raman ID/IG [-]
Co-Cellulose-CA N2	-	1.5 ± 0.1	-	-	-	1.24
Co-Cellulose-CA H2	-	1.5 ± 0.1	-	-	-	1.26
Pt-Cellulose-CA N2	5.5 ± 0.2	-	1.1 ± 0.3	72.28	80	1.24
Pt-Cellulose-CA H2	5.5 ± 0.2	-	2.2 ± 0.6	71.58	82	1.22
Pt-Co-Cellulose-CA N2	2.8 ± 0.3	0.6 ± 0.07	1.3 ± 0.3	72.18	59	1.22
Pt-Co-Cellulose-CA H2	2.8 ± 0.3	0.6 ± 0.07	2.2 ± 0.6	71.58	66	1.24

Regarding the effect of Co doping, the successful incorporation of Co was confirmed by both XPS and EDX mapping, with the latter showing a clear overlap between Pt and Co signals (Fig. 2e and Fig. 2h). XPS analysis further revealed that upon Co doping, the atomic percentage of metallic Pt (Pt^0) decreased from 80% to 60% in the N_2-reduced electrocatalyst and from 82% to 65% in the H_2-reduced electrocatalyst. A slight shift in the binding energy of Pt^0 and Pt^{2+} was observed in the thermally reduced electrocatalyst, whereas no shift was detected in the chemically reduced sample. This indicates that Co doping had a slightly higher effect on the Pt electronic structure in the thermally reduced electrocatalyst compared to the chemically reduced one. Additionally, TEM analysis (Fig. 2f–g) showed that the average nanoparticle sizes for Pt-Co-Cellulose-CA N_2 and Pt-Co-Cellulose-CA H_2 were 1.3 nm and 2.2 nm, respectively. Despite containing only half the Pt loading compared to the non-Co-doped electrocatalysts, the nanoparticle sizes remained nearly unchanged. This suggests that nanoparticle growth on the cellulose-CA support was independent of Pt loading. The slight increase in nanoparticle size observed in the Co-doped electrocatalysts is likely due to the incorporation (merging) of approximately 0.6 wt% Co with Pt.

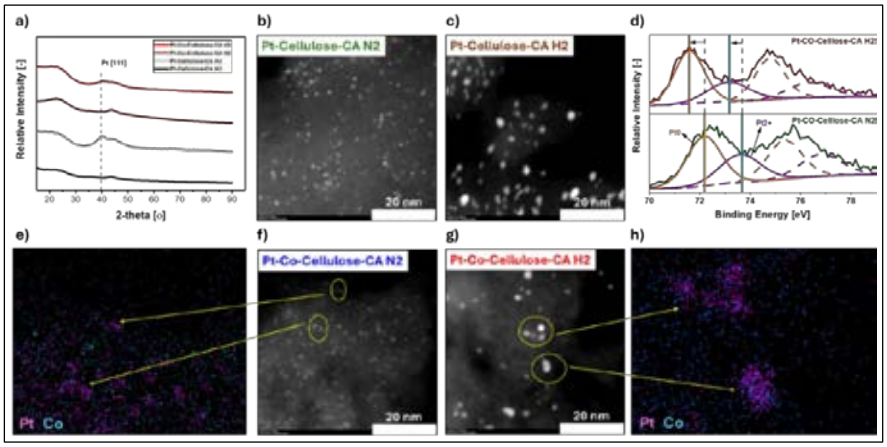

Fig. 2. Physical characterization of the synthesized electrocatalysts, including (a) XRD analysis and (b, c, f, g) STEM images of Co-doped and non-doped electrocatalysts. (d) XPS analysis and (e, h) EDX mapping of Co-doped electrocatalysts reduced via thermal and chemical reduction routes.

3.1. Electrochemical characterizations

HER activity was evaluated by conducting LSV for all electrocatalysts over a potential range of -153 to 20 mV vs. RHE at a scan rate of 2 mV/s and the data are shown in Fig. 3a. Co-Cellulose-CA electrocatalysts exhibited almost no HER activity. The overpotentials measured from the LSV at a current density of 20 mA/cm² were 63.8 ± 1.6, 67.9 ± 2.3, 64.1 ± 0.4, and 65.5 ± 0.8 mV for Pt-Co-Cellulose-CA N_2, Pt-Co-Cellulose-CA H_2, Pt-Cellulose-CA N_2, and Pt-Cellulose-CA H_2, respectively. Moreover, Tafel slopes for these electrocatalysts were found to be within the range of 29–32 mV/dec. Notably, for the non-Co-doped electrocatalysts, the reduction route did not significantly affect HER activity. However, the

Co-doped catalyst reduced under N_2 exhibited a slightly lower overpotential at 20 mA/cm². Although the intrinsic kinetic mass activity cannot be accurately measured due to mass transfer limitations for HER in acidic media [11], the beneficial effect of Co doping cannot be neglected. The Co-doped electrocatalysts achieved current densities comparable to the non-Co-doped ones, despite having nearly half the Pt loading. Co doping is known to improve PtNP dispersion and modify the electronic structure of Pt, thereby enhancing HER activity [10, 12]. Furthermore, stress test involving 1000 cycles between -153 and 20 mV vs. RHE at 100 mV/s, followed by LSV measurements, revealed that the Co-doped electrocatalyst prepared via the thermal reduction route exhibited the highest stability, with a potential shift of only ~4 mV as can be seen in Fig. 3b. This minimal shift indicates that the Co-doped catalyst maintains its electrochemical performance better over prolonged cycling, reinforcing the positive impact of Co incorporation on electrocatalyst stability.

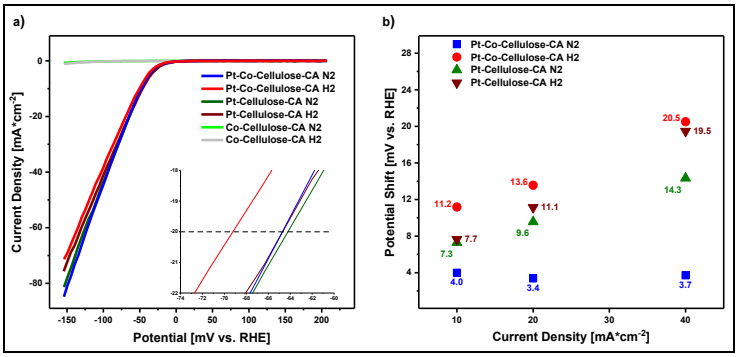

Fig. 3. (a) LSV test for all synthesized electrocatalysts and (b) potential shift after the stress test.

4. CONCLUSIONS

This study demonstrated that Co doping in Pt-based electrocatalysts supported on cellulose-derived carbon aerogels positively affected HER activity and stability. Successfull deposition of Co and Pt by SCD were confirmed through multiple characterization techniques. Among the tested electrocatalysts, the thermally reduced Pt-Co-Cellulose-CA exhibited the lowest overpotential (64 mV) at 20 mA/cm^2 and the highest stability (4 mV potential shift after 1000 cycles). These findings highlight Co doping as a promising strategy to enhance the efficiency and durability of low-Pt electrocatalysts, contributing to the advancement of green hydrogen production via water electrolysis.

ABSTRACT

Hydrogen is a pivotal energy carrier in the transition toward sustainable energy systems, necessitating the development of efficient and scalable production methods. In this study, hydrogen generation is investigated via the methanolysis of sodium borohydride ($NaBH_4$) using lanthanum-based nanowire catalysts, La_2O_3 and $La_2O_2CO_3$. A comprehensive analysis of reaction kinetics, hydrogen yield, and catalyst stability is conducted to elucidate the role of these catalysts in optimizing the methanolysis process. The findings demonstrate that La_2O_3 and $La_2O_2CO_3$ nanowire catalysts significantly enhance hydrogen production efficiency, highlighting their potential for practical applications in clean energy and hydrogen storage technologies.

Keywords: Hydrogen production, sodium borohydride, methanolysis, nanowire catalysts.

1.INTRODUCTION

Hydrogen has emerged as a promising energy carrier due to its high energy density and environmentally friendly nature, making it a key component in the transition to sustainable energy systems. Among various hydrogen production methods, the methanolysis of sodium borohydride ($NaBH_4$) has attracted significant attention due to its ability to generate hydrogen efficiently under mild conditions. $NaBH_4$ is a well-known chemical hydrogen storage material with a high hydrogen content and stability, enabling hydrogen release through catalytic decomposition.

Recent studies have focused on developing efficient catalysts to enhance hydrogen production via $NaBH_4$ methanolysis. Various transition metal-based catalysts, including noble metals such as Pt, Ru, and Pd, have demonstrated high catalytic activity [1]. However, the high cost and scarcity of these metals have driven research toward alternative catalyst materials. Lanthanum-based oxides, such as lanthanum oxide (La_2O_3) and lanthanum oxycarbonate ($La_2O_2CO_3$), have shown promising catalytic properties due to their high surface activity, stability, and tunable electronic structures.

Despite extensive research on $NaBH_4$ methanolysis, no studies in the literature have specifically investigated the catalytic behavior of La_2O_3 and $La_2O_2CO_3$ in nanowire form. This study aims to address this gap by synthesizing and characterizing La_2O_3 and $La_2O_2CO_3$ nanowire catalysts for hydrogen production via $NaBH_4$ methanolysis. The catalytic performance of these materials is systematically evaluated in terms of hydrogen yield, reaction kinetics, and stability under various operating conditions. The findings of this study provide valuable insights into the design of cost-effective and efficient catalysts for hydrogen generation, contributing to the advancement of clean energy technologies.

2. MATERIALS AND METHODS

2.1. Catalyst preparation

The catalysts were synthesized via the hydrothermal method. Initially, 2 mmol of $La(NO_3)_3{\bullet}6H_2O$ was dissolved in deionized water, and the pH was adjusted using an ammonia solution. The solution was stirred at room temperature for 1 hour before being transferred to a hydrothermal reactor, where it underwent aging at 200°C for 24 hours in an oven. Following cooling to room temperature, the resulting $La(OH)_3$ precipitate was filtered, washed with deionized water and ethanol, and subsequently dried at 70°C for 12 hours. To obtain nanowire-structured La_2O_3 catalysts, the dried sample was calcined at 700°C for 2 hours in a muffle furnace. Likewise, nanowire-structured $La_2O_2CO_3$ catalysts were produced by calcining the dried sample at 500°C for 2 hours.

Figure 1. Schematic representation of catalyst preparation by hydrothermal method.

2.2. Catalyst Characterization

The catalysts were characterized using XRD for phase identification, BET for surface area analysis, FE-SEM for morphological examination and TGA for thermal stability assessment. These techniques confirmed the structural and textural properties of the synthesized La_2O_3 and $La_2O_2CO_3$ nanowire catalysts.

2.3. Catalyst Testing

The experimental setup for $NaBH_4$ methanolysis and hydrogen gas measurement comprised a 50 mL jacketed reaction flask equipped with a Teflon-coated stir bar and placed on a magnetic stirrer (Heidolph MR-301, operating within a temperature range of 10–90°C). Temperature regulation was maintained by circulating water through the reactor jacket from a constant-temperature bath (PolyScience water bath). The evolved hydrogen gas was quantified using a graduated glass tube (50 cm in height, 2.5 cm in diameter) filled with water, which was connected to the reaction flask. Additionally, a thermocouple inserted into the reactor ensured precise temperature monitoring [2].

2.4. Determination of activation parameters in the $NaBH_4$ methanolysis

Activation energy was determined by using the catalytic activity of nanowire-structured $La_2O_2CO_3$ catalyst through $NaBH_4$ methanolysis. In order to investigate the effect of temperature and to determine the activation parameters (activation energy (E_a), activation entalphy (ΔH) and activation entrophy (ΔS)), temperature experiments were performed for the 2.0 mmol $NaBH_4$ methanolysis catalyzed by 4.06 mM nanowire catalyst in the range of 20-40°C.

3. RESULTS AND DISCUSSION

3.1.Characterizations of Nanowire Catalysts

The thermal decomposition of the sample at elevated temperatures, as illustrated in Figure 2, progresses through four distinct stages.

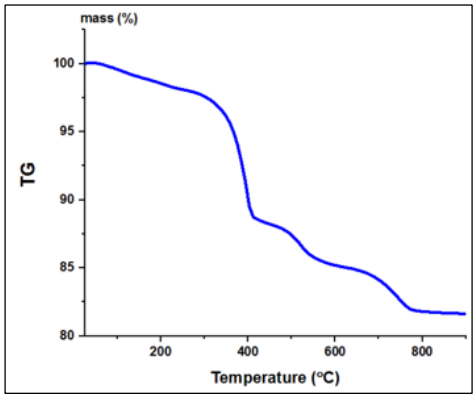

Figure 2. TG curves of synthesized $La(OH)_3$ samples.

The first stage occurs between room temperature and approximately 200°C, followed by the second stage from 200°C to 400°C, both of which correspond to the release of adsorbed and structural water. Thermogravimetric analysis (TG) confirms that water is the only volatile species released during these initial stages, whereas CO_2 evolution is observed exclusively in the third and fourth stages. Between 400°C and 600°C, the formation of $La_2O_2CO_3$ is observed, likely due to interaction with atmospheric CO_2. Finally, above 600°C, $La_2O_2CO_3$ decomposes completely, yielding La_2O_3 as the final product.

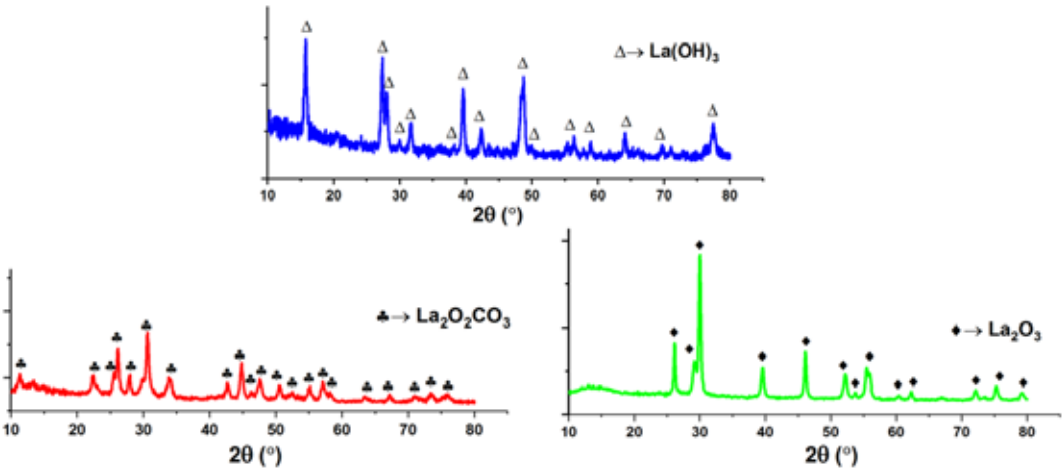

Figure 3. XRD patterns of $La(OH)_3$, $La_2O_2CO_3$ and La_2O_3 nanowire catalysts

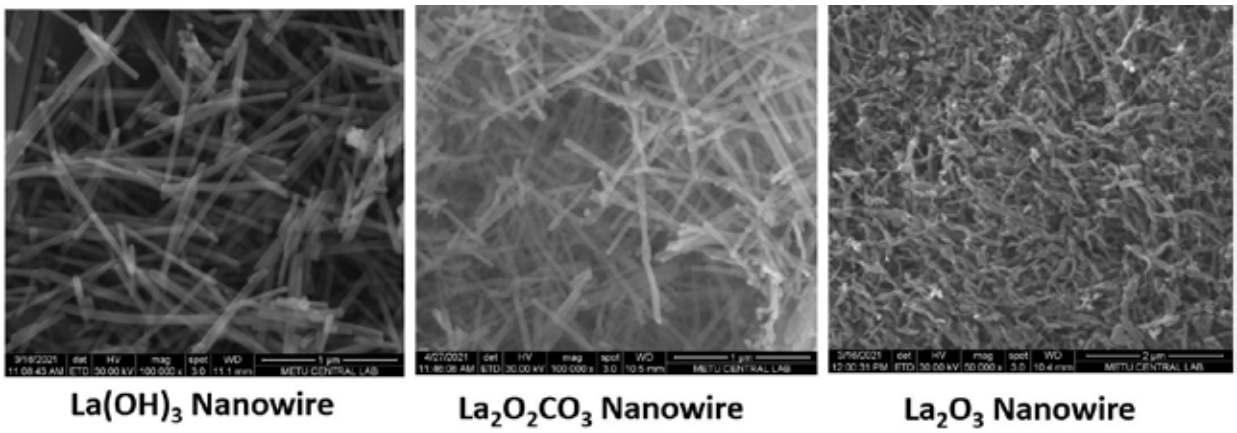

Figure 4. FE-SEM images of nanowire samples

The structural and morphological properties of the synthesized nanowire catalysts were analyzed using XRD, FE-SEM, and BET techniques. Figure 3 presents the XRD patterns, confirming the crystalline phases of $La(OH)_3$, $La_2O_2CO_3$, and La_2O_3. The nanowire morphology is observed in the FE-SEM images (Figure 4), while the textural properties are summarized in Table 1.

Table 1. BET Surface Area

Sample	Specific Surface Area (m^2/g)
$La(OH)_3$	23.5
$La_2O_2CO_3$	21.6
La_2O_3	17.9

3.2. Kinetics study for $NaBH_4$ methanolysis

Nanowire-structured La_2O_3 and $La_2O_2CO_3$ catalysts were firstly tested during both hydrolysis and the methanolysis of $NaBH_4$ at 25.0±0.1°C (Figure 5a). It was observed that Nanowire-structured La_2O_3 and $La_2O_2CO_3$ catalysts showed high activity and stability during the methanolysis of $NaBH_4$, but was rather unstable in its hydrolysis (Figure 5a). This behavior may be due to better dissolution of nanowire-structured catalyst in methanol. In order to investigate the effect of temperature and to determine the activation energy, temperature experiments were performed for the 400 mM $NaBH_4$ methanolysis catalyzed by nanowire-structured $La_2O_2CO_3$ catalysts in the range of 20-40°C (Figure 5b). The rate constant (k) values were obtained from the linear region of the plots and utilized to calculate the activation parameters for catalytic $NaBH_4$ methanolysis using the Arrhenius (Figure 5c) and Eyring (Figure 5d) equations. The activation parameters (Ea, ΔH and ΔS) are found to be E_a=32±2 $kJmol^{-1}$, 35±2 $kJmol^{-1}$ and -106±5 $JK^{-1}mol^{-1}$, respectively. These values can be compared with other catalysts under similar reaction conditions in the literature

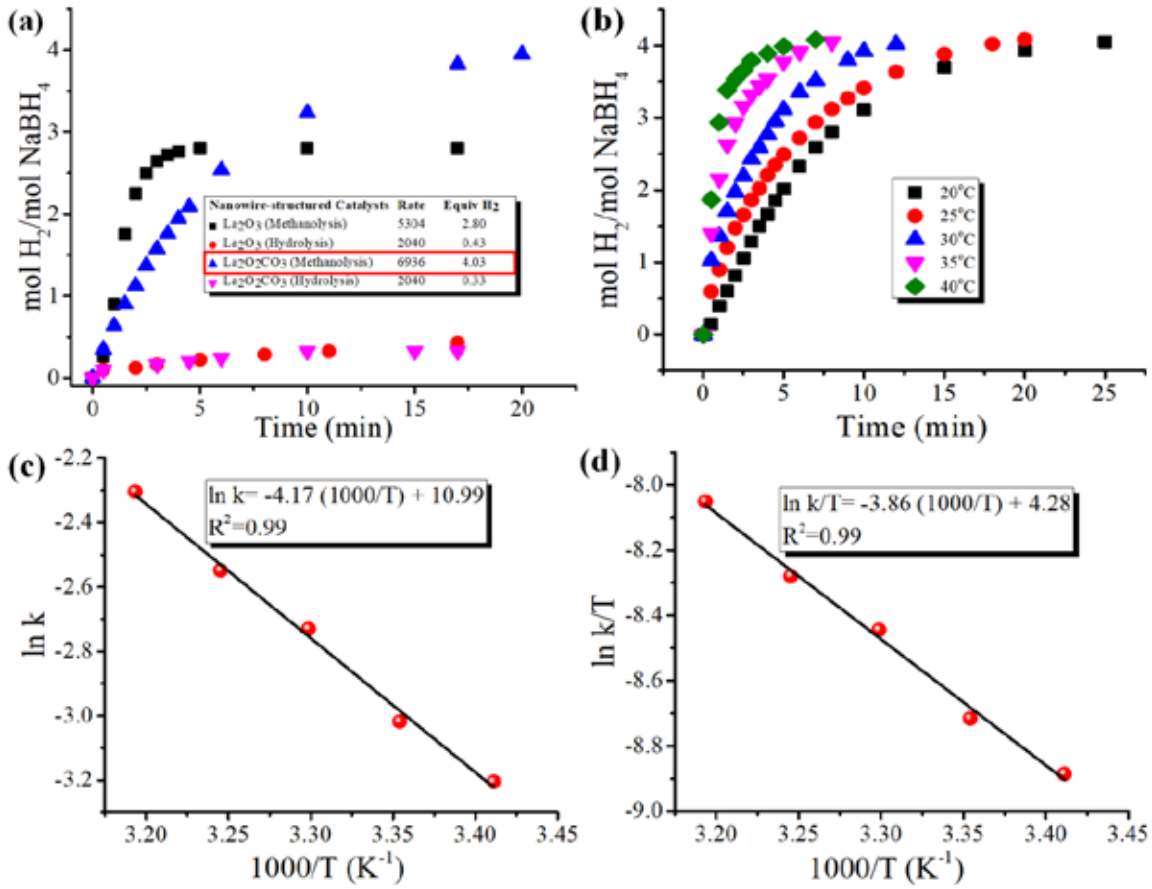

Figure 5. Plots of mol H_2 per mol $NaBH_4$ versus time (min) for (a) hydrolysis and methanolysis reactions (b) The methanolysis of SB in the presence of various temperature ([$La_2O_2CO_3$]=. 4.06 mM, [$NaBH_4$]=400 mM) (c) The Arrhenius plot; ln k versus 1000/T. (d) The Eyring plot, lnk/T versus 1000/T.

4. CONCLUSIONS

In this work, highly active nanowire-structured catalysts were used for the $NaBH_4$ methanolysis at 25.0±0.1ºC. $La_2O_2CO_3$ catalysts exhibited significantly higher catalytic activity compared to La_2O_3. The effect of temperature on the hydrogen generation rate in $NaBH_4$ methanolysis catalyzed by $La_2O_2CO_3$ was investigated by conducting reactions at varying temperatures. The activation energy for the nanowire-structured $La_2O_2CO_3$ catalyst was determined to be Ea = 32± 2 kJ mol^{-1}. All samples were characterized using XRD, FE-SEM, and BET analyses.

ABSTRACT
Hydrogen, being an energy source, is considered as one of the most important solutions that will enable countries to achieve their carbon neutralization goals. Conversion of low rank Turkish lignite into valuable chemicals and energy, namely hydrogen, through gasification has a strategic importance for Türkiye. TRIJEN is a project, leaded by TÜBİTAK incorporation with TKİ that aims to convert Turkish lignite into valuable liquid fuel and energy. “Hydrogen Production from Coal Gasification” project is a follow-up project of TRIJEN project, aims produce hydrogen in TRIJEN Soma pilot plant after required modifications. In this phase of the project, the main goal is to produce H_2 from low rank Turkish lignite, Tufanbeyli coal, via gasification and obtain pure hydrogen. In this paper, Aspen Hysys simulation of hydrogen production process from low rank lignite studied in the project were presented. It was found that thermal efficiency of overall process for hydrogen production from Tufanbeyli coal is 50.6% and 60.5% Nm^3 hydrogen is produced per 100 kg coal feed. Final product H_2 is 99.999% after PSA process.
Keywords: Low rank coal, gasification, hydrogen production, process simulation

1. INTRODUCTION

Coal, a fossil fuel has continued to serve as the dominant energy source worldwide over the past century, mainly for use in the cement industry, iron and steel production and electricity generation. In addition, the combustion of coal in these industries causes significant emissions of greenhouse gases, nitrogen oxides, sulphur oxides and particulate matter, resulting in environmental problems such as global warming, acid rain, sudden climate change, ozone depletion, and air pollution [1]. Clean and efficient use of coal is important in the fight against global climate change in line with the net zero targets of countries and in limiting the temperature increase in the world to no more than 1.5 °C compared to pre-industrial levels [2, 3].

Thanks to coal gasification technology, which is one of the methods of using coal in a clean and efficient way, coal-based chemical synthesis (ammonia, methanol, acetic acid, olefin, etc.), synthetic liquid fuels (dimethyl ether, gasoline, diesel, etc.), electricity generation and hydrogen production can be achieved as a result of converting the fuel into synthesis gas (syngas) under high temperatures in aerobic environment using gasification agents such as O_2, H_2O and CO_2 [1, 4].

Hydrogen energy, a clean, efficient, safe and sustainable source that can also be produced through gasification, is poised to play an important role in the decarbonization of various industries, including transport, heavy industry and power generation, and is seen as one of the most promising energy sources of the 21st century [5, 6]. According to the IEA's Global Hydrogen Review 2024 Report, 20% of the approximately 97 Mt of Hydrogen produced in 2023 was produced by coal gasification [7]. On the other hand, according to the Net Zero Emission Scenario (NZE Scenario) published by the IEA, 38% of the 530 Mt of hydrogen estimated to be produced in 2050 is foreseen to be produced by gasification of CCUS-integrated fossil fuels (natural gas, oil, coal, etc.), and it is important to integrate carbon capture and storage technologies into the hydrogen production process from fossil fuels in terms of low carbon hydrogen energy production [6, 8].

Countries consider their domestic resources in terms of energy cost, energy security and supply chain in hydrogen production [9]. Establishing facilities for gasification technology of coal, which is a domestic resource in Turkey, is considered as a strategic investment [10]. Lignite, one of Turkey's most important domestic energy sources with 16.3 billion tons of reserves, have low calorific value due to their high moisture, mineral matter and organic oxygen content, and can also have high ash content [11,12]. The type of reactor used varies according to coal properties and fixed bed, entrained flow and fluidized bed gasifiers are widely used in the industry. For gasification of coals with high ash content, fluidized bed gasifiers with various advantages such as fuel flexibility, better gas/solids mixture, high heat/mass transfer rates and uniform bed temperature are preferred [12].

According to the literature, although most of the industrial gasifiers used in the world are designed according to high quality coal characteristics, technological development studies continues for gasifier designs suitable for low rank and high ash content coals. Conversion of low rank Turkish lignite into valuable chemicals and energy through gasification has a strategic importance for Türkiye. With this vision the “Liquid Fuel Production from Biomass and Coal Mixtures - TRIJEN” Project, in corporation of TÜBİTAK and Turkish Coal Enterprises (TKİ) started in 2009 aiming to produce liquid fuel from lignite through gasification, gas cleaning, gas conditioning and liquid fuel production (Fischer Tropsch) Technologies. A pilot plant with a thermal capacity of 1.1 MW was designed, constructed and operated in Soma and the Project was completed in 2020. Thus, a great deal of experience has been gained in the design, manufacturing, commissioning, operation and techno-economic feasibility required for establishment of industrial plants for such

applications.
Hydrogen stands out as one of the most important solutions that will enable countries to achieve their carbon neutralization goals without reducing economic development and welfare. TKİ aimed to produce hydrogen from low rank lignite, which are of great commercial and strategic importance for Türkiye, in corporation with TÜBİTAK. In this study, it is aimed to develop technology for hydrogen production from coal with low calorific value, high ash and volatile matter content.

2. MATERIALS AND METHODS

Tufanbeyli coal was selected as the design coal in simulation studies to produce hydrogen. After physical and chemical properties of coal were determined the project team made a technology evaluation for hydrogen production from low rank lignite, made the optimum process determinations and prepared the process flow diagram of the plant. At the end of the project, it is aimed to produce hydrogen from Tufanbeyli lignite through gasification followed by gas cleaning and conditioning units and a PSA unit to purify the hydrogen. In this paper simulation studies of the process of hydrogen production from low rank Turkish lignite will be presented.

2.1. Materials and Feedstock analysis

Ultimate and proximate analysis were carried out to characterize Tufanbeyli coal. Coal properties are given in Table 1.

Table 1 Proximate and Heating value analysis results of Tufanbeyli lignite

	As Received	Air Dried	Dried
Moisture (%)	47.87	7.23	-
Ash (%)	22.40	39.87	42.97
Volatile Matter (%)	22.10	39.33	42.39
Fixed Carbon (%)	7.63	13.58	14.64
Total Sulphur (%)	3.16	5.63	6.07
Heating Value (kcal/kg)			
-Lower Heating Value (LHV)	1313	2766	3024
-Higher Heating Value (HHV)	1669	2970	3202

The as-received moisture content of original coal was found to be quite high with a value of 47.87%. The high ash content of approx. 40% in dried coal requires a detailed and careful reconsideration of ash removal systems in the gasification process. The high volatile matter content of 42% on dry basis provides a positive feature for hydrogen production in gasification. The low fixed carbon content of around 13% on dry basis requires the selection of appropriate coal feeding point and coal size. Total Sulphur content was measured between 4.5% and 6% (Sulfur in ash 2%, Burning Sulfur >2.5%). The high sulfur ratios are important for designing of desulfurization process after gasification. The heating value was found to be low with the measured Higher Heating Value being 3000 kcal/kg (12.36 MJ/kg) and the Lower Heating Value being 2900 kcal/kg (12.1 MJ/kg). Low ash melting temperatures make it important to control the bed temperature so that it does not exceed 900°C.

2.3. Overall Process Simulation

In the first stage of conceptual design, hydrogen production processes from coal was modelled buy using a software program, ASPEN HYSYS. The flowsheet screen of the whole process is given in Figure 1. The hydrogen production process from coal consists of 4 sub-processes: (1) Gasification, (2) Gas Cleaning and Sour Water Gas Shift (SWGS), (3) H_2S and CO_2 Removal, (4) Pressure Swing Adsorption.

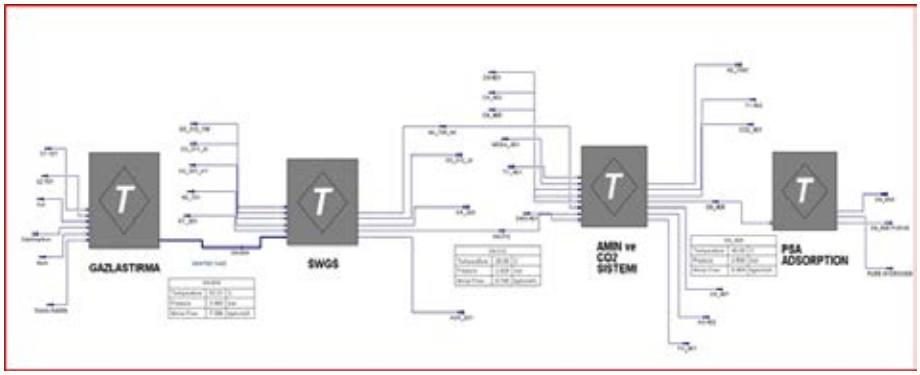

Figure 1. ASPEN HYSYS flowsheet screen of whole system

The main results obtained from the modeling are given in Table 2. As can be seen form Table 2, the thermal efficiency of the process is found as 50.62% and 7.5 kg pure hydrogen can be obtained from 140 kg of Tufanbeyli lignite.

The modeling scheme showing the “Amine Absorption System” for H_2S removal created in ASPEN HYSYS is given in Figure 2. The synthesis gas enters the absorption column at 20°C where the H_2S (hydrogen sulfide) gas will be absorbed. The rich amine solution taken from the bottom of the absorption column is sent to the desorption column for regeneration at 99°C. After the rich amine solution is regenerated, acid gas (H_2S) is taken from the top of the column, cooled to 40°C and after gas/liquid separation, the gas stream is directed to the “Flare”.

Table 2. Results obtained from ASPEN HYSYS modelling

Coal Feed Flow Rate	140	kg/hr
Coal LHV	3024	kcal/kg
Produced Hydrogen Mass Flow Rate	7.5	kg/hr
Produced Hydrogen Volumetric Flow Rate	84.8	Nm^3/hr
Hydrogen Heating Value	120	MJ/kg
Hydrogen Heating Value	28,571.43	kcal/kg
Thermal Efficiency	**50.62%**	
Produced Hydrogen per 100 kg Coal Feed	**5.36**	**kg**
Produced Hydrogen per 100 kg Coal Feed	**60.57**	**Nm^3**

After acid gas removal, synthesis gas, free of H_2S, leaves absorption column. The synthesis is then sent to the “Sulfur Adsorbent Bed” where the H_2S concentration is reduced to <1.0 ppmv.

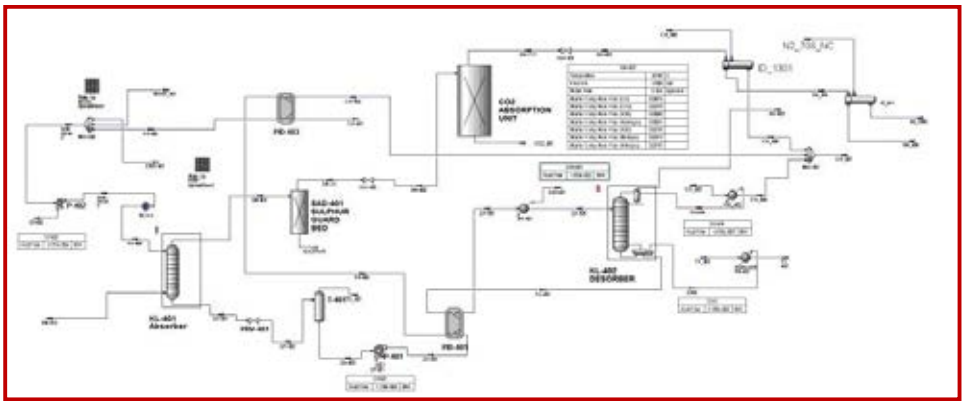

Figure 2. ASPEN HYSYS flowsheet screen of “Amine Absorption Process”

2.4. Design of sub-processes

For the design of sub-systems, the main design parameters (length, diameter, surface area vb.) of the equipment’s (columns, heat exchangers, reactors vb.) is determined.
Using kinetics taken from literature, the required catalyst amounts and reactor dimensions depending on the catalyst amount were determined for the three WGS reactors in SWGS system. The determined dimensions of the reactors were compared with the dimensions given by the catalyst manufacturer from which the SWGS catalyst was supplied. Main parameters of the system are given in Table 3.

Table 3. SWGS system main parameters

Inlet Syngas Mass Flow Rate, kg/hr	158.1
Temperature, °C and Pressure, bara	321 / 3.22
Inlet Syngas CO Concentration, %	22.19
Outlet Syngas CO Concentration, %	0.35
Reactor Number	3
1. Reactor Catalyst Volume, L	319
2. Reactor Catalyst Volume, L	801
3. Reactor Catalyst Volume, L	943

The designs of the absorption and desorption columns in the “Amine Absorption Process” used for H_2S removal were performed by using the ASPEN HYSYS program. Column dimensions (length, diameter), column packing type and flow rate of amine solution and H_2S concentration of the syngas leaving the absorption column were optimized and main properties of the system are given in Table 4. The amine absorption system can be able to reduce the H_2S amount from 12100 ppmv input value to 300 ppmv output value.

In order to reduce the H_2S concentration in the syngas coming from the “Amine Absorption Process” to <1 ppmv, it was decided to use an iron oxide based adsorbent operating at ambient temperature. An offer was received from a commercial company for this purpose. Adsorbent bed system properties are given in Table 5.

Table 4. "Amine Absorption Process" main properties

Inlet Syngas Mass Flow Rate, kg/hr	206.4
Temperature, °C and Pressure, bara	20.0 / 2.99
Inlet Syngas H_2S Concentration, ppmv	12100
Outlet Syngas H_2S Concentration, ppmv	300
Amine Flow Rate, kg/hr	1.571
Amine Concentration, % MDEA	45
Absorption Column Diameter, cm	21
Absorption Packed Height, cm	400
Desorption Column Diameter, cm	20
Desorption Packed Height, cm	400
Packing Type	MELLAPAK 250Y

Table 5. Adsorbent Bed Process properties

Syngas Flow Rate	161.1	kg/hr
H_2S concentration in syngas	**300**	**ppmv**
Adsorbent Amount Needed Adsorbent	1907	kg
Adsorbent Type	FerroSorp S (5-25 mm) FerroSorp S (2-4 mm)	
Total Bed Volume	1.6	m^3
Bed Diameter	1.2	m
Bed Height	1.5	m

PSA process will be used for H_2 purification. Syngas leaving the CO_2 removal system is sent to the PSA unit where active carbon and Zeolits will be used as adsorbent for H_2 purification. According to the simulation result H_2 concentration the final product is %99,999.

3. RESULTS AND DISCUSSION

A study of modifying TRIJEN pilot plant for hydrogen production instead of liquid fuel is being carried out. The study includes every single detail of a plant design e.g., conceptual design, process simulation, detailed design, P&ID, sizing, material and equipment selection, control and automation, HAZOP and LOPA analysis and etc..

The characterization of selected design coal, Tufanbeyli coal, showed the characteristics of this coal are far too different from the design coal, Dereköy coal, of existing TRIJEN pilot plant. Tufanbeyli coal has a low calorific value (HHV=2970 kcal/kg), high ash (39,9) %) and volatile matter content (39,3 %). This high ash content requires a modification in bottom ash removal system. The low fixed carbon content of around 13% on dry basis requires the selection of an appropriate coal feeding point and coal size, whereas the high volatile matter content of 42% on dry basis provides a positive feature for hydrogen production in gasification. The high sulfur content requires design of a new desulfurization process after gasification. After a process evaluation it was decided that some modifications in gasification system and new units for H_2S removal, SWGS and PSA system are required. Design studies are being carried out accordingly.

Aspen Hysys simulation results showed that low rank Turkish lignite can be used in production of hydrogen with a thermal efficiency of 50,62%. It was simulated that 60.57 Nm^3 hydrogen of 99,999% purity is produced per 100 kg coal feed. The high H_2S concentration, which is 12100 ppmv at the gasifier outlet according to the simulation studies, is reduced down to 300 ppmv with the new acid gas removal unit. After a final process of sulfur adsorbent bed the H_2S concentration is reduced to <1.0 ppmv.

4. CONCLUSIONS

This study gives brief information on the project "Hydrogen Production from Coal Gasification" in TRIJEN Pilot Plant, with a 1.1 MW thermal capacity, located in Soma/Manisa. The plant, which was operated between 2016-2020 for experimental purpose, was constructed to produce liquid fuel from biomass and coal mixtures. It is aimed to produce hydrogen in the same pilot plant with low rank lignite. Detailed design of the units is planned to be completed in July 2025 and after construction and installation studies, pilot plant test results are due December 2026.

ACKNOWLEDGEMENT

The authors would like to thank all the team members and partners of TRIJEN project for their grate effort to do such a work, first and only plant of its kind in Türkiye, TKİ and TÜBİTAK for supporting the project.

ABSTRACT
The growing demand for clean and efficient Electric Vehicle (EV) charging solutions has led to the development of hybrid energy-based charging stations. This study presents the design of a standalone DC fast charging station powered by a hybrid energy system combining Photovoltaic (PV) panels and Fuel Cells (FCs) for a holiday resort. The proposed system is designed to enhance energy efficiency and sustainability while reducing dependency on the grid. A detailed system model is developed and simulated using MATLAB/Simulink, analyzing energy production, hydrogen production and consumption, and power management strategies. It is obtained from the results that integrating PV and FC systems improves charging station reliability. The findings highlight that hybrid charging stations can provide an eco-friendly and efficient alternative to conventional charging infrastructures, making them convenient for remote and off-grid locations.

Keywords: DC Charging Station, Fuel Cell, Photovoltaic, Electric Vehicle, Hybrid Energy System.

1. INTRODUCTION

Nowadays, the increasing demand for clean and sustainable energy solutions has led to the development of hybrid charging stations that combine renewable energy sources, such as solar power, with advanced energy storage technologies like the FCs. These hybrid systems aim to address the limitations of traditional charging infrastructure by offering an eco-friendlier, efficient, and reliable energy supply [1, 2]. Solar energy, with its abundance and zero-emission characteristics, provides a promising source for electricity generation, while the FCs offer a flexible and reliable means of energy storage, ensuring continuous power supply even when solar generation is low or unavailable [3].

Hybrid solar and FC charging stations are especially significant in the context of an EV charging infrastructure, where the need for sustainable energy solutions is becoming more critical. Integrating these two technologies can not only reduce the dependency on grid-based electricity but also mitigate environmental impacts associated with fossil fuels [4, 5]. These systems can also operate in remote or off-grid locations, providing energy independence and enhanced resilience.

In recent literature, various aspects of hybrid solar and FC charging stations, including system design, energy management strategies, performance optimization, and economic feasibility have been explored [6]. Researchers have focused on developing models and algorithms for effective integration, aiming to balance energy generation, storage, and consumption. Additionally, the environmental and economic benefits of these hybrid systems have been widely discussed, emphasizing their potential to contribute to global efforts for reducing greenhouse gas emissions and promoting sustainable energy transitions. Firstly, a hybrid renewable energy-based EV charging station that combines solar power, wind turbines, and FCs is proposed [7]. A control strategy is implemented to efficiently manage power distribution across multiple charging ports while reducing grid dependency by exporting excess energy. The effectiveness of the system is validated by the MATLAB/Simulink simulations, demonstrating its ability to simultaneously charge an electric car, an electric bike, and an electric auto using a three-input, three-output port structure. [8], In the context of standalone hybrid energy systems combining the FCs and PV, component costs play a crucial role in overall economic feasibility. In the study, the specifications and costs of system components, including PV panels, FCs, hydrogen tanks, and electrolyzers are examined. The findings suggest that the FCs presents more economic solution than PV panels.

A 100-kW standalone DC fast charging station in Alamein, Egypt which is powered by PV and battery energy storage is designed and controlled by [9]. Using HOMER software for sizing and MATLAB Simulink for performance verification under real weather conditions, the station demonstrates the capability to meet various load conditions effectively. The size of the charging station for Alamein, Egypt is determined as a real load profile by analyzing with HOMER software. Furthermore, MATLAB Simulink simulations are performed to assess the performance of the station under real-world weather conditions and solar irradiance levels. The results confirm that the proposed station can reliably accommodate different load demands. A novel standalone charging station powered by PV and FC is proposed for charging of the EVs [10]. Besides, a new MPPT method is used for obtaining maximally electric power from the PV in the designed system. In the system, a FC stack, an electrolyzer, two hydrogen tanks, and a FC controller are placed. In the case of the greater charge demand than PV output power, the remaining of the demand is provided by the FC. Conversely, when the PV power exceeds the charging demand, the electrolyzer utilizes the surplus energy to produce hydrogen by splitting water. The experimental results and recorded data from the normal operation of the developed charging station are presented. It is observed that the proposed system has a permanent lifetime and lower costs than conventional battery banks that have a limited lifespan. Another study [11] presents a techno-economic evaluation of an innovative standalone hybrid PV-hydrogen energy-based charging station located in Jamshoro, Sindh, Pakistan for plug-in EVs. The simulations of

the presented system are realized by using HOMER software. It is seen from the results that the hybrid PV-hydrogen-battery system is more cost-effective than the PV-hydrogen system. Total electricity generation in the system is primarily sourced from the solar PV and in addition, the FCs also provides the contribution to it. As a result, a cost-effective hybrid EV charging station is designed for the proposed location. In [12], an off-grid solar powered charging station consisting of the FC and hydrogen storage is proposed for the electric and hydrogen vehicles. In the charging station powered by the solar panels, some of the solar power is used for charging the EVs and the rest of it is converted to the hydrogen by working the electrolyzer. The stored hydrogen is utilized for charging the hydrogen vehicles. The consumed power by the EVs and hydrogen vehicles and energy are modeled in the charging station. In the system, an electrical energy is produced for supplying to the electrical loading by the FC. The diesel generator is also used in the system, and the investment and operational costs of solar and diesel systems are reduced by the solar system and diesel generator. The cost, footprint, and reliability effects of deploying hydrogen in off-grid EV charging stations are examined by using a geographic information system for the city of Riyadh, Saudi Arabia [13]. The PV, wind, battery, and hydrogen FC are used in the designed model. The capacity of the charging station which has two level charging is 11 kW and the microgrid is desired without carbon. While a microgrid inluding the PV/Battery/Wind has low cost, the PV/Battery/Wind/Hydrogen configuration has the least footprint. By using the hydrogen, the required footprint of off-grid charging station is reduced by 25% at a small incremental cost. However, in the following years, both the footprint and cost are decreased based on learning-curve assumptions. [14] presents an optimal design of a charging station using solar energy and FC to charge both EV and hydrogen-powered vehicles. In the system, solar panels, a FC, a water electrolyzer, hydrogen storage, and dual-mode vehicles operating on either electricity or hydrogen are placed. The optimal power capacities for the solar system, FC, and hydrogen storage are determined by the mathematical modeling. The simulation results show that the system predominantly depends on solar energy and the FC, while excess energy is directed to a diesel generator. Then, the FC and diesel generator are operated in low solar energy availability and energy distribution analysis is realized. It is observed that 20%, 50%, and 30% of the solar energy are utilized for electrical loads, production, and diesel generator, respectively.

Once examining the studies in the literature, hybrid solar-FC charging stations emerge as a sustainable and cost-effective solution for the EV infrastructure by integrating renewable energy sources and energy storage. Studies show that combining PV systems with the FCs enhances energy efficiency, reduces grid dependence, and ensures reliable power supply, especially in off-grid and remote locations. Besides, it is observed that optimized hybrid systems have lower operational costs, extend system lifetime, and improve overall performance compared to conventional charging methods. Hence, in this study, a DC fast charging station is designed for a standalone EV using a hybrid energy sources which are the FC and PV in tourist destinations. The proposed system is modeled using MATLAB/Simulink and energy production, hydrogen production and consumption, and power management strategies are examined by the simulations. As a result, it is seen that a reliable and robust charging station is developed by this work.

2. MATERIALS AND METHODS

The model of designed system is illustrated in Fig. 1. In the diagram, the electricity generation including the solar PV, battery, and hydrogen FC is shown in blue color. The hydrogen production including the electrolyzer and hydrogen storage is shown in green color. In the charging station powered by the PVs, while some of the solar power is utilized for charging the EVs, the remaining energy is converted into hydrogen through an electrolyzer. The produced hydrogen can either be utilized directly by the FC or stored in a hydrogen tank for using later. Therefore, a charge station model is designed for realizing an optimal energy management by modeling the hydrogen power production and consumption of the EVs.

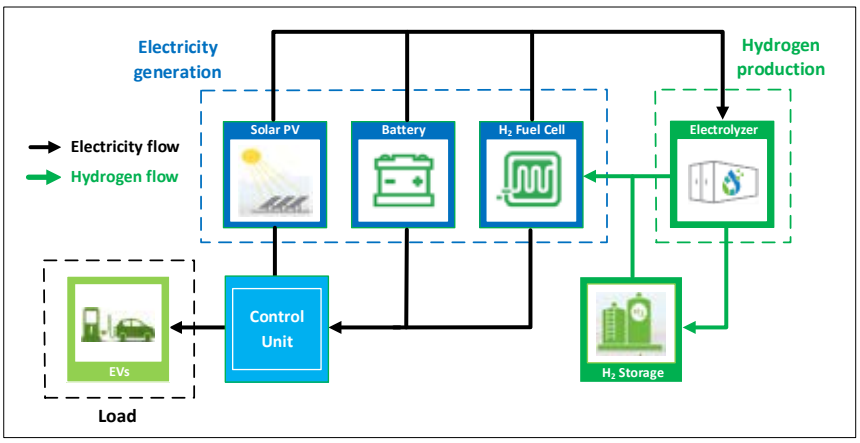

Fig. 1. The designed DC charge station model

2.1. Solar Panel System

In this study, a solar PV system with a total installation capacity of 100 kW consisting of 455 W PVs is designed. The maximum power of the PV is 455 W, optimum operating voltage and current are 43.65 V and 10.43 A, respectively. The open circuit voltage is 52.08 V and short circuit current is 10.74 A. The module efficiency is 20.90% and maximum system voltage is 1500 V DC.

2.2. Fuel Cell System

A HFC-130 model of the Horizon company is chosen as the FC pack in this work. The rated output voltage range of this FC is 500-730 V DC and maximum rated output power is 130 kW. Expected life of the FC stack is max.>25000 h. H_2 purity is >99.97% and the system efficiency at maximum rated output power is ≥42.5%. Hydrogen pressure is also 12-14 barg.

3. RESULTS AND DISCUSSION

In this study, a fast EV DC charging station based on a hybrid energy system with FC and PV is modeled by using Matlab/Simulink. Accordingly, the results are obtained. In Fig. 2, fuel tank pressure, hydrogen consumption, and energy production results are given versus the time. A steady decline in fuel tank pressure suggests continuous hydrogen depletion, while energy output increases proportionally to hydrogen consumption. This behavior corresponds to literature findings that energy efficiency in the hydrogen production depends on the method used, with electrolytic hydrogen requiring between 154% to 614% of its chemical energy equivalent for production [15]. The energy optimization strategies, such as combining hydrogen production with metallurgical processes, could improve overall efficiency.

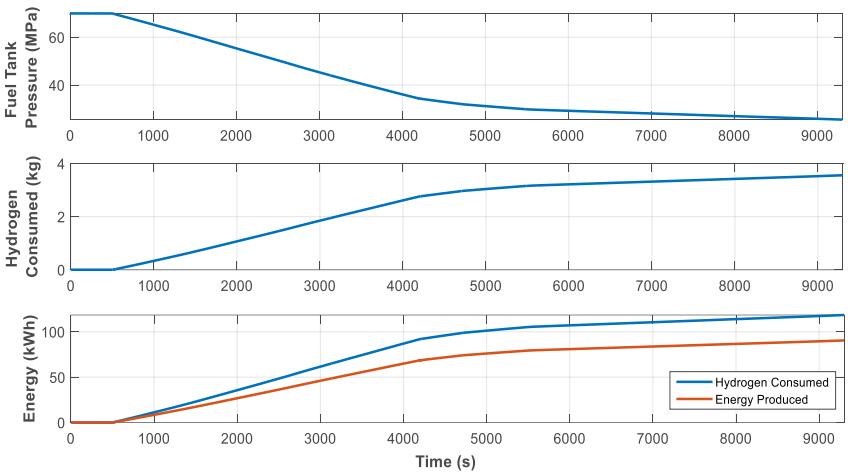

Fig. 2. The curves of the fuel tank pressure, hydrogen consumption, and energy production

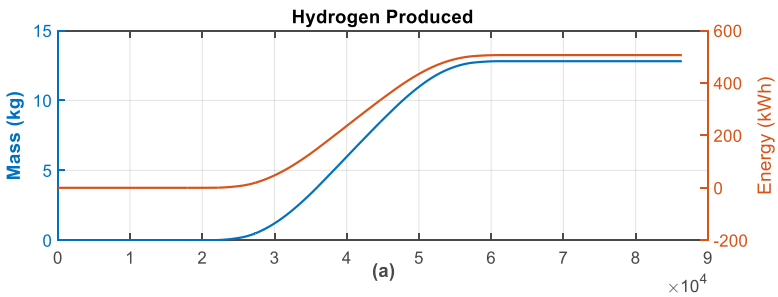
As seen in the Fig. 2, the pressure drop in the fuel tank is directly related to the amount of hydrogen consumed. The decrease in tank pressure and the increase in energy production are among the factors that determine the consumption efficiency of the system. According to literature reviews, the energy efficiency of the hydrogen production process can reach 60-70%, while the total system efficiency including the FC can reach up to 90%.

The mass and energy of the hydrogen produced and power of the solar system are illustrated in Fig. 3.(a) and (b), respectively. The cumulative hydrogen production graph shows a sharp increase in mass over time, correlating with energy generation. This aligns with studies highlighting that hydrogen FCs can achieve the efficiencies exceeding 60%, with ongoing research targeting improvements beyond 70% [16].



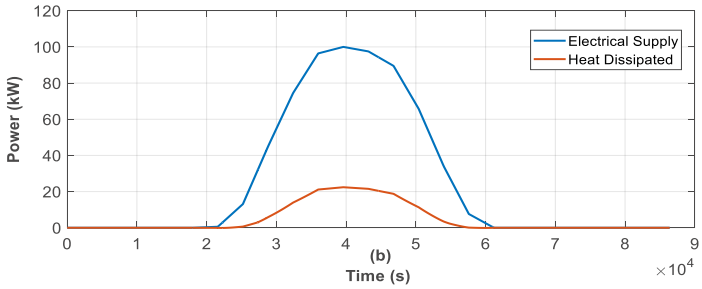


Fig. 3. (a) The mass and energy of the hydrogen produced **(b)** Power of the solar system

In Fig. 3, as the electricity supply increases, hydrogen production also rises, indicating that the system effectively utilizes excess energy for hydrogen storage. Heat dissipation, while present, remains relatively low compared to total energy production, suggesting a reasonably efficient energy conversion process. This system consisting of the combination of the PV and FC provides a balanced solution for an EV fast-charging station, ensuring both instant power supply and hydrogen storage. It can be considered a hybrid energy solution that maximizes solar energy utilization. During peak sunlight hours, excess energy is stored as hydrogen, allowing the FCs to generate power during nighttime or low solar radiation periods. Thus, with this study, a reliable EV DC fast charging station with hybrid energy system is designed for tourism resorts.

4. CONCLUSIONS

This study presents the design and analysis of a standalone DC fast charging station utilizing a hybrid PV and FC system by Matlab/Simulink. In the designed system, the fuel tank pressure, hydrogen prediction and consumption, energy production, and the mass and energy of the hydrogen produced and power of the solar system are examined. The simulation results show that the integration of PV and FC technologies effectively balances energy demand and supply, optimizing hydrogen utilization while maintaining energy efficiency. The proposed system ensures a reliable and sustainable energy supply for EV charging, making it suitable for remote locations. The findings confirm that hybrid energy-based charging stations can significantly reduce reliance on the conventional grid, lower carbon emissions, and improve economic feasibility.

ABSTRACT

In this study, nanostructured La_2O_3-based catalysts were synthesized using the hydrothermal method and characterized by X-ray diffraction (XRD), Brunauer-Emmett-Teller (BET) surface area analysis, and Field Emission Scanning Electron Microscopy (FE-SEM) to examine their structural, textural, and morphological properties. The catalytic activity of the synthesized nanomaterials was evaluated in $NaBH_4$ methanolysis for hydrogen production. The results demonstrated that the nanostructured La_2O_3 catalyst exhibited superior performance, achieving a high hydrogen generation rate. These findings highlight the potential of nanostructured La_2O_3-based catalysts for efficient hydrogen production, contributing to the advancement of sustainable energy technologies.

Keywords: lanthanum oxide, hydrothermal synthesis, $NaBH_4$ methanolysis, hydrogen production

1. INTRODUCTION

Hydrogen is considered a promising clean energy carrier due to its high energy density and environmental sustainability. Among various hydrogen production methods, sodium borohydride ($NaBH_4$) methanolysis has gained significant attention as an efficient and safe approach [1]. In this reaction, $NaBH_4$ reacts with methanol (CH_3OH) to produce hydrogen gas (H_2) and sodium tetramethoxyborate ($NaB(OCH_3)_4$), as shown in the balanced chemical equation:

$$NaBH_4 + 4CH_3OH \rightarrow NaB(OCH_3)_4 + 4H_2 \quad (1)$$

This method offers several advantages, including the high hydrogen yield per unit mass of $NaBH_4$, rapid reaction kinetics, and the use of readily available, cost-effective reactants. Additionally, $NaBH_4$ is a non-toxic and non-flammable compound, making it a safer alternative for hydrogen generation and storage. These characteristics make $NaBH_4$ methanolysis particularly attractive for portable and on-demand hydrogen production applications [1].

The efficiency of this reaction is highly dependent on the choice of catalyst. While various catalysts have been explored for $NaBH_4$ methanolysis, to the best of our knowledge, there are no reported studies on the use of La_2O_3 for this reaction. Given its promising properties in other catalytic applications, investigating La_2O_3 for $NaBH_4$ methanolysis could provide valuable insights into catalyst design for hydrogen production. In this study, La_2O_3 nanostructures were synthesized using the hydrothermal method and evaluated for their catalytic performance. The findings aim to introduce La_2O_3 as a potential catalyst for $NaBH_4$ methanolysis and contribute to the development of novel materials for sustainable hydrogen generation.

2. MATERIALS AND METHODS

2.1. Catalyst Preparation and Characterization

The catalysts were synthesized via a hydrothermal approach. For the preparation of nanorod-structured La_2O_3 (NR), 2 mmol of $La(NO_3)_3 \cdot 6H_2O$ was dissolved in 40 mL of deionized water, and the pH of the solution was adjusted to 9 using a 10 wt% ammonia solution. The mixture was stirred at room temperature for 1 hour before being transferred to a 50 mL hydrothermal reactor, where it was aged at 160°C for 16 hours. After cooling, the precipitate was filtered, washed with deionized water and ethanol, and dried at 70°C for 12 hours. The final catalyst was obtained by calcination at 700°C for 2 hours. The synthesis of nanowire-structured La_2O_3 (NW) followed the same procedure, with the only modification being an increase in the aging temperature to 220°C.

The structural and textural characteristics of the synthesized La_2O_3 nanostructured catalysts were thoroughly analyzed using multiple characterization techniques. X-ray diffraction (XRD) was employed to determine the crystalline phase composition, while Brunauer-Emmett-Teller (BET) analysis was conducted to evaluate the surface area. Additionally, Field Emission Scanning Electron Microscopy (FE-SEM) was utilized to examine the morphological features of the catalysts. These analytical techniques provided comprehensive and systematic insights into the physicochemical properties of the synthesized materials.

2.2. Catalyst Testing

The experimental setup for $NaBH_4$ methanolysis and hydrogen gas measurement comprised a 50 mL jacketed reaction flask equipped with a Teflon-coated stir bar and placed on a magnetic stirrer (Heidolph MR-301, operating within a temperature range of 10–90°C). Temperature regulation was maintained by circulating water through the reactor jacket from a constant-temperature bath (PolyScience water bath). The evolved hydrogen gas was quantified using a graduated glass tube (50 cm in height, 2.5 cm in diameter) filled with water, which was connected to the reaction flask. Additionally, a thermocouple inserted into the reactor ensured precise temperature monitoring [2].

2.3. Determination of Effect of Nanostructured La_2O_3-Based Catalysts Amount in the $NaBH_4$ Methanolysis

In order to investigate the effect of catalyst amount and to determine its high active amount, catalyst amount experiments were performed for the $NaBH_4$ methanolysis (400 mM) catalyzed by *La_2O_3-based catalysts* in the range of 2.5-10 mg.

3. RESULTS AND DISCUSSION

3.1. Characterizations of Catalysts

The morphology of the synthesized catalysts was examined using Field Emission Scanning Electron Microscopy (FE-SEM). As shown in Figure 1, The sample aged hydrothermally at 160°C for 16 hours exhibited a nanorod structure, while the sample aged at 220°C for 16 hours resulted in a nanowire structure. This shift from nanorods to nanowires indicates a change in the growth mechanism or crystal structure. The increase in temperature accelerates the chemical reactions, causing ammonium hydroxide to decompose rapidly and release OH^- ions, promoting axial growth and resulting in longer nanowires. These results suggest that the hydrothermal conditions significantly influenced the shape and size of the La_2O_3 particles.

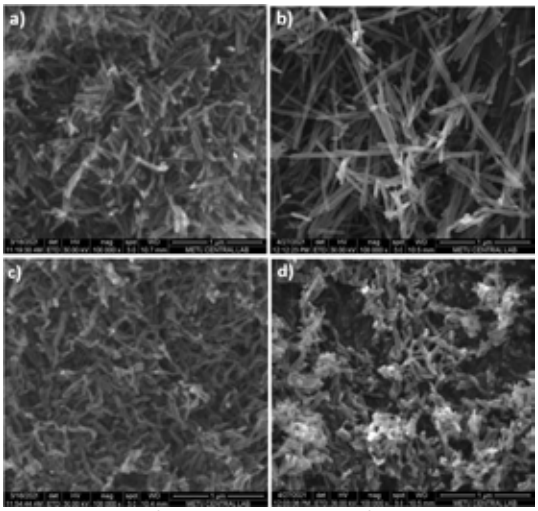

Figure 1.FE-SEM images of MR and NW catalysts. a) uncalcinated NR, b) uncalcinated NW, c) calcinated NR, and d) calcinated NW

The crystalline structure of the catalysts was analyzed by X-ray diffraction (XRD), and the patterns are presented in Figure 2. Both NR and NW catalysts show characteristic peaks of La_2O_3, confirming the successful synthesis of the desired phase.

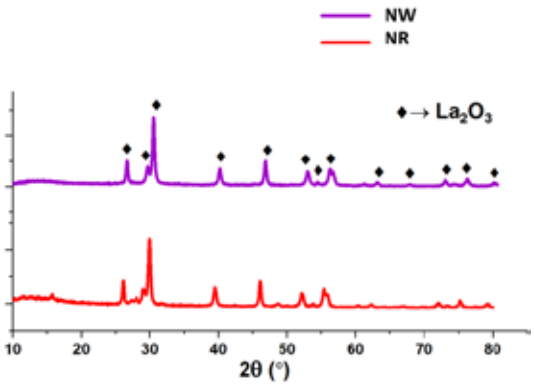

Figure 2. XRD patterns of La_2O_3 catalysts

The surface area of the catalysts was assessed using the Brunauer–Emmett–Teller (BET) technique, and the findings are presented in Table 1. The BET surface area of NR was observed to be greater than that of NW, suggesting that NR provides a higher number of active sites for catalytic reactions.

Table 1. BET Surface Area

Catalysts	BET surface area (m^2/g)
NR	22.9
NW	12.2

3.2. Effect of La_2O_3-based catalysts amount in the $NaBH_4$ methanolysis

NR-La_2O_3 and NW-La_2O_3 catalysts were firstly tested during both hydrolysis and the methanolysis of $NaBH_4$ at 25.0±0.1°C (Figure 3a). It was observed that NR-La_2O_3 catalyst showed high activity and stability during the methanolysis of $NaBH_4$, but was rather unstable in its hydrolysis (Figure 3a). This behavior may be due to better dissolution of NR-La_2O_3 catalyst in methanol. To investigate the effect of the amount of NR-La_2O_3 and to determine the amount of most active NR-La_2O_3, a series of experiments were performed for methanolysis of 400 mM $NaBH_4$ catalyzed by NR-La_2O_3 taken in the range of 2.5-10 mg (Figure 3b). Hydrogen generation rate (HGR) values were determined by taking the highest value of the graphs at 0.5 minutes ($HGR_{0.5}$) and used to determine the most active amount of NR-La_2O_3 for the catalytic methanolysis of $NaBH_4$ using the HGR graph (Figure 3c). Accordingly, the most active amount of NR-La_2O_3 that catalyzes the catalytic methanolysis of $NaBH_4$ was found to be 7.5 mg (4.05 mM). This value will be used as a constant in the following stages of the study.

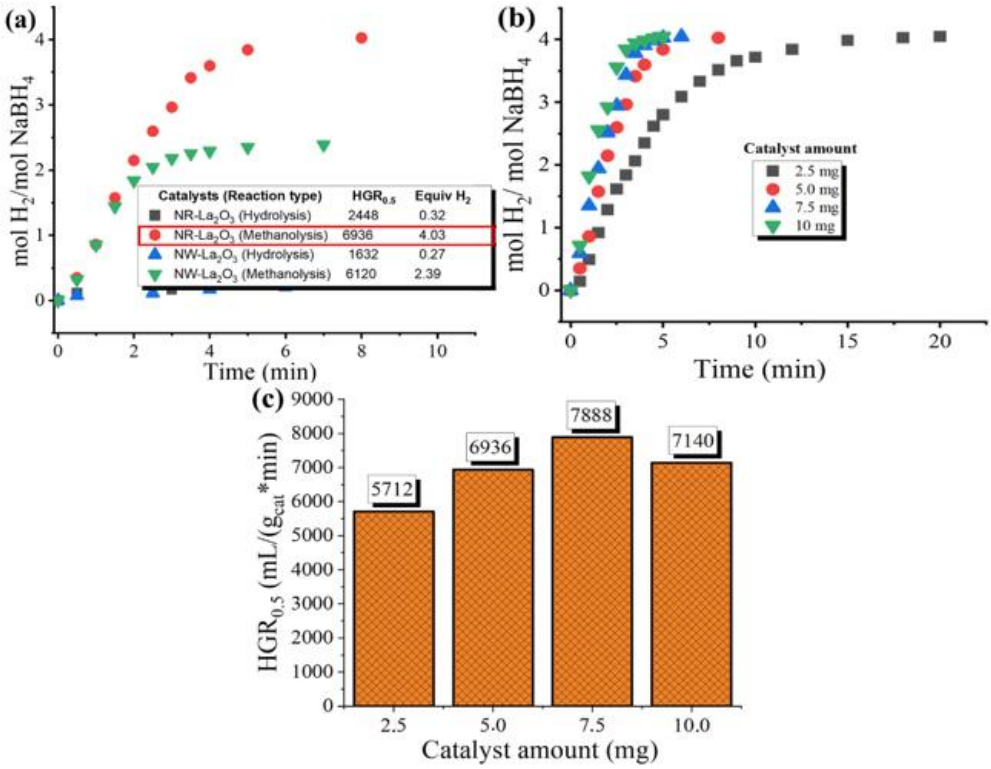

Figure 3. Plots of mole H_2 per mole of $NaBH_4$ versus time (min) for (a) hydrolysis and methanolysis of $NaBH_4$ (400 mM) in the presence of La_2O_3-based catalysts (5 mg) at 25.0 ± 0.1°C. (b) The $NaBH_4$ methanolysis starting with 400 mM SB in the presence of various NR-La_2O_3 amount at 25.0 ± 0.1°C. (c) Plot of $HGR_{0.5}$ versus NR-La_2O_3 amount.

4. CONCLUSIONS

This study is the first to explore the use of nanostructured La_2O_3-based catalysts for facilitating both the hydrolysis and methanolysis of $NaBH_4$ under controlled conditions at 25.0±0.1°C.. Due to the higher solubility of NR-La_2O_3 in methanol than in water, it was found that $NaBH_4$ has much higher catalytic activity and stability in methanolysis than in its hydrolysis. The dependence of the rate of hydrogen production from NR-La_2O_3 catalyzed $NaBH_4$ methanolysis on the amount of

NR-La_2O_3 was investigated by performing a series of catalytic reactions using different amounts of NR-La_2O_3. It was determined that the amount providing the highest activity of catalyst was 7.5 mg. In addition, the chemical structure of NR-La_2O_3 was characterized by XRD, BET surface area analysis, and FE-SEM analysis

ABSTRACT
The growing global energy demand has intensified the need for alternative energy sources to reduce dependence on fossil fuels and mitigate climate change. Hydrogen energy is a promising solution, thanks to its stable energy supply and efficient storage capabilities, overcoming the variability and intermittency issues related to solar and wind energy. However, taking advantage of the opportunities offered by hydrogen energy depends on developing a well-designed hydrogen supply chain (HSC). One key aspect of such a supply chain is its resilience. In this study, we are taking the first step to design such an HSC. In particular, we design the HSC of the Central Anatolia Region of Turkey using Mixed Integer Linear programming (MILP) to minimize the total daily cost related to production, storage and distribution. Then we identify the critical paths in the HSC by calculating costs related to each path when it's not active. The results show that the total transportation cost can increase up to 11.57%.

Keywords: Hydrogen Supply Chain, Mixed Integer Linear Programming, Critical Path Analysis

1. INTRODUCTION

Global energy demand has been steadily increasing due to population growth, industrialization, and urbanization [1]. To meet this rising demand, the use of fossil energy sources such as coal, oil, and natural gas has also increased. However, burning these fuels for energy production releases higher levels of greenhouse gases into the atmosphere. As a result, global temperature continues to rise, emphasizing the urgency of taking immediate action [2]. This has led to an increasing focus on alternative energy sources, such as hydrogen, solar, and wind energy, to reduce reliance on fossil fuels and mitigate the effects of climate change. On the other hand, the variability and unpredictability of solar and wind energy makes their widespread adaptation unpractical on a large scale. At this point, hydrogen energy could be a reasonable solution, as hydrogen production technology stands out by offering a stable and reliable energy supply along with efficient storage options [3,4]. Therefore, hydrogen has been gaining increasing attention, especially as countries like the Netherlands, Spain, Norway, France, the UK, Sweden, Denmark, and Ireland have announced plans to gradually phase out the sale of fossil fuel vehicles [5]. Similarly, Turkey, which has nearly all forms of renewable energy and abundant water resources, outlined its hydrogen technology strategy and roadmap [6]. These advantages position Turkey as a strong candidate for global hydrogen exports if its resources are effectively utilized for hydrogen production. Additionally, not only coastal regions but also Central Anatolian cities have significant potential for hydrogen energy production [7].

Taking Turkey's hydrogen production potential into account, several studies [8, 9,10,11] were conducted to design Turkey's HSC through mathematical optimization problems. Additionally, some studies [12,13] have explored the optimal locations for hydrogen fuel stations in Istanbul, Turkey's most populated city, using various methodological approaches.

One of the important issues that should be considered in supply chain design is resilience. A resilient supply chain is one that can anticipate, adapt to, and recover quickly from disruptions while maintaining the flow of goods and services. In the energy supply chain, resilience is particularly critical due to the sector's reliance on complex infrastructure, global raw material sourcing, and fluctuating demand. Energy supply chains must withstand disruptions such as geopolitical conflicts, natural disasters, and market volatility to ensure continuous energy availability. Identifying critical paths within a supply chain is essential for resilience, as it helps pinpoint the most vulnerable points where disruptions could have the greatest impact. In this study, we aim to investigate the critical paths of the HSC network of the Central Anatolia region of Turkey in 2050. By identifying these critical paths, it becomes possible to implement preventive measures, develop alternative supply sources, and create risk management strategies to increase resilience.

2. METHOD

At the scope of this study, we handle the HSC design problem of Central Anatolia, utilizing a MILP model developed by Almansoori and Shah [14]. This model aims to minimize the Total Daily Cost (TDC) of the HSC. We, then, identify critical paths to gain deeper insights into the network cost. We adapt the model for 2050, which is the earliest year this potential can be realized, by utilizing Turkey's energy potential [15]. Table 1 presents the forecasted number of automobiles and

large vehicles in each city of Central Anatolia in 2050, along with a projection of hydrogen energy demand based on this forecast. Among the cities in Central Anatolia, Ankara, with the largest population, also accounts for the highest number of cars and large vehicles, leading to the highest hydrogen energy demand. Unlike Ankara, Çankırı, as the least populated city in the region, has the lowest demand for hydrogen energy.

Table 1. A projection for the number of automobiles and large vehicles, and hydrogen energy demand in 2050

City	Forecasted Number of Automobiles	Forecasted Number of Large Vehicles	Forecasted Hydrogen Energy Demand (kg/day)
Ankara	4,056,964	953,003	4,347,471
Konya	901,915	370,675	1,641,481
Kayseri	604,580	191,497	858,164
Eskişehir	416,268	128,784	577,836
Aksaray	165,186	57,113	254,836
Sivas	211,438	72,791	324,858
Nevşehir	135,452	64,952	285,978
Niğde	118,934	57,113	251,451
Yozgat	115,630	40,315	179,813
Kırıkkale	93,426	24,737	112,486
Kırşehir	92,504	24,633	111,580
Karaman	89,200	33,596	149,320
Çankırı	52,860	22,397	99,063

The MILP model is solved using the Gurobi solver in Python on a computer with an M1 chip and an 8-core CPU.

3. RESULTS AND DISCUSSION

In the optimal solution of the model, the total demand of the cities—Aksaray, Çankırı, Karaman, Kırıkkale, Kırşehir, Niğde, Sivas, and Yozgat—cannot be satisfied locally, these cities need to import hydrogen from Ankara, Kayseri, Konya, and Nevşehir, where production facilities are to be established. Although a production facility is to be established in Eskişehir, there is no need for hydrogen exports, as the produced amount is sufficient to meet local demand. Furthermore, it can be concluded that to minimize transportation costs, hydrogen flows should occur between cities that are as close to each other as possible.

We then examine the critical paths in this HSC network by sequentially closing each path in the optimal solution and optimizing the resulting problem independently. The paths are closed in descending order of hydrogen flow. Totally 12 optimization problems are solved and summarized in Table 2 which shows the impacts of closing a path on the total cost. It represents the percentage change in TCC (Transportation Capital Cost), and TOC (Transportation Operating Cost), resulting from various path shutdowns, as well as, nominal value of Total Transportation Cost (TTC), change in TTC, and optimum amount of hydrogen flow in a given path.

It can be observed that the cost resulting from path failure can range from almost zero up to more than 11%. This shows that paths are not equal in terms of their critical levels. Therefore, some paths are really costly if they stop working whereas others almost have no effect on the total cost. Another result is that the change in the total transportation cost is not the same as the magnitude of the flow in that path. It turns out that the cost is not affected only by the flow, but it's also affected by other criteria like distance and available alternatives. Therefore, the identification of critical paths needs independent optimization of each scenario.

Table 2. The percentage changes in the HSC network costs (%)

Closed Path	Change in TCC (%)	Change in TOC (%)	TTC ($ / day)	Change in TTC (%)	The optimum amount of hydrogen flow (kg/day)
Konya-Karaman	15.385	7.102	294,481	11,573	149,320
Nevşehir-Niğde	7.692	12.380	289,933	9.850	251,451
Ankara-Çankırı	12.821	1.242	283,710	7.492	99,063
Ankara-Kırıkkale	12.180	0.255	281,598	6.692	111,485

Nevşehir-Sivas	10.897	-11.426	265,582	0.624	164,809

4. CONCLUSIONS

In this study, we aim to explore the critical paths in HSC of Central Anatolia in 2050. This analysis is the starting point of designing a resilient HSC which is robust to disruptions in the infrastructure. The results show that in order to identify the critical paths in an HSC, one needs to account for different criteria of each path. Hence optimization of several different alternative scenarios is needed, which may be very time consuming in large problem instances. Future studies could investigate further steps for designing resilient HSC and make it in a more efficient way to be able to cope with large problems like HSC of Turkey as a whole.

ABSTRACT

This study explores a novel method to enhance the performance of proton-exchange membrane fuel cells (PEMFCs) by electrochemically depositing platinum (Pt) catalysts on carbon paper using a non-ionic surface-active agent, Tween 80. PEMFCs have significant potential in renewable energy systems and portable applications, but their efficiency is limited by the slow kinetics of the oxygen reduction reaction (ORR). Pt-based catalysts are commonly used to accelerate the ORR and improve performance. Recently, electrochemical deposition of Pt has gained attention due to its simplicity, high purity, and cost-effectiveness. Among various deposition techniques, cyclic voltammetry (CV) stands out for its ability to control deposition quality, uniformity, and electrochemically active surface area. The applied potential range in CV governs the nucleation and growth of Pt on the substrate. However, challenges such as poor uniformity and weak adhesion of Pt to substrate can lead to catalyst degradation. This study investigates the use of Tween 80 to promote uniform distribution of Pt nanoparticles, enhance adhesion, and improve catalyst stability. The proposed approach optimizes Pt usage, increases the active surface area, and increases the efficiency and lifespan of PEMFCs. Preliminary results show that Tween 80 significantly eliminates the mentioned challenges, providing a promising solution to Pt electrodeposition.

Keywords: Catalysts, Platinum, Carbon Paper, Electrodeposition, Tween 80

1. INTRODUCTION

Proton-Exchange Membrane fuel cells (PEMFCs) represent a promising technology for clean energy production, offering significant potential for integration into sustainable energy solutions and mobile technologies. The performance of PEMFCs is directly related to the efficiency of the catalysts used at the electrodes, particularly in enhancing the oxygen reduction reaction (ORR), which exhibits slow kinetic rates [1]. Noble-metal platinum (Pt) catalysts are widely utilized to enhance the rate of this reaction, leading to improved performance in PEMFCs. Nowadays, one of the Pt synthesis methods electrodeposition, has emerged as a preferred technique for Pt deposition on substrate material. It is gaining attention for its benefits such as simplicity, high purity, alloying flexibility, and efficiency in both time and cost [2]. Electrodeposition can be performed by the applied current or potential, as well as whether the process is conducted continuously or pulsed manner [3]. This technique is primarily classified into potentiostatic, galvanostatic, and cyclic voltammetry (CV) depositions. Among these routes, CV provides notable advantages in electrochemical deposition, particularly in controlling coating quality, uniformity, and electrochemically active surface area. By monitoring current responses to potential variations on the electrode surface, CV enables a detailed examination of reaction dynamics [4].

Carbon paper is widely utilized as a substrate for Pt catalyst deposition due to its favorable properties such as high electrical conductivity, chemical stability, high-temperature resistance, low cost, availability, and allowing uniform and homogeneous distribution of catalyst particles. Electrochemical deposition of Pt catalysts on carbon paper minimizes Pt usage while simultaneously increasing the active surface area, thus optimizing the catalyst's performance [2]. In the case of platinum (Pt) deposition on carbon paper using CV, the applied potential range from -0.283 V to 1 V (versus the Ag/AgCl electrode) plays a crucial role in governing nucleation and growth mechanisms. When the potential approaches negative values (e.g.-0.283 V), $[PtCl6]^{2-}$ ions undergo reduction at the electrode surface, leading to the formation of Pt atoms. At more negative potentials, the reduction reaction proceeds more rapidly, thereby enhancing the nucleation rate. As the potential shifts toward positive values, the initially formed Pt nuclei begin to grow, with ion diffusion playing a key role in determining the growth rate [5]. Although the electrochemical deposition of Pt catalysts on carbon paper via the CV technique has yielded positive results, certain challenges may arise, including a reduction in the electrochemically active surface area due to inhomogeneous Pt deposition or catalyst degradation resulting from incomplete adhesion of Pt to the carbon paper surface.

Surface-active agents offer an effective solution to achieve a more uniform distribution of Pt nanoparticles during electrochemical deposition. These agents enhance the active surface area of Pt by promoting the even adsorption and accumulation of Pt ions on the substrate. Furthermore, surface-active agents can improve the catalyst's stability and

reduce Pt loss by ensuring stronger adhesion of Pt to the electrode surface. This ultimately contributes to a longer catalyst lifespan and improves the overall efficiency of the PEM fuel cell [6]. This study aims to investigate a new strategy that uses Tween 80 as the non-ionic surface-active agent to enhance the efficiency of PEMFCs by employing electrochemical deposition techniques for the application of Pt catalysts on carbon paper, thereby offering a solution to improve the performance of PEMFCs.

2. MATERIALS AND METHODS

2.1 Preparation of Carbon Paper Substrates

For the electrochemical deposition process, commercially available Freudenberg carbon papers were utilized as the substrate material. The carbon papers, each with an area of 5 cm², were precisely cut using a 31-mm punch and subjected to a cleaning procedure before deposition. Following this process, the carbon papers were dried in an oven and subsequently weighed to determine their initial mass before platinum deposition. The average weight was then calculated to establish a baseline for deposition efficiency.

2.2 Preparation of the Electrochemical Deposition Solution

The electrolyte solution, serving as the coating bath, was prepared by dissolving 0.5 M H_2SO_4 (150 mL) and the required amount of platinum precursor solution (Chloroplatinic acid hexahydrate, Sigma-Aldrich, 37%, 0.05 M). The pH of the solution was carefully adjusted to 2 using NaOH to ensure a controlled acidic environment. Maintaining a stable pH is crucial, as it directly influences the deposition mechanism, surface morphology, and coating properties. To achieve a uniform and well-controlled platinum deposition on carbon paper, a pH 2 environment was selected for this study.

2.3 Electrochemical Deposition of Platinum

The cyclic voltammetry (CV) technique was employed for platinum electrodeposition. The carbon paper substrates were placed in a Teflon sample holder, and their electrical conductivity was verified before each deposition using a multimeter (Tt Technic, 9808). The electrochemical deposition system comprised a Pt plate as the counter electrode and an Ag/AgCl electrode as the reference electrode, in addition to the working electrode.

Following the completion of the designated number of CV cycles at the specified scan rate, a post-deposition cleaning procedure was conducted in 0.5 M H_2SO_4, with a scanning rate of 100 mV/s for 50 cycles, to remove any residual impurities. After both the electrochemical deposition and subsequent cleaning steps, the obtained Pt/C catalyst samples underwent a final washing and drying process. Finally, the deposited samples were weighed, and the average value was determined to quantify the platinum loading on the carbon paper substrates. After determination of Pt deposition parameters on carbon paper with CV, the effect of the addition of different amounts of Tween 80 will be comparatively investigated.

3. RESULTS AND DISCUSSION

The platinum catalysts were coated using a 3-electrode system with cyclic voltammetry. Carbon paper (Fraudenberg) was used as the working electrode, platinum wire as the counter electrode and Ag/AgCl electrode as the reference electrode. The open circuit potential of the electrodes placed in the immersion solution was first measured and cathodic polarization was performed starting from the open circuit potential to -1V. After -1V, anodic polarization was performed again to the open circuit potential and this cycle was performed 10 times. The polarization curves where the coating process was performed are given in Figure 1.

As given in Figure 1, the reduction reaction of platinum begins with the application of cathodic overvoltages. The limiting current value was reached at approximately -0,8V (vs. Ag/AgCl). The platinum particles reduced during the first cathodic scan form the hydrogen desorption peak during anodic oxidation. In the second cathodic scan, the reduction potential of platinum shifted to more negative potential values compared to the first scan. On the other hand, the current value of the hydrogen evolution reaction increases with the number of cycles. After coating, the electrodes were removed from the coating electrolyte and immersed in 0.5 M H_2SO_4 solution for cleaning. 50 cycles were performed between -0.283 V and 1 V with a scan rate of 100 mV/s in acid. The electrochemical active surface area of the catalysts was calculated by calculating the area under the absorption and desorption peaks of hydrogen from the cyclic voltammetry curve obtained.

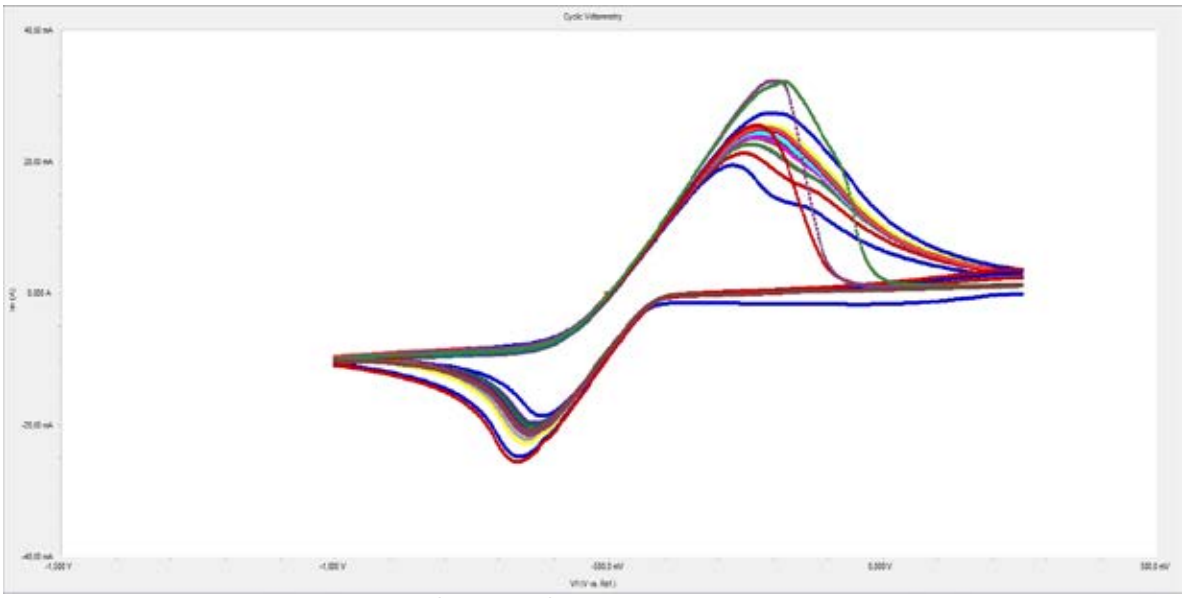

Figure 1. CV curves for catalysts electrodeposition.

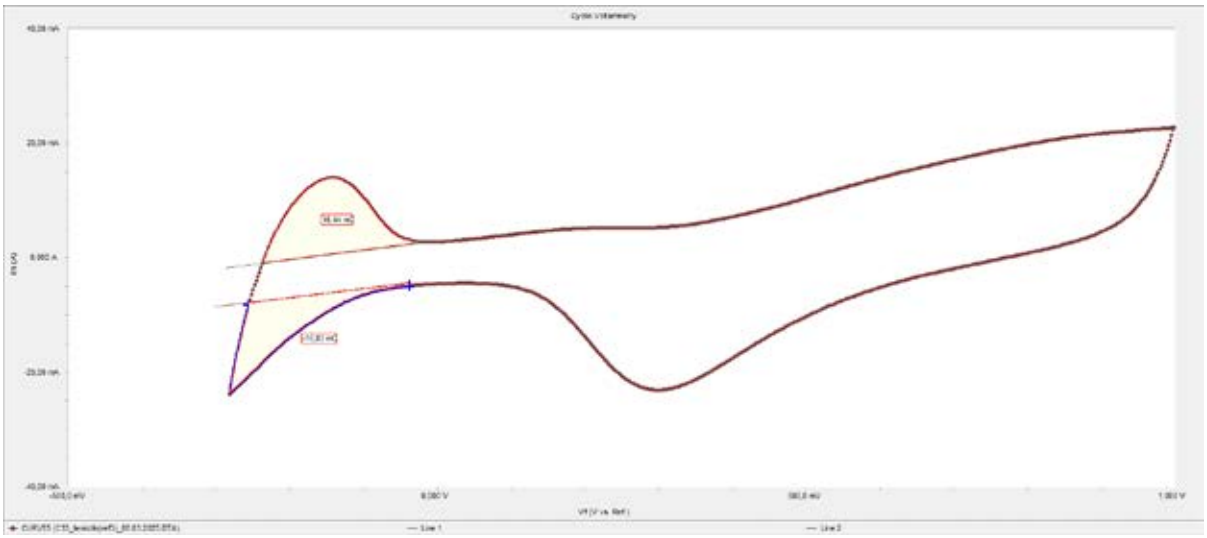

Figure 2. CV curve of electrodeposited Pt catalyst.

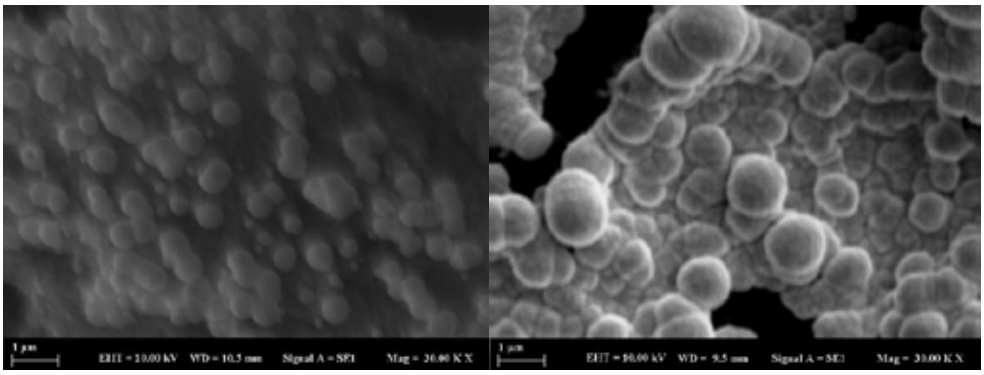
As shown in Figure 2, the cyclic voltammetry curve, which is well known in the literature to belong to platinum, was obtained. Surface roughness of the catalysts was calculated by calculating the areas under the peaks. The reduction reaction of oxygen is also clearly visible in the polarization curve. After coating, the open circuit potential was taken as a function of time and the open circuit potential, which was positive before coating, shifted to a negative potential value after coating. Figure 3 shows SEM images and EDS results of platinum catalysts coated on carbon paper by the electrochemical method.



Element	Weight (%)	Atomic (%)	Net Int.	Error (%)	K (Ratio)	Z	A	F
C K	75.73	98.06	706.10	5.11	0.6266	1.1313	0.7314	1.0000
PtM	24.27	1.94	62.44	9.32	0.1614	0.5671	1.1736	0.9992

Figure 3. SEM images at different magnifications.

As can be seen from SEM images, Pt catalysts are reduced in spherical form on the carbon support. However, the particle size of Pt catalysts is quite high. EDS analysis confirms the presence of Platinum and carbon on the coating surface.

4. CONCLUSIONS

This study suggests that the use of Tween 80 as a non-ionic surfactant in the electrochemical deposition of Pt catalysts is expected to enhance the performance and stability of PEMFCs. By incorporating Tween 80 during cyclic voltammetry-based Pt deposition, a more uniform nanoparticle distribution and improved adhesion to the carbon paper substrate are expected. These improvements are predicted to increase the electrochemically active surface area, optimize Pt utilization, and enhance oxygen reduction reaction kinetics. Furthermore, the proposed method is likely to address common challenges such as poor uniformity and weak adhesion, ultimately contributing to the long-term durability of the catalyst layer. This approach is considered a cost-effective and enhanced strategy for improving PEMFC catalyst performance, making it a promising solution for future fuel cell applications.

ABSTRACT
This research paper focuses on hydrogen value chain (HVC) in positive energy districts (PEDs) with emphasis on the dynamics between energy transition plan and integrated spatial planning. The aim is to resolve the strategic frameworks on trajectories towards 2030 and 2050 by modelling through a multi-level analysis on the dynamics of 'infrastructural' and 'inter-operational' dimensions in order to reveal the path towards integrated energy planning and management (IEPM) for systemic resilience. The role of hydrogen in sustainable and integrated development is explained with reference to scaling-up clean energy technologies that target a decarbonized resilient future through energy transition by cyber-physical systems. The multi-level performance character of coopetitive models is evaluated by multi-criteria decision analysis/analytic hierarchy process (MCDA/AHP) method with a multi-scalar parametric framework on IEPM for systemic resilience. The research framework designed from global to macro-regional and micro-regional levels is built by 30 key performance indicators ('m') and 4 key performance values ('n'). The research revealed that HVC is the common denominator for developing PEDs. The findings demonstrate that challenges and innovations for integrating advanced energy technologies into urban regions to achieve energy-based systemic resilience can be fulfilled through multi-level dynamics between 'system-based clean energy frameworks' and 'strategy-based multi-scalar operations'.

Keywords: Positive Energy Districts, Hydrogen Value Chain, Energy Transition Plan, Integrated Spatial Planning, Integrated Energy Planning and Management.

1. INTRODUCTION
Throughout the history of sustainable development, energy crises that puts energy sovereignty in a conjunctural gridlock have been overcome by either a change in production methods or an innovation in operational models. Radical transition from conventional energy resources to renewable energy alternatives had denoted a paradigm shift diffused in every aspect of the relationship between human and environment. Radical innovations in the frameworks of advanced energy technologies and accelerated progress in clean energy mechanisms has triggered coopetitive processes to be regulated by multi- and trans-disciplinary collaborations on the issues of integrated and sustainable development. Both of the radicals converged on Positive Energy Districts (PEDs) which are developed as both a localized response to the global strategy for energy transition [1] and a coopetitive instrument in the energy transition mechanism for achieving systemic resilience. Because, PEDs are defined through their annually energy balance characteristics that indicate surplus energy due to a mix of integrated renewable systems within a value chain [2], wherein energy flows between actors (consumers, producers, prosumers and storage systems) get optimized in order to improve energy efficiency among the district [3]. Moreover, Energy Transition Plan (ETP) refers to a strategic framework aimed at shifting energy systems from fossil fuel reliance to sustainable and renewable energy sources for facilitating the establishment of Hydrogen Value Chains (HVCs)[4] in PEDs, while Integrated Spatial Planning (ISP) involves a coordinated design and management of land use and infrastructure for optimizing energy efficiency and encouraging the development of self-sustaining urban areas [5] that align with the targets in Strategic Energy Technology (SET) Plans [6] synchronized with Sustainable Development Goals [7]. The joint need for HVC in PEDs arises from ongoing global energy crisis, fueled by factors such as energy bottlenecks stemmed from regional conflicts and the climate mitigation targets of decarbonization outlined in the Paris Agreement. As urban populations are expected to reach two-thirds of the total by 2050 [8], it is essential to integrate ETPs with ISPs to develop sustainable energy systems that are both resilient and self-sufficient. Furthermore, the emphasis on hydrogen as a key element of the clean energy policy on global agenda highlights the importance of developing effective infrastructure to meet urban energy demands and foster competition in clean hydrogen technologies. Due to extensive technological advances and innovations in clean energy research, deploying hydrogen infrastructure and shaping HVCs, which are structured by generation, transmission, distribution and either utilization or storage of hydrogen energy, have become at the forefront of achieving carbon-neutral future and empowering energy sovereignty[9]. Therefore, HVCs integrated into PEDs make an innovative contribution to the catalyzing effect for building mechanism-instrument relationship on the multi-dimensional dynamics of clean energy-oriented integrated and sustainable development. Moreover, ETPs bridged with ISPs make a transformative contribution to authorize the coopetitive framework and strategic tools necessary to effectively plan and implement hydrogen-based energy policies and spatial strategies. The novelty of this research is modelling of the 2030 and 2050 scenarios that include HVC for and/or PEDs from a holistic perspective by a multi-level analysis and integrated synthesis on systemic resilience.

2. MODELING AND METHODS

The scope of the research is to resolve the multi-dimensional dynamics of clean energy-driven integrated and sustainable development modelled by a qualitative-quantitative mixed research method. The research hypothesis is that 'dynamics of the inter-operational dimension, which comprised of ETP and ISP, designate an exclusive type of operative performance character of integrated energy strategy for designing, planning and managing the infrastructural dimension, which involves HVC in PEDs. In conformity with the research hypothesis, 'research-based strategic agendas' (KPIs, 'm') and 'practice-based systemic frameworks' (KPVs, 'n') in the last five years are selected for addressing the question of hydrogen energy, especially the HVC in PEDs, for resolving holistic models on systemic resilience to unveil the encoded 2030 and 2050 scenarios. Then models are configured on excel by the theory-based principles of multi-criteria decision making (MCDM) that is employed under the frameworks of soft systems methodology without any special software [10]. The parametric framework of this research is structured by the KPIs (Figure 1.a) and the KPVs (Figure 1.b) by a holistic approach on systemic resilience. The KPVs ('n') of multi-criteria set is structured by interlocking systemic layers in practice for PEDs and HVC on the (infra)structural dimension as well as for ETP and ISP on the inter-operational dimension. The KPIs ('m') of multi-criteria set is structured by dynamically strategic levels of multi-scalar interconnectivity in holistic approach ranging from global level at macro scale to regional level at meso scale and local level at micro scale. The modelling is executed by the integrated approach on "MCDA/AHP method" [11], which is a qualitative-quantitative mixed research method in multi-criteria decision-making approach on modelling and simulation for resolving real-world problems and/or testing the scenario-based hypothesis.

Figure 1: Key Performance Values (KPVs) and Key Performance Approaches (KPAs) of the performance modelling framework

Information is quantified into data by the rule of three-tiered fuzzy logic principle (1). Then, quantified data is systematized on basis of the rule of value distribution (2) to formulate the characteristic function of the models. The characteristic performance of the model(s) is evaluated regarding the ratio between infrastructural to inter-operational dimensions on the "5-point-characterization scale" [10] from coopetitive (48/52; collaborative leadership), competitive (49/51; strategic collaboration), neutral (50/50), competitive (51/49; strategic partnership), and coopetitive (52/48; sovereign leadership).

$$criteria \rightarrow non-existing: 0 \quad uncertain: 0.5 \quad existing: 1 \tag{1}$$

$$\sum_{i=1}^{n} w_i = 1 \tag{2}$$

The integrated performance is calculated through weighted value measurement in a mxn matrix format (3) whereas the comparative performance is calculated through pairwise comparison of parametric framework in a m/m matrix format (4).

$$\sum_{j=1}^{n} a_{ij}\, w_j \quad (for\ i = 1, 2, 3 \ldots m) \rightarrow A_m, C_n(W_n) = a_{ij\ (m\ x\ n)} \tag{3}$$

$$C_i(W_i), C_j(W_j) = C_{ij}(W_{i/j}) \rightarrow C_{ij_{(m/m)}} \tag{4}$$

Evaluating the comparative performance of the model(s) is achieved by attributing relative weights to criteria from 1-9 with reference to the Saaty scale. Pairwise comparison scores under 1.000 are treated as bias, thus excluded [10]. All of the performance measurements are evaluated through the ranking rule on score and order of importance by not only the max-min strategy (5 and 6) but also the min-max strategy. Overlapping the max-min and min-max strategies provides deciphering the control code(s) of scenario(s) out the models [11].

$$A_{max.1} \geq A_{max.2} \geq A_{max.3} \dots \geq A_{max.m} \quad (5)$$
$$C_{max.1} \geq C_{max.2} \geq C_{max.3} \dots \geq C_{max.m} \quad (6)$$

Checking the consistency ratio of the models' performance (7) is excluded from the holistic modelling approach, because evaluating the reliability and validity measure of preferences limited to 10 alternatives and/or criteria by Saaty in the decision-making process [11].

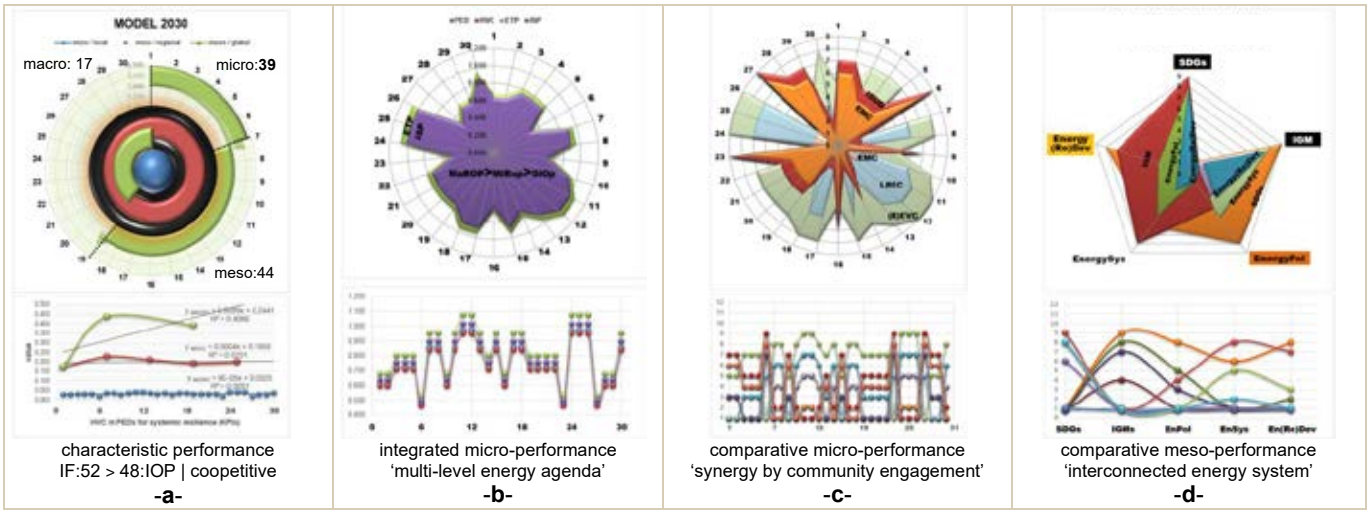
$$CI = \frac{\lambda_{max} - n}{n-1}, \text{ where } \det(\sum_{model} - \lambda I) = 0 \leftarrow CR = \frac{CI}{RI} \quad (7)$$

Calculating the Yearly Energy Balance [2] in PEDs (8) is also excluded from the models as a result of hypothetical nature of the research in which practice-based strategic frameworks are employed instead of district-specific case studies in order to reveal the holistic character of the models.

$$[Onsite\ Renewable\ Energy_{generation}] + [Climate\ neutral\ Energy_{import}] - [Energy_{export}] = [PED\ Energy_{consumption}] \quad (8)$$

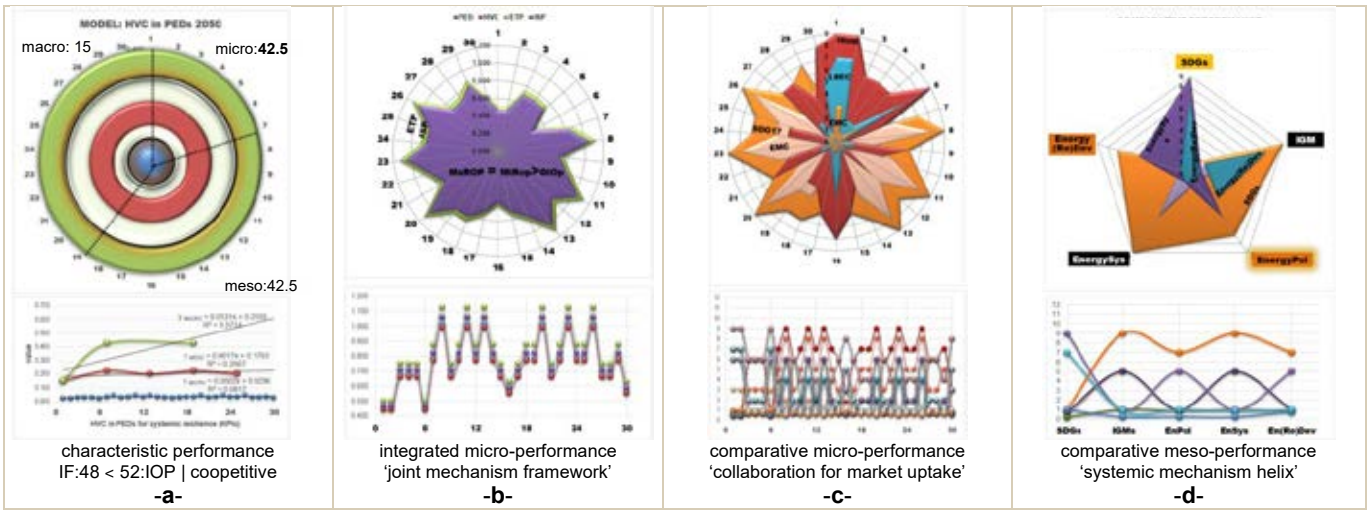
3. RESULTS AND DISCUSSION

The characteristic performance of the models is compatible with the targeted agenda of the SDGs for 2030 and 2050: Scenario 2030 has a "coopetitive" character (IF: 52 > IOP: 48) with 'escalating spiral shield' effect that accelerates 'clean energy frameworks' on infrastructure of HVCs in PEDs for carbon-neutral economy (Figure 2.a). Whereas, Scenario 2050 has a "coopetitive" character (IF: 48 < IOP: 52) with 'clean energy trajectory' effect that innovates interoperability of 'green hydrogen mechanism' for HVCs in PEDs for hydrogen economy (Figure 3.a).



characteristic performance IF:52 > 48:IOP | coopetitive -a-
integrated micro-performance 'multi-level energy agenda' -b-
comparative micro-performance 'synergy by community engagement' -c-
comparative meso-performance 'interconnected energy system' -d-

Figure 2: Existing framework model of Scenario 2030 – hydrogen in carbon- and climate-neutral future | (green) HVC for PEDs



characteristic performance IF:48 < 52:IOP | coopetitive -a-
integrated micro-performance 'joint mechanism framework' -b-
comparative micro-performance 'collaboration for market uptake' -c-
comparative meso-performance 'systemic mechanism helix' -d-

Figure 3: Projected framework model of Scenario 2030 – hydrogen in low-carbon and climate-resilient future | (clean) HVC in PEDs

The integrated micro-performance converges on ETP-driven ISP approach for empowering HVC in PEDs: Although Scenario 2030 is controlled by ISP at local level, it is managed from regional level by energy market characteristics in ETPs by strategies of cooperation and participation in IGMs, i.e.: PEDs, Hydrogen Valleys, Hydrogen Hubs, etc. (Figure 2.b). Scenario 2050 is not only controlled by ISP through policy and redevelopment triggered multi-scalar interconnectivity but also managed by joint mechanism framework of regional IGMs and local ETPs, i.e.: Regional Hydrogen Unions/Cooperations/Initiatives, higher readiness levels for technology, market and community engagement, deployment of cyber-physical systems for HVC in PEDs, etc. (Figure 3.b).
The comparative micro-performance converges on multi-scalar inter-operability of integrated energy framework even if it diverges from the route for clean energy mechanism frameworks for systemic resilience: Scenario 2030 is managed by enhancing global partnership on power grid resilience, security in energy systems and local renewable energy value chain besides ensuring cooperation and participation in IGMs from global to regional level, therefore it is controlled by financial incentives defined in IGMs from regional to local level fostering competitive advantage of the HVC targeted in policy-based national energy mechanism in line with SDG 7 and 9. (Figure 2.c). Although Scenario 2050 is controlled by not only scaling-up the national renewable energy strategies with action plans and regional coopetitive advantage of the HVC targeted in policy-based national energy mechanism but also (re)developing by local renewable energy strategies with hydrogen energy schemes, it is managed by triadic cooperation of SDG 7, 9 and 17 transmitted into policy-based regional energy mechanism via IGMs on nationally determined contributions (Figure 3.c).
The comparative meso-performance not only converges on Energy(Re)Dev mechanism at local level but also diverges from each other in EnergySys strategies on clean energy mechanism frameworks for systemic resilience: In Scenario 2030, integrated mechanism framework is not only employed to manage strategic IGMs interconnecting with systemic Energy(Re)Dev on the basis of global targets in the SDGs but also exploited to control (re)development of local energy systems as well as formulating regional energy policies (Figure 2.d). Whereas in Scenario 2050, cross-relational mechanism frameworks on IGMs integrated with regional energy systems are employed not only to manage the holistic approach on energy management but also to control sustainability-led local energy policies synchronized with policy-led regional energy (re)developments (Figure 3.d).

4. CONCLUSIONS

PEDs, which not only embody principles of resilience, sustainability and innovation but also promote community welfare and environmental governance, represent a shift towards more sustainable type of urban development having energy sovereignty as a result of harnessing local resources to meet energy needs of local communities. The main findings of research indicates that HVCs provide inter-operational coopetitiveness for PEDs, if 'integrated energy planning and management approach for systemic resilience' is authorized by ETPs and controlled by ISPs. Because, the infrastructural and inter-operational dimensions of clean energy-based frameworks converge and interlock with the diverse mechanisms diffusing through multi-level dynamics. Therefore, these findings verify the hypothesis of this research (Figure 3.c). Consequently, 'value engineering' through the methods of techno-economic assessment emerges as one of the advanced research areas aimed at structuring and enhancing HVC in PEDs in further research studies. Integrating clean energy technologies within urban environments poses both challenges and innovations. Fostering dynamic interactions between 'system-based clean energy frameworks' and 'strategy-based multi-scalar operations' have potential to strengthen the connection between cyber and physical environments. As a concluding remark, trajectory on more sustainable and resilient urban future pull towards successful implementation of clean and green energy transition, which have been already addressed as complexities on the global agenda, by innovative framework of cyber-physical systems.

ABSTRACT
This research paper focuses on comparing the systemic performance with emphasis on the framework models of hydrogen strategies in (inter)national energy policies for clean energy transition. The aim is to resolve not only the existing scenario2030 but also the projected scenario2050 by modelling through a multi-scalar (re)programming on the dynamics of 'regulatory' and 'operative' dimensions in order to reveal the path towards integrated policy planning and management (IPPM) for resilient development. The role of hydrogen energy in resilient development is explained with reference to accelerated energy transition that targets green energy in 2030 and clean energy in 2050 through (inter)national energy policies by holistic approaches from geographies of the World. The strategic performance character of cooperative models is evaluated by the multi-criteria decision analysis/analytic hierarchy process (MCDA/AHP) method with a multi-scalar parametric framework on (clean) energy transition for resilient development. The research framework designed from global to region-specific multi-national and country-specific national levels is built by 41 key performance approaches ('m') and 24 key performance indicators ('n'). The research revealed that energy policies have innovative power for structuring and accelerating clean energy transition. The findings demonstrate the need for political impact assessment for 'transformative mechanism design' through policy-based performance (re)programming.

Keywords: Hydrogen Energy Policies, Clean Energy Transition, Political Impact Assessment, Scenario (Re)Programming, Integrated Policy Planning and Management.

1. INTRODUCTION
Energy transition, which is also called as energy system transformation by International Energy Agency (IEA), is defined as a paradigm shift in supply-demand models and consumption patterns of the prevailing energy system either responding to energy crises or resolving anthropocentric problems by major structural changes in energy technologies and policies [1]. Even though energy transition was not specifically identified at the 6th Assessment Report of the UN-IPCC in 2021, "transition" is defined as "the process of changing from one state or condition to another in a given period of time. Transition can occur in individuals, firms, cities, regions and nations, and can be based on incremental or transformative change" [2]. The process of energy transition has stemmed from three-tiered challenge on the issues of resource management, energy and climate, and addressed questions of energy justice, energy sovereignty and energy diplomacy on the global agenda [3]. Therefore, the performance of energy systems has been measured with reference to the trilemma dimensions of energy security, energy equity and environmental sustainability by World Energy Council since 2010. Moreover, the progress and preparedness of different geographical regions and countries for equitable, secure and sustainable energy future through energy transition has been tracked under the title of Energy Transition Index by World Economic Forum since 2018. Although, the performance of framework models on (inter)national energy policies for clean energy transition has never been holistically put under Political Impact Assessment in order to resolve the transformative performance power of policy-based planning and sustainability-based management. The novelty of this research is modelling of the 2030 and 2050 scenarios by a Hydrogen Strategy-based Political Assessment (H2-SPA) from a holistic perspective by a multi-level analysis and integrated synthesis on resilient development.

2. MODELING AND METHODS
The scope of the research is to resolve the framework models of hydrogen strategies in (inter)national energy policies for clean energy transition modelled by a qualitative-quantitative mixed research method. The research hypothesis is that interconnections between 'policy planning that encompasses technology, policy and agency on regulatory dimension' and 'sustainability management that deals with environment, social and governance (ESG) issues on operative dimension' both designates transformative performance character for clean energy transition and delineates an outline for transformative mechanism framework on clean energy transition that can be (re)programmed by integrated policy planning and management for resilient development. In conformity with the research hypothesis, 'practice-based strategic approaches (KPAs, 'm') and 'research-based systemic frameworks' (KPVs, 'n') in the last five years are selected for addressing the question of hydrogen energy, especially the international energy policy for clean energy transition ((I)NEP for CET), for resolving holistic models on resilient development to unveil the encoded existing scenario2030 and projected scenario2050. Then models are configured on excel by the theory-based principles of multi-criteria decision making (MCDM) that is employed under the frameworks of soft systems methodology without any special software [4].

The parametric framework of this research is structured by the KPAs (Figure 1.a) and the KPIs (Figure 1.b) by a holistic approach on resilient development. The KPIs ('n') of multi-criteria set is structured by interlocking systemic layers in practice for technology, policy and agency (TPA) coordinated for policy planning on the regulatory dimension as well as for environment, social and governance (ESG) cooperated for sustainability management on the operative dimension. The KPAs ('m') of multi-criteria set is structured by dynamically strategic levels of multi-scalar interconnectivity in holistic approach ranging from global level at macro-scale to regional level at meso-scale and local level at micro-scale. The KPAs represented as the selected case studies in the form of multi-level geo-political spectrum of this research obtained from open source platforms and/or information portals of the global institutional organizations, i.e.: UN and UNDP, the EU, the OECD, IPCC, WEC, WEF, McKinsey, as well as IEA, IRENA, European Hydrogen Observatory, Clean Hydrogen Partnership and Hydrogen Europe Research, etc.. The modelling is executed by the integrated approach on "MCDA/AHP method" [5], which is a qualitative-quantitative mixed research method in multi-criteria decision-making approach on modelling and simulation for resolving real-world problems and/or testing the scenario-based hypothesis.

Figure 1: Key Performance Indicators (KPIs) and Key Performance Approaches (KPAs) of the performance modelling framework

Information is quantified into data by the rule of three-tiered fuzzy logic principle (1). Then, quantified data is systematized on basis of the rule of value distribution (2) to formulate the characteristic function of the models. The characteristic performance of the model(s) is evaluated regarding the ratio between infrastructural to inter-operational dimensions on the "5-point-characterization scale" [4] from coopetitive (47/53; collaborative leadership on operations), strategic (49/51; multilateral collaboration for regulatory operations), neutral (50/50; balanced engagement by participatory commitment), strategic (51/49; unilateral partnership for operational policies) and coopetitive (53/47; sovereign leadership on policies).

$$criteria \ \rightarrow non-existing: 0 \quad uncertain: 0.5 \quad existing: 1 \tag{1}$$

$$\sum_{i=1}^{n} w_i = 1 \tag{2}$$

The integrated performance is calculated through weighted value measurement in a mxn matrix format (3) whereas the comparative performance is calculated through pairwise comparison of parametric framework in a n/n matrix format (4).

$$\sum_{j=1}^{n} a_{ij}\, w_j \quad (for\ i = 1, 2, 3 \ldots m) \ \rightarrow \ A_m, C_n(W_n) = \ a_{ij\ (m\ x\ n)} \tag{3}$$

$$C_i(W_i), C_j(W_j) = \ C_{ij}(W_{i/j}) \rightarrow \ C_{ij_{(n/n)}} \tag{4}$$

Evaluating the comparative performance of the model(s) is achieved by attributing relative weights to criteria from 1-9 with reference to the Saaty scale. Pairwise comparison scores under 1.000 are treated as bias, thus excluded [4]. All the performance measurements are evaluated through the ranking rule on score and order of importance by not only the max-min strategy (5 and 6) but also the min-max strategy. Overlapping the max-min and min-max strategies provides deciphering the control code(s) of scenario(s) out the models [5].

$$A_{max.1} \geq A_{max.2} \geq A_{max.3} \ldots \geq A_{max.m} \tag{5}$$

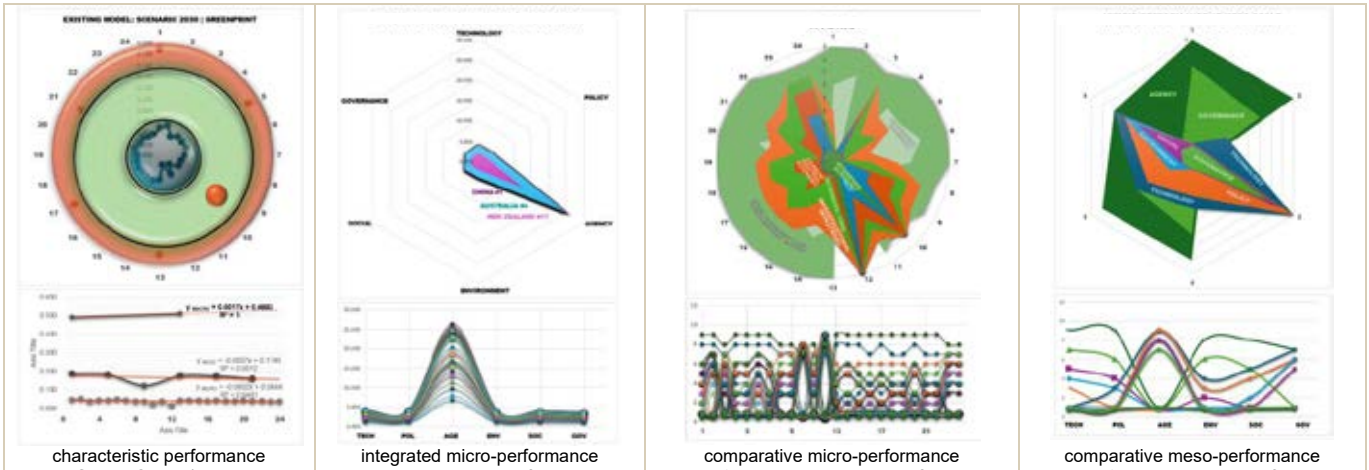
$$C_{max.1} \geq C_{max.2} \geq C_{max.3} \ldots \geq C_{max.m} \tag{6}$$

Checking the consistency ratio of the models' performance (7) is excluded from the holistic modelling approach, because evaluating the reliability and validity measure of preferences limited to 10 alternatives and/or criteria by Saaty in the decision-making process [4].

$$CI = \frac{\lambda_{max} - n}{n-1}, \text{ where } \det(\textstyle\sum_{model} - \lambda I) = 0 \ \leftarrow CR = \frac{CI}{RI} \tag{7}$$

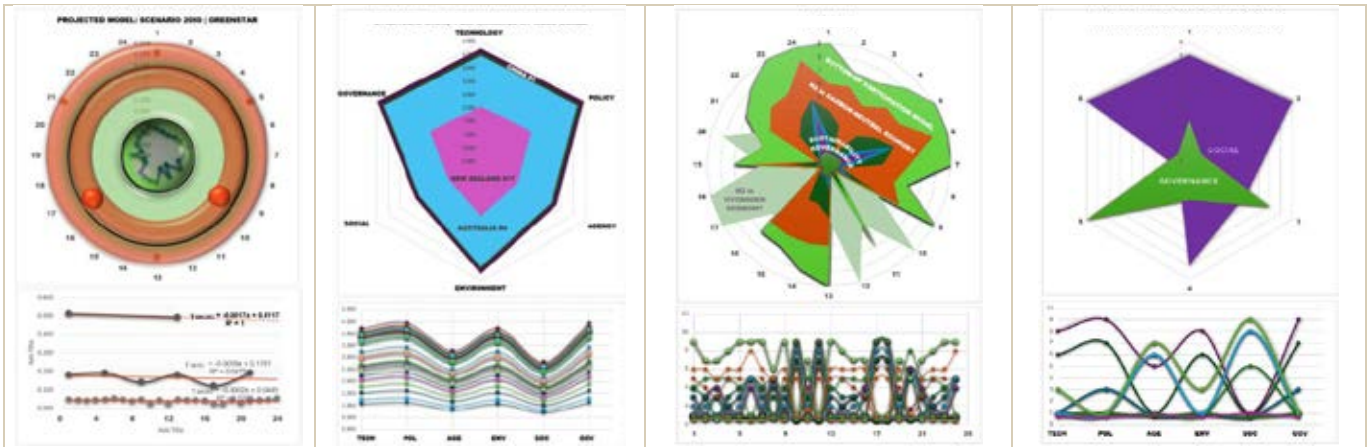
3. RESULTS AND DISCUSSION

The characteristic performance of the models is compatible with the targeted agenda of the SDGs for 2030 and 2050: Scenario 2030 has an operationally 'strategic' character (REG: 49 < OP: 51) with 'integrated framework' for scaling-up the electrolyzer-driven hydrogen production systems in carbon-neutral economy (Figure 2.a). Whereas, Scenario 2050 has a legislatively 'strategic' character (REG: 51 > OP: 49) with 'relational mechanism' for proliferating hydride-based hydrogen storage systems and critical minerals value chain in carbon-free economy (Figure 3.a). Therefore, the former is a 'Greenprint Model' of hydrogen as energy carrier for net-zero and climate-resilient future whereas the latter is a 'Greenstar Model' of hydride as hydrogen carrier for nature-positive resilient development. In both models, the top-three best practices are situated in 1.China; 2.Canada; 3.USA, Norway and Japan.



characteristic performance REG:49 < OP:51 | strategic 'integrated framework'	integrated micro-performance instrument of '(sustainability) index'	comparative micro-performance 'multi-level governance' for infrastructural energy policies	comparative meso-performance 'compass strategy of regulatory framework'
-a-	-b-	-c-	-d-

Figure 2: Existing framework model of Scenario 2030 – H2 production technologies in carbon-neutral economy | 'Greenprint Model'



characteristic performance REG:51 > OP:49 | strategic 'relational mechanism'	integrated micro-performance mechanism of 'resilience shield'	comparative micro-performance 'sustainability governance' by operational energy policies	comparative meso-performance 'ESG strategy of operative mechanism'
-a-	-b-	-c-	-d-

Figure 3: Projected framework model of scenario 2050 – H2 storage technologies in hydrogen economy | 'Greenstar Model'

The integrated micro-performance shifts from technology policy to policy governance for achieving CET: In Scenario 2030, (H2) strategies in (I)NEPs are employed as a 'sustainability index instrument' for energy transition in which operational regulation for environmental governance is controlled by not only macro-regional policy-based intergovernmental cooperation for H2 in carbon-neutral economy but also multi-level governance of H2 strategy for developing value chains (Figure 2.b). Whereas in Scenario 2050, the H2 strategies are employed as 'regional resilience shield' in energy transition in which regulatory operations for twin transition are controlled by not only intergovernmental cooperation for deploying clean energy technologies in H2 economy but also managed by intergovernmental mechanisms for hydrogen economy (Figure 3.b).

The comparative micro-performance converges on local community-led bottom-up participation even if it diverges from the route for clean energy mechanism frameworks for resilient development: In Scenario 2030, multi-level governance

for infrastructural energy policies is managed through socio-environmental IA on renewable energy strategies for carbon-neutral economy (Figure 2.c) whereas in Scenario 2050 sustainability governance is managed through integrated management of energy framework on energy transition instruments for hydrogen economy (Figure 3.c).
The comparative meso-performance is differentiated due to the shift from project to portfolio and program management by sustainability-based technologies and policy governance for nature-positive resilient development: In Scenario 2030, regulatory CET mechanism is accelerated by policy-based strategy for sustainability management , i.e: OECD Science Tech. and Innovation (STIP) Compass strategy [6] (Figure 2.d) whereas in Scenario 2050, operative CET mechanism scaled-up by nature-based strategy of social governance by technology-based policy governance system. (Figure 3.d).
The energy transition from scenario 2030 to 2050, There are two geographies as agents of change for controlling the degree of transformative change: Brazil's path for environmental governance and Türkiye's path for policy governance.
The transformative power of the models' performance converges on nature positive policies at the intersection of technology policy and environmental operations on regional level and multi-scalar interconnectivity for integrated policy planning and management at local level (Figure 4).

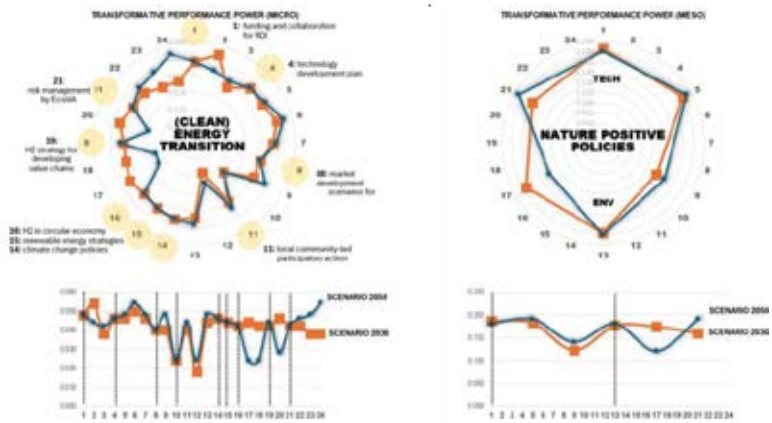


Figure 4: Comparison of transformative power of performance in the existing Scenario 2030 and projected Scenario 2050.

4. CONCLUSIONS

The main findings of research indicates that 'integrated policy planning and management approach [3] for resilient development', provide (re)programming the transformative mechanism framework, if it is authorized by (inter)national energy policies and controlled during the process of clean energy transition [7]. Therefore, these findings verify the hypothesis of this research (Figure 4). Consequently, 'value engineering' bridged with 'systems engineering' and 'transition engineering' through the methods of policy and sustainability impact assessment are advanced research areas in order not only to (re)structure and (re)program transformative mechanism framework for "clean energy transition" [8] but also to shape and accelerate "clean energy transition process" [9]. As a concluding remark, H2-SPA provides multi-dimensional simulation on systemic interaction between performance (re)programming and resilient development by the transformative power of performance by policy-based planning and sustainability-based management.

ABSTRACT
Increasing energy demand due to technological developments in the world puts fossil fuels, which have limited reserves, in danger of depletion. Fossil fuel use leads to uncontrolled carbon emissions and negatively affects the ecosystem. In order to improve the conditions, research on environmentally friendly and clean green/biodegradable fuels and fuel additives has gained importance. Solketal levulinate has an environmentally friendly and green fuel additive and alternative to traditional fuel additives. Solketal levulinate (SoLE) is produced by esterification of solketal and levulinic acid in the presence of an acid catalyst. Removal of water, which is a by-product, increases the reaction conversion. Producing catalytic membranes by blending with suitable polymer solutions is an excellent alternative to converting catalysts used in the reaction from homogeneous to heterogeneous form and increasing conversion by removing the unwanted by-product. In addition, clays used to convert homogeneous catalysts to heterogeneous form was also quite suitable for use as support materials due to their cheapness and easy availability.
In this study; bentonite was functionalized with sulfuric-acid and added to poly(vinylalcohol)(PVA) solution to prepare catalytic membranes. SoLE; T=105°C; M=6 and catalytic membrane with 3mmol H_2SO_4 catalyst loading at the end of 6h, highest reaction conversion obtained as 96%.

Keywords: Esterification, Fuel Additive, Catalytic Membrane, Solketal Levulinate.

1. INTRODUCTION

The need for energy resources in the world continues day by day in line with the increasing number of people. The fact that fossil fuel reserves are in danger of depletion has also increased the search for alternative fuels to meet energy needs. Among the many studies conducted in this direction, interest in the development of bio-based fuels has increased, as they are both environmentally friendly and renewable resources. The biggest problem of bio-based fuels, which are frequently studied in the literature, is related to combustion events. The production of new generation fuel additives to improve the combustion properties of both fossil fuels and bio-based fuels is an important step towards solving this problem.
Toxic emissions resulting from the combustion of fuels are being reduced for engine-based uses by optimizing the engines and equipment used, using catalytic converters, expanding the use of NOx reducers and particulate filters, and also by revisions in the chemical composition of the fuels used. However, these regulations alone are not sufficient. For this reason, efforts to achieve low emission values and the use of fuels blended with new generation fuel additives with high oxygen numbers for better combustion performance are among the environmentally friendly alternatives [1].
In addition to traditional methods (isomerization, catalytic cracking, reforming-dehydrocyclization) to increase the octane number of gasoline and the cetane number of diesel, oxygen-rich fuel additives (oxygenates) can be added. The octane number of gasoline or the cetane number of diesel is increased by adding oxygen-rich oxygenates (such as alcohol and ether) after the refining process of crude oil [2].
Bio-ethanol, which is one of the leading bio-based fuel additives, is obtained by chemical means as well as fermentation. However, in both cases, long-term production processes cause both carbon emissions and system costs to increase. This makes the production process less environmentally friendly.
Levulinate-based oxygenates frequently encountered in the literature are solketal levulinate, glycerol levulinate, ethyl levulinate, methyl levulinate, and the like. However, the production of these levulinate-based fuel additives is basically produced by the reaction of alcohols or ketals with oxo-carboxylic acid anions (methyl levulinate, ethyl levulinate, etc.). In such reactions, alcohol is released as a by-product, and these alcohols (except ethyl alcohol) are highly toxic and ecologically dangerous.
Almost all chemical reactions carried out on an industrial or laboratory scale are carried out in the presence of a homogeneous or heterogeneous catalyst. However, it is quite difficult and costly to separate the catalysts used in the reaction (regardless of whether they are homogeneous or heterogeneous) from the reaction medium. For this reason, the use of catalytically active catalytic membranes is increasing day by day.
In chemical reactions carried out by means of catalytic membranes; separation, purification and product production can be carried out simultaneously in a single unit. Thus, the desired or undesired product/by-product of the relevant reaction could be easily selected from the reaction medium. While catalytic membranes can be used as green and environmentally friendly catalysts in chemical reactions, their catalytic properties improved with homogeneous or heterogeneous catalysts added to their structures. In addition, it is quite possible to easily separate catalytic membranes from the reaction medium and reuse them. In the literature, the production of solketal levulinate has generally been achieved by transesterification

and is very limited in number and also, no previous solketal levulinate sorption enhanced reaction study from solketal and levulinic acid has been found with catalytic membranes. In this context, it is thought that the original value and contribution of our study to the literature will be quite high.
Studies on the synthesis of solketal levulinate in the literature are very limited and were carried out by transesterification reaction using base catalyst. Mariam et al., 2022; Solketal levulinate as a potential fuel additive for palm biodiesel; with solketal and methyl levulinate has produced with the highest yield of 74.83% at the end of 6 hours of reaction with T=140°C; Molar Ratio (Methyl levulinate: Solketal)=1:4 and 1.5% catalyst loading [3]. Another limited study was conducted by MARIAM et al. in 2024: MARIAM et al., investigated the effects of Solketal levulinate (SoLE) on improving the cold flow properties of palm biodiesel by adding SoLE, which they produced by transesterification, to palm biodiesel at certain rates, while determining the density, kinematic viscosity, pour point, cloud point and cold flow plugging point values of the new fuel blend. As a result of their analysis, they concluded that the SoLE they produced has the potential to improve the cold flow properties of palm biodiesel [4]. In another study has; Chang et al., 2024; produced Methyl levulinate glycerol ketal from methyl levulinate and glycerol. The effects of different factors on the yield of Methyl levulinate glycerol ketal and glycerol conversion were investigated and the optimum reaction conditions were determined as reaction temperature T = 140 °C, catalyst loading (HZSM-5) = 0.50 g, ML/GLY molar ratio 4:1. Under these conditions, glycerol conversion were found to be 97% and Methyl levulinate glycerol ketal yield was found to be 94.7% [5].
In this study, solketal levulinate was synthesized from solketal and levulinic acid by the developed catalytic membrane.

2. MATERIALS AND METHODS

2.1. Materials

The chemicals used in this study were Solketal (2,2-Dimethyl-1,3-dioxolan-4-yl)methanol was supplied by BLDpharm, PVA (poly vinylalcohol) (Mw~125,000) polymer , Levulinic Acid and Sulfuric Acid (98%) were supplied by Merck and finally Bentonite Clay was supplied by SAMAŞ Mining in Türkiye.Method.

2.2. Preparation of Sulfonated Bentonite Clay

A certain amount of bentonite clay mineral has had left to dry overnight at 100 °C. The dried bentonite clay impregnated with 3 mmol H2SO4 was weighed to be 10% according to the PVA polymer solution and left to dry again at room temperature. As the last step, the bentonite clay, which was impregnated with acid and dried, was mechanically ground until it reached the finest mesh size and was made ready for used.

2.3. Preparation of Catalytic Membrane

Catalytic membranes were prepared based on poly(vinyl alcohol) (PVA). 6% PVA solution was prepared in a magnetic stirrer at a constant temperature of 85°C and a stirring speed of 400 rpm. The systems were supported with a reflux condenser to prevent any solvent loss during dissolution. Catalytic membrane was formed by adding 10% by weight of Sulfonated Bentonite clay to the prepared polymeric membrane solution.

2.4. Batch Reaction System

The batch reactor system is given in Figure 1. The prepared catalytic membranes were cut into small pieces and added to the system with the reactants.

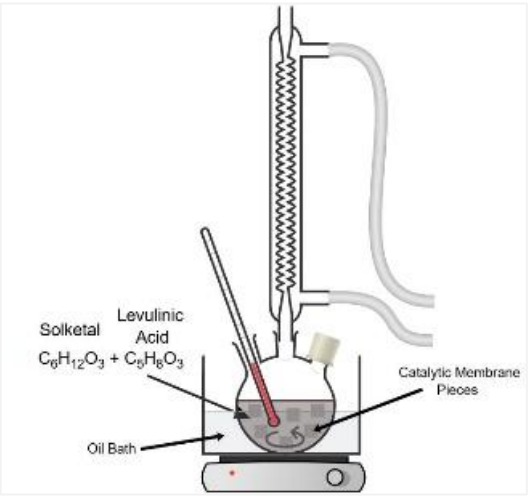

Fig. 1. Batch Reractor System

Solketal levulinate production reaction was carried out in a batch reactor at 105 °C with a molar ratio (Levulinic acid: Solketal) M = 1:6 and a catalyst loading of 3 mmol H2SO4 to 10% bentonite clay relative to PVA for 6 hours.

3. RESULTS AND DISCUSSION

3.1. Chacterizations of the Catalytic Membrane

3.1.1. FT-IR &TGA Analysis

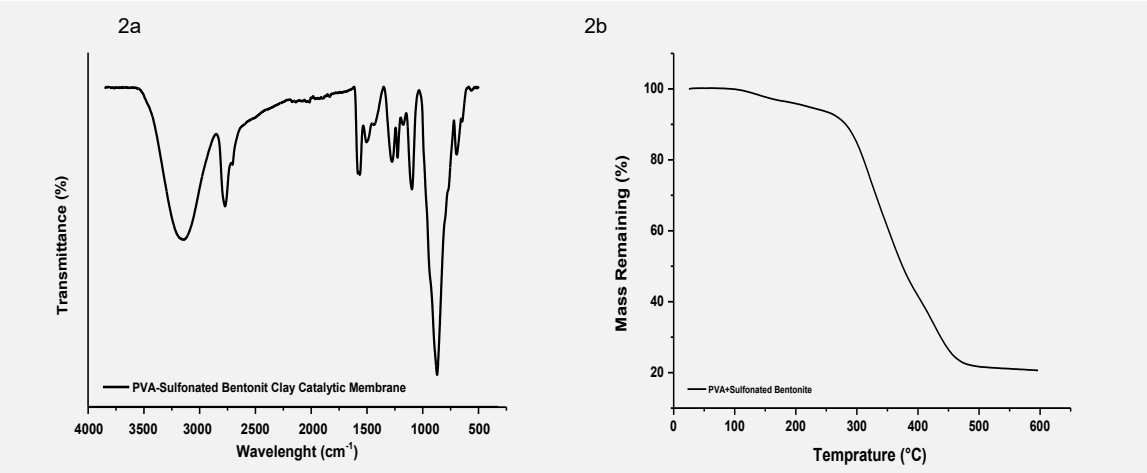

Fig. 2. (a) FT-IR Analysis of PVA-Sulfonated Bentonite Clay Catalytic Membrane; (b) TGA Analysis of PVA-Sulfonated Bentonite Clay Catalytic Membrane

FT-IR characterizations of the prepared PVA- Sulfonated Bentonite Clay catalytic membranes are given in Figure 2a. According to the FT-IR characterization, the broad peak around 3550–3200 cm^{-1} can be explained as -OH stretching vibration from intermolecular hydrogen bonds. The vibration band between 2980 and 2800 cm^{-1} represents the C–H group. The frequent peaks around 1000-1100 cm^{-1} show the strong S=O stretching and the placement of sulfo groups.
PVA-Sulfonated Bentonite Clay Catalytic Membrane is given in Figure 2b. Thermal decomposition curves of the prepared PVA-sulfonated Bentonite clay catalytic membrane were investigated in the range of 25 °C to 600 °C with a Mettler Toledo brand thermal gravimetric analysis (TGA) device.
The solvent of the PVA polymeric membrane used in this study is water and water exists in different states inside the PVA blend membranes; solvent water; forms the polymeric solution in two different ways: first, as water molecules held by weak bonds on the outer or inner surface without interacting with the chemical matrix forming the polymer, and second, as water molecules strongly bonded to hydroxyl groups.
The primary region between 50-150 °C is the loss of water molecules in the polymer solution forming the membrane, while the secondary region between 150-300 °C is related to the loss of water due to the polymer matrix.
The weight loss in the tertiary region occurred between approximately 300-450 °C due to the loss of organic components. The weight loss in the quaternary region is due to the dissociation of the sulfo group member bonds in the structure of the sulfonated bentonite clay between 450-600 °C, and the stable appearance of the graph explains that only bentonite clay residues remain.

3.2. Swelling Testing of PVA-Sulfonated Bentonite Clay Catalytic Membrane

Swelling tests are performed to determine the affinity of a material to its solvent or to the reactants present in the medium to be applied or to the products produced by the input reactants in the reaction to be used. The water sorption results of PVA-Sulfonated Bentonite Clay Catalytic Membrane used in the reaction are given in Fig. 3. Sorption % values were calculated with Eq. 1

$$Swelling\ (\%) = \frac{W_{wet} - W_{dry}}{W_{dry}} x100 \quad (1)$$

As a result of weighings made at 30-minute intervals for 6 hours, the swelling value of the membrane was determined as 139.65%. The swelling percentage did not change as a result of 24-hour weighing.

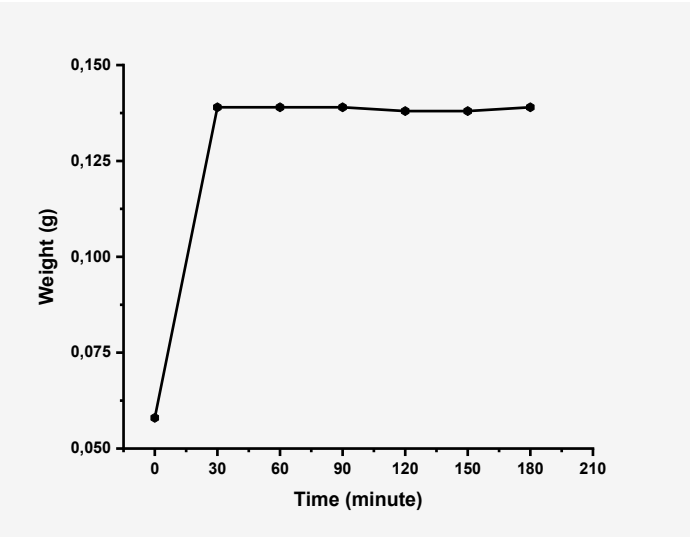

Fig. 3. Swelling testing of PVA-Sulfonated Bentonite Clay Catalytic Membrane

4. CONCLUSIONS

Oxygen-rich fuel additives are chemical substances traditionally used to increase engine performance by improving the physicochemical properties of fuels during the combustion process (reducing the number of knocks, preventing gum formation, increasing the octane or cetane number, etc.). In this context, it is aimed that the fuel additives to be used are also environmentally friendly. These substances are intended to reduce carbon emissions and make the fuel environmentally friendly by being added to fuels.

In this study; bentonite clay mineral used as support material; sulfuric acid functionalized; poly(vinylalcohol)(PVA) blended and catalytic membranes were prepared. Solketal levulinate, ambient conditions; T=105°C; M=6 and catalyst loading ratio of 3mmol H_2SO_4 with catalytic membrane at the end of 6 hours reaction time, the highest reaction conversion was obtained as 96%. In addition, the investigation of the physicochemical properties of the produced SoLE fuel additive is still ongoing.

ABSTRACT
Green fuel additives that can be added to fuels to mitigate the adverse effects of fossil fuel use on the environment have become an attractive research topic. Green glycerin carbonate, which can be used as a fuel additive for efficient and safe fossil fuel use, was synthesized from dimethyl carbonate and glycerin via transesterification under mild conditions. The catalyst used in the reaction is a catalytic membrane obtained by loading KOH/Clinoptilolite into a polyvinyl alcohol-sodium alginate blend matrix. The polymer structure of the catalytic membrane provided sorption support, while the KOH/Clinoptilolite side catalyzed the reaction. Catalytic membrane was characterized by FTIR for chemical structure analysis, SEM and EDX analysis to observe the distribution of the catalyst in the polymer matrix, and swelling test in methanol to determine the affinity for methanol, a by-product in the reaction. Batch reaction was carried out under certain conditions (%7.9 catalyst amount, 85°C, DMC/glycerin:3/1, 4 hours). A glycerin carbonate yield of 24.5% was obtained at the end of 4 hours. Reaction parameters will be analyzed in the next steps. Methanol swelling tests showed that the catalytic membrane has an affinity for methanol. It was found that the catalytic membrane produced was suitable for the reaction.

1. INTRODUCTION

Today, dependence on fossil fuels prevents efficient and secure energy use. In particular, the environmental problems associated with the use of fossil fuels are due to the poor efficiency and safety of these fuels. To make fossil fuel use more environmentally friendly, new generation green fuel additives can be added to fuels to improve fuel properties. Glycerin carbonate, one of the new generation fuel additives, is an important candidate in this field with its high oxygen content (59%) [1]. Glycerin carbonate is produced under mild conditions (no toxic solvents, atmospheric pressure) by glycerin and green reagent dimethyl carbonate (DMC) via a base catalyst. Methanol emerged as a by-product in the reaction [2]. As shown in Fig. 1, glycerin carbonate, a five-membered cyclic carbonate, is an environmentally friendly molecule with a wide range of uses, such as polymers, cosmetics, solvents, and battery electrolytes [3]. In glycerin carbonate synthesis using homogeneous and heterogeneous catalysts, the ease of recovery and reusability of heterogeneous catalysts have increased the interest in heterogeneous catalysts. However, some heterogeneous catalysts have disadvantages, such as poor thermal stability, deactivation, and low surface area [4]. Catalytic membranes, which can be recovered from the reaction and reused, are prepared by adding catalysts to polymeric matrices. Environmentally friendly and heterogeneous catalytic membranes can increase the reaction yield by simultaneously removing the by-product from the reaction medium while catalyzing the reaction [5]. Polyvinyl alcohol (PVA) used as a polymeric matrix in the preparation of catalytic membranes is a non-toxic, biocompatible, high hydrophilic polymer [6]. Sodium alginate from brown algae is a non-toxic biopolymer with high hydrophilicity that can be blended with PVA [7]. Highly hydrophilic matrices in the catalytic membrane can sorb polar by-products in reactions, shifting the reaction equilibrium to the product side [8]. Zeolites can play an active role in catalytic reactions as catalyst supports with their high surface area, adjustable acidity, and basicity properties [9]. Clinoptilolite, a common natural zeolite, has been used as a catalyst in reactions with acidic and basic modifications [10,11]. Mahdi et al. 2016 produced glycerin carbonate from glycerin and sodium bicarbonate in a batch reactor with a modified clinoptilolite catalyst. They obtained the maximum glycerin conversion (29%) at 100°C and 9% catalyst concentration for 10 min reaction time.[12]. There are a limited number of studies in the literature on the production of glycerin carbonate from DMC with a catalytic membrane. Hasirci and Hilmioglu, 2024 produced glycerin carbonate from DMC and glycerin with the catalytic membrane produced by adding NaOH to PVA. A yield of 93.03% glycerin carbonate was obtained under the optimum conditions (75°C, 7.5% catalyst amount, DMC/glycerin:3/1, 2h) [8].

This study aimed to synthesize sorption-assisted glycerin carbonate with PVA/SA-KOH/clinoptilolite composite catalytic membrane under mild conditions. There is no synthesis of glycerin carbonate with KOH-modified clinoptilolite loaded catalytic membrane in the literature.

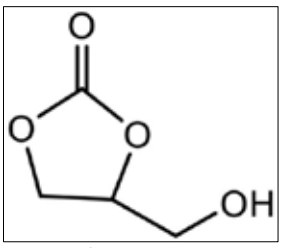

Fig. 1. Glycerin carbonate

2. MATERIALS AND METHODS

2.1. Materials

PVA (poly vinylalcohol) (Mw~125,000) polymer and glutaraldehyde (25% solution in water) used in catalytic membrane preparation were obtained from Sigma Aldrich, and sodium alginate was purchased from Isolab. KOH used in catalyst preparation was obtained from Sigma Aldrich, and clinoptilolite was obtained from ROTA mining in Türkiye. Glycerin and DMC used as reactants in the reaction were purchased from Sigma Aldrich.

2.2. Preparation of KOH/Clinoptilolite catalyst

KOH/clinoptilolite catalyst was prepared by the wet impregnation method. 2M KOH impregnated with clinoptilolite was dried at 110°C for 3 hours and finally calcined at 400°C for 5 hours. KOH/clinoptilolite ratio was prepared as 1/2.

2.3. Preparation of KOH/Clinoptilolite catalyst loaded PVA/SA blend

10 wt% PVA and 5 wt% SA were dissolved in water. The obtained PVA and SA solutions were blended at a ratio of 90/10 and mixed at 700 rpm for 1 hour. After 1 hour, KOH/clinoptilolite catalyst was added to the PVA/SA blend. Then, 0.030 g glutaraldehyde was added to the PVA/SA-KOH/Klinoptilolite mixture as a crosslinking agent and stirred for one hour. Finally, the polymer-catalyst mixture was poured onto Teflon plates and left to dry.

2.4. *Batch reactor system*

In the batch reactor system shown in Fig. 2, the catalytic membrane was cut into small pieces and added to the reactor.

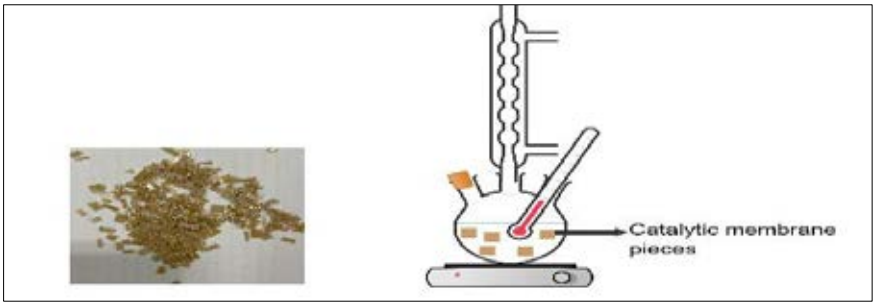

Fig. 2. Catalytic membrane and batch reactor system

2.5. Analysis of Glycerol carbonate

The amount of glycerin carbonate produced by the reaction was analyzed by gas chromatography. The formula used in the calculations is shown in Eq. (1) [5]

$$Glycerin\ carbonate\ yield\ (\%) = \frac{Produced\ \ glycerol\ carbonate\ amount\ (mol)}{initial\ amount\ of\ glycerin\ (mol)} x100 \quad (1)$$

3. RESULTS AND DISCUSSION

3.1. FTIR charactherization of PVA/SA-KOH/Clinoptilolite Catalytic membrane

FTIR analysis of PVA/SA-KOH/Klinoptilolite catalytic membrane is shown in Fig.3. Peaks at 3294.60 cm^{-1}, 2919.55 cm^{-1}, and 1088 cm^{-1} are due to O-H, C-O, and C-H groups of PVA, respectively [13]. The peak at 1424.7 cm^{-1} is associated with the COO group in the structure of SA [14]. The peak at 1712.12 cm^{-1} belongs to C=O groups originating from glutaraldehyde crosslinking agent [15].

3.2. SEM analysis of PVA/SA-KOH/Clinoptilolite Catalytic membrane

The surface morphology of the produced PVA/SA-KOH/Clinoptilolite catalytic membrane is shown in Fig. 4 by SEM and EDX analysis. KOH/Clinoptilolite catalyst agglomerated on PVA/SA matrix [16]. The high Si content in the EDX results indicates the presence of clinoptilolite in the structure [17].

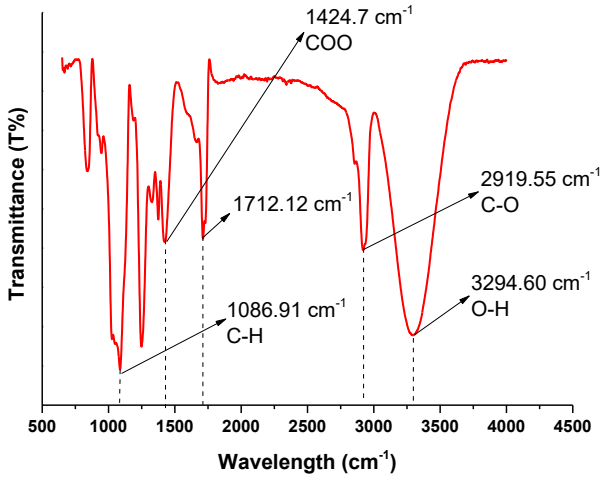

Fig. 3. FTIR spectra of PVA/SA-KOH/Clinoptilolite Catalytic membrane

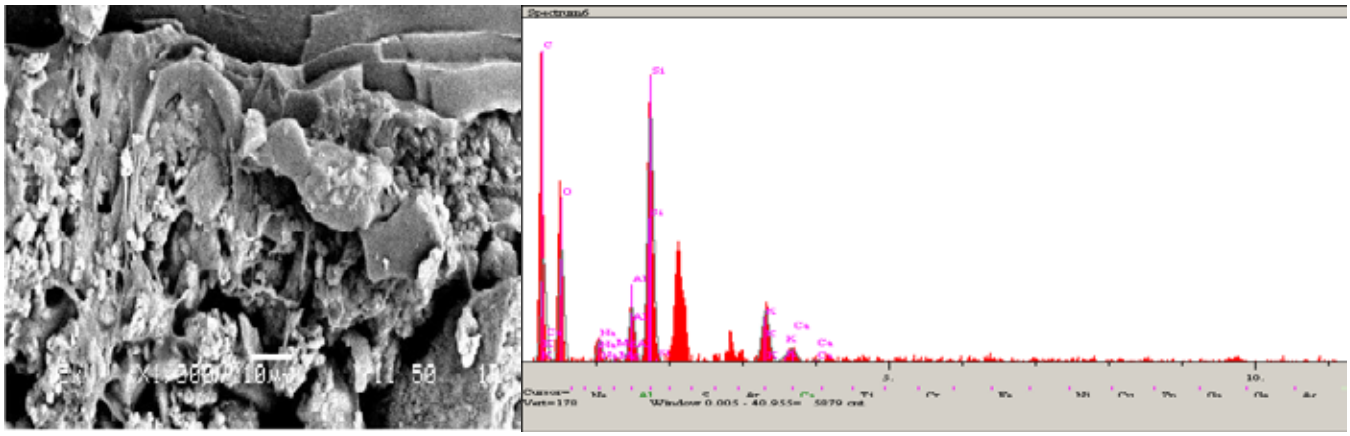

Fig. 4. SEM photo and EDX of PVA/SA-KOH/Clinoptilolite Catalytic membrane

3.3. Swelling tests of PVA/SA-KOH/Clinoptilolite Catalytic membrane

The swelling test results of the catalytic membrane in methanol are shown in Fig. 5. The Swelling test was carried out in 100% methanol for 4 hours. The percentage swelling was stabilized at 150 minutes. The maximum swelling degree was obtained as 30.8%.

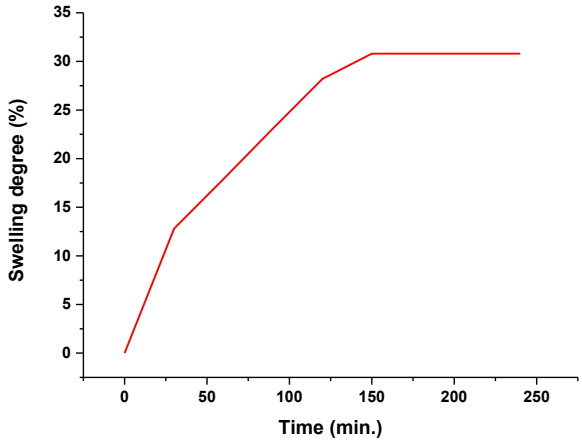

Fig. 5. Swelling of PVA/SA-KOH/Clinoptilolite Catalytic membrane

4. CONCLUSIONS

Glycerin carbonate with added value and high oxygen content offers the potential to improve fuel properties when used as a fuel additive. In this study, KOH/Klinoptilolite loaded PVA/SA catalytic membrane was preliminarily tested in a batch reactor for 4 hours reaction time at 85°C, M:3/1 with 7.9% catalyst amount. Functional group analysis and morphological distribution of the catalyst in the polymer matrix were investigated by FTIR and SEM characterizations. Methanol affinity was determined by swelling tests to contribute to the reaction yield by by-product sorption. In the batch reactor trial, a 24.5% glycerin carbonate yield was obtained. However, it is aimed to increase this ratio in the following experiments. SEM analysis showed that the catalyst agglomerated in the membrane matrix. By swelling tests in methanol, it was determined that the catalytic membrane has an affinity for methanol, and a maximum swelling degree of 30.8% was reached in 150 minutes.

ABSTRACT
This study explores the integration of hydrogen-based fuel cells into unmanned aerial vehicles (UAVs), focusing on integration factors, the advantages of hybrid fuel cell systems over lithium polymer batteries, and necessary safety precautions. Lithium polymer batteries, Proton Exchange Membrane Fuel Cells (PEMFCs), Direct Methanol Fuel Cells (DMFCs), and hydrogen storage systems are analyzed.
The research utilizes data from lithium polymer-based UAVs we developed, UAVs produced by other companies, hydrogen fuel cell data, and academic articles. Various hydrogen-based fuel and storage systems are examined in detail.
Findings show that lithium polymer-based UAVs are the most cost-effective to produce. However, PEMFCs in hybrid systems are more efficient in flight when operating costs are considered, offering longer flight durations despite comparable weights. In contrast, DMFCs are not yet suitable for UAVs in the 20-25 kg range due to limited industrial development. Hybrid systems require stricter safety measures than lithium polymer battery systems.
Overall, the study highlights the superior efficiency of hydrogen-based fuel cells for UAVs, particularly in flight duration, and outlines critical considerations for hybrid integration.

Keywords: Proton Exchange Membrane Fuel Cells (PEMFCs), Unmanned Aerial Vehicles (UAVs), Lithium Polymer Batteries, Hybrid System, Hydrogen Storage

1. INTRODUCTION

A fuel cell, also known as a fuel cell system, is an electrochemical device that converts the chemical energy contained in a fuel and its oxidizing agent directly into electrical energy without combustion. This conversion is achieved through a fixed electrode–electrolyte system. Fuel cells operate with high efficiency and produce emissions that are significantly lower than the limits specified by current standards. Although their operation is analogous to that of a battery, fuel cells require a continuous supply of fuel to maintain the energy conversion process [1].

Fuel cells continuously convert chemical energy into electrical energy through an electrochemical process, operating like batteries but without recharging. They require a hydrogen–oxygen or hydrogen–air system to function. A fuel cell consists of an electrolyte between two electrodes. Hydrogen at the anode undergoes oxidation, releasing electrons that travel through an external circuit to the cathode. Meanwhile, hydrogen ions pass through the electrolyte and react with oxygen at the cathode, forming water and generating electricity. Due to their high efficiency, fuel cells produce mainly heat, water vapor, and electricity. Unlike conventional combustion, they prevent energy losses and pollution by directly converting fuel into power without burning [2].

PEMFCs use hydrogen and oxygen (from air) as fuel and oxidizer, respectively. They employ carbon-based electrodes and a thin, proton-selective polymer membrane. At the anode, hydrogen atoms ionize, releasing protons that pass through the membrane while electrons flow out, generating electricity. At the cathode, protons, electrons, and oxygen react to form water, with water vapor as the only byproduct. A thin layer of platinum on the electrodes acts as a catalyst. PEMFCs convert the chemical energy of hydrogen into electricity, producing only water and heat as byproducts, achieving an efficiency of 40-50% under optimal conditions [3].
Anode Reaction: Hydrogen gas (H_2) is oxidized at the anode, resulting in the formation of two hydrogen ions ($2H^+$) and two electrons ($2e^-$):

$$H_2 \rightarrow 2H^+ + 2e^-$$

Cathode Reaction: At the cathode, molecular oxygen (O_2) reacts with four hydrogen ions ($4H^+$) and four electrons ($4e^-$) to produce two molecules of water ($2H_2O$):

$$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O$$

Overall Reaction: When the anode and cathode reactions are combined, the overall reaction for the fuel cell is:

$$2H_2 + O_2 \rightarrow 2H_2O + \text{heat} + \text{electrical energy}$$

This overall reaction shows that the fuel cell converts the chemical energy of hydrogen and oxygen into water, releasing heat and generating electrical energy in the process.

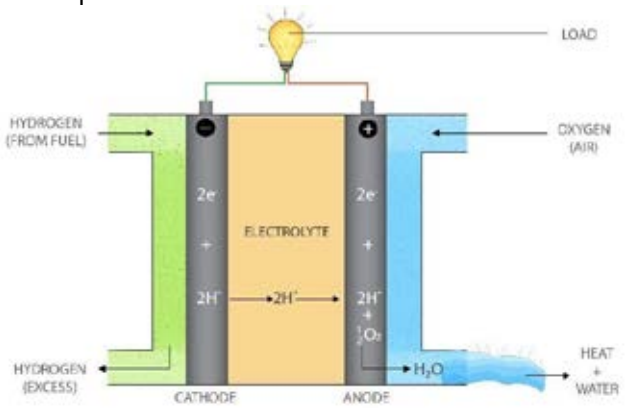

Fig. 1. Polymer Electrolyte Membrane Fuel Cell (PEMFC) [4]

Fuel cells release about 45% of hydrogen energy as heat, requiring efficient cooling to maintain stable operation. Cooling systems are categorized as water-cooled and air-cooled. Water-cooled systems circulate liquid, typically water, to dissipate heat, while air-cooled systems use airflow and are further classified into area air-cooled, edge air-cooled, and open-cathode types. The open-cathode proton exchange membrane fuel cell (PEMFC) system is efficient for a wide power range. It consists of a fuel cell stack, fan, hydrogen cylinder and regulator, lithium battery, and control module. The fan provides both oxygen and cooling, while the battery stabilizes power fluctuations. With high energy density, low noise, and minimal emissions, open-cathode PEMFCs are ideal for multirotor UAVs, where lightweight and effective cooling are essential [5]

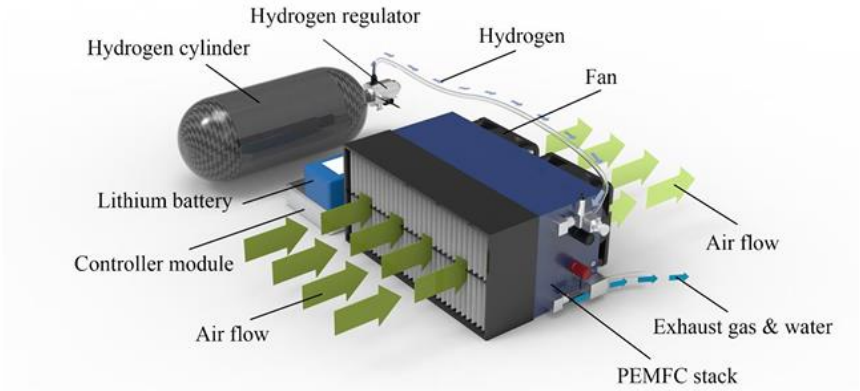

Fig. 2. Typical configuration of an open-cathode PEMFC power system [5]

2. DRONE INTEGRATION

When integrating the hybrid system into the drone, a connection diagram similar to that shown in Figure 11 can be used. The hybrid system can be incorporated into the drone through the use of a battery management system (BMS) and DC-DC converters. It is crucial that all components are securely fastened, particularly the hydrogen tank and the PEM fuel cell—to ensure that they remain undamaged during any impact and to help prevent potential accidents. A critical aspect of this integration involves the calculations for both the electronic requirements and the necessary hydrogen quantity. First, an average drone weight is determined based on the components to be used. Following that, the required thrust, power, voltage, and current values are calculated. Once these calculations are completed, the necessary amount of hydrogen is determined; subsequently, an appropriate hydrogen storage tank is selected based on this required amount. In choosing the tank, both the tank type and its cost are taken into consideration. The various tank types and their associated calculations are discussed in detail in the subsequent section. Our system has a mass of 20 kg. Based on this mass, the current drawn by an individual motor was measured to be approximately 18.72 A, leading to a total current draw of about 150 A for all eight motors. Of this total current, 80 A is supplied by the PEM fuel cell, which means that the remaining 70 A (150 A − 80 A) must be provided by the LiPo battery. Given a LiPo battery capacity of 50 Ah, the estimated flight duration under these conditions is calculated as follows:
50 Ah / 70 A ≈ 0.714 hours, which is approximately 42 minutes.

Furthermore, considering the instantaneous current draw of 150 A, when three batteries rated at 22,000 mAh (22 Ah) are configured appropriately (resulting in an effective capacity of 66 Ah) with a total battery mass of 7.5 kg, the flight duration becomes:
66 Ah / 150 A ≈ 0.44 hours, which is about 26.4 minutes.
In contrast, when using an equivalent mass of hydrogen fuel and a PEM fuel cell, the flight duration can be extended up to 42 minutes.

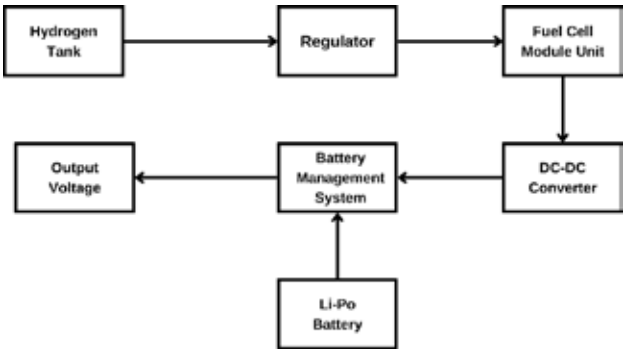

Fig. 3. Example Connection Diagram

3. DRONE DESIGNED FOR THE HYBRID SYSTEM

Initially, the motor configuration was chosen based on the components' weights and thrust requirements. Calculations indicated that an eight-motor configuration would provide sufficient thrust, leading to its selection. Subsequently, decisions were made regarding the placement of the PEM fuel cell, the hydrogen storage tank, and the LiPo battery. The hydrogen storage tank was positioned at the top to facilitate easy removal during refueling. The PEM fuel cell was placed at the bottom to ensure that, considering the operating temperature ranges of the PEM fuel cell and the LiPo battery, these critical components remain isolated from other parts and from each other. This placement also minimizes the risk of water vapor, produced by the PEM fuel cell, adversely affecting other components. The LiPo battery was located in the middle section.
The three most critical elements—the PEM fuel cell, the LiPo battery, and the hydrogen storage tank—are distinctly separated by plates to prevent any intermixing of systems. A crucial aspect of this design is the assembly of these components. To ensure secure installation, specialized mounting elements were designed. For example, two clamps were engineered to secure the hydrogen storage tank. In the design of these clamps as well as all other mounting components, careful consideration was given to weight constraints, aiming for the lightest yet most durable configuration possible.

ABSTRACT
Fuel reformers are among the most critical components of fuel cell systems. Their essential thermodynamic performance can be analyzed using Gibbs free energy minimization. The models investigated in this article will utilize this method to calculate energy balances and exit gas formation from the reformer. The simulation models are prepared using the Java programming language. This study will investigate Autothermal, partial oxidation, and steam reformers. Four different case studies concerning various types of steam reformer applications are comparatively analyzed, and reactive products obtained from these devices have been investigated.

Keywords: Fuel Cell, Gibbs Free Energy, Reformer

1. INTRODUCTION

Solid oxide fuel cells convert chemical energy directly to electrical energy. The basic building blocks of the fuel cells are electrodes and electrolytes. The electrolyte layer of the solid oxide fuel cells are made of yttrium stabilized zirconia (For example 0.08 Y_2O_3 0.92 ZrO_2), Strontium doped lanthanum manganite ($LaSrMnO_3$ ..) and nickel zirconia cermets ($Ni - ZrO_3$) as anode, cathode and electrolyte respectively.
Wang et al. [1] presented a deatailed investigation of catalyst metal support interaction to enhance the hydrohgen production from steam reformer. Szablowski et al. [2] conducted comprehensive research on steam methane reforming to obtain hydrogen. Their research includes technological directions, mathematical representation, and various methods to overcome the energy demand of the stean reforming operations. Besides, Zhang et al. [3] investigated the different types of catalysts utilized in methanol steam reformers. Li et al. [4] used the free energy minimization method to evaluate the performance of an air-blown circulating fluidized bed gasifier. Tang and Kitagawa [5] have implemented the Gibbs free energy minimization approach to calculate the gasification product. Ezgi et al. [6] analyzed to examine diesel-fueled SOFC as a supporting engine for naval ship application.
Air is ionized in the cathode by using electrons coming through the electrical connections from anode site.

$$O_2 + 4e^- \rightarrow 2O^{2-} \quad (1)$$

Where O^{2-} ions pass through the electrolyte to the anode site. In the anode site fuel reacts with ionized air, combustion products and electrons resulted.

$$CO + O^{2-} \rightarrow CO_2 + 2e^- \quad (2)$$
$$H_2 + O^{2-} \rightarrow H_2O + 2e^- \quad (3)$$
$$CH_4 + O^{2-} \rightarrow 2H_2O + CO_2 + 8e^- \quad (4)$$

Electrons are sent through the external wires to the cathode and are used as electrical energy. The optimum operation Temperature of this device is approximately 900 °C at atmospheric pressure. Temperatures as low as 700 °C have been achieved in recent developments. The enthalpy of the exhaust gases is very high due to high operating temperatures. Some of this available energy is utilized to heat incoming air and fuel streams. Fuel is not utilized fully in fuel cells. Approximately 85% can be converted through these reactions. The rest is exhausted from the fuel cells together with the exhaust gases. These mixtures can be combusted using an exhaust air stream and additional air if required. If the mixture is combustible, the combustion process is used. For the poor mixtures, catalytic reactors can make the combustion process.

Hydrogen is an ideal fuel for fuel cells. Unfortunately, it is not a natural fuel, and storing it is incredibly challenging. Other fuels are generally converted to hydrogen, carbon, monoxide, and methane for solid oxide fuel cells. Several methods are used for this conversion (fuel reforming) process. The most common reactions are as follows [7]:

1-Water shift reaction:

$C_nH_{2n+2} + 2nH_2O \rightarrow nCO_2 + (3n+1)H_2$ (5)
$C_nH_{2n+2} + nH_2O \rightarrow nCO + (2n+1)H_2$ (6)
2- Partial oxidation reaction:
$C_nH_{2n+2} + n(O_2 + 79/21N_2) \rightarrow nCO_2 + (n+1)H_2 + 79/21N_2$ (7)

The water shift reaction is endothermic, which requires a significant amount of heat input. Heat input can be supplied with a heat exchanger before entering the reactor. This will cause the temperature to drop during the water shift reaction. This type of water shift reactor is called an adiabatic reactor. The heat exchanger can be integrated into the reactor body so that the response occurs isothermally. However, the reactor design is much more complicated in this case. Water shift reactions can be combined with partial oxidation reactions. This type of reactor is called an autothermal reactor.

2. MODELING OF REFORMERS

To model fuel cells, it will be assumed that reactors will reach a chemical equilibrium state at the exit of the reactors. Gibbs free energy minimization methods will be used to compute chemical equilibrium. The reactive species' state equation uses the NASA ideal gas equation of state.

A rich data collection is presented to calculate ideal gas thermodynamic properties [8]. The equations below outline the procedure for calculating the specific heat, enthalpy, and entropies of reacting gas components at a constant operating pressure.

$\frac{C_p^0(T)}{R} = a_1T^{-2} + a_2T^{-1} + a_3 + a_4T + a_5T^2 + a_6T^3 + a_7T^4$ (8)
$\frac{H^0(T)}{RT} = -a_1T^{-2} + a_2\frac{ln(T)}{T} + a_3 + a_4\frac{T}{2} + a_5\frac{T^2}{3} + a_6\frac{T^3}{4} + a_7\frac{T^4}{5} + b_1T$ (9)
$\frac{S^0(T)}{R} = -a_1\frac{T^{-2}}{2} - a_2T^{-1} + a_3ln\,(T) + a_4T + a_5\frac{T^2}{2} + a_6\frac{T^3}{3} + a_7\frac{T^4}{4} + b_2$ (10)
b_1 and b_2 is integral constant for the equations.

$S(T,P)=S^0(T)-Rln\left(\frac{P}{P_0}\right)$ (11)
Chemical enthalpy:
$H_T(T)=H(T)-H(298.15)+\Delta h_f(298.15)$ (12)
Chemical entropy:
$S_T(T,P) = S(T,P) - S(298.15, P0)$ (13)
where P_0=101.325 kPa
$G^0(T) = H^0(T) - T * S^0(T)$ (14)
Gibbs energy:
$G(T,P)=h(T)-S(T,P)=G^0(T)-RTln\left(\frac{P}{P_0}\right)$ (15)
Chemical Gibbs energy:
$G_T(T,P) = H_T(T) - TS_T(T,P)$ (16)

The Gibbs energy minimization process also uses methods to linearize and solve the nonlinear equation system. Definition of Gibbs energy for the reaction [9]:
$g = \sum_{j=1}^{NG} \mu_j n_j$ (17)
In equation (17) μ_j represts the chemical potential which is defined as follows
$\mu_j = \frac{\partial g}{\partial n_j}$ (18)
We should minimize the Gibbs free energy, but at the same time, the mass balance of the species should hold in the equations. The mass balance of the species can be written as follows.

$\sum_{j=1}^{NS} A_{ij}n_j - b_i^0 = 0$ (19)

So, both sides of the equations can be solved together. The mass balance equation is added to the Gibbs equation as a restriction criterion. As a result, the Gibbs free energy equation that we will minimize can be written as:

$G = \sum_{j=1}^{NG} \mu_j n_j + \sum_{i=1}^{na} \lambda_i\,(b_i - b_i^0) = \sum_{j=1}^{NG} \mu_j n_j + \sum_{i=1}^{na} \lambda_i\left(\sum_{j=1}^{NS} A_{ij}n_j - b_i^0\right)$ (20)

Where λ_i represents Lagrangian multipliers, equations (20) will be solved using Gibbs energy minimization using the NASA method. The minimum value of the equation will give the solution, but this equation is entirely non-linear and

relatively challenging to solve. We would like to introduce the NASA method for solving the equation here. The condition for equilibrium becomes:

$$\delta G = \sum_{j=1}^{NG}\left(\mu_j + \sum_{i=1}^{na} \lambda_i A_{ij}\right) \delta n_j \quad (21)$$

Treating the variations δn_j and $\delta\lambda_i$ as independent variables give the following equations

$$\left(\mu_j + \sum_{i=1}^{na} \lambda_i A_{ij}\right) = 0 \quad (22)$$

$$(b_i - b_i^0) = 0 \quad (23)$$

To carry out the computation, computer codes in Java language are developed

3. RESULTS AND DISCUSSION

Hydrocarbon converters (reformers) of various types are modeled using equations of state and Gibbs energy minimization programs written in Java. It should be noted that the purpose of these specific fuel converters is to prepare fuel for solid oxide fuel cells that can process fuels such as methane, carbon monoxide, and hydrogen. These outputs are unsuitable for other fuel cells, such as the Polymer electrolyte membrane (PEM). When the performances are compared, isothermal steam reformers are integrated devices that facilitate both mass and heat transfer. The results are listed in Table 1-Table 4, respectively.

ABSTRACT
This study investigates the foundational steps for establishing a Hydrogen Pipeline Corridor (HPC) traversing Türkiye, intended to connect European countries with growing energy demand to Asian countries with substantial energy potential. Türkiye, leveraging its strategic position as an energy bridge between Asia and Europe, applies a hybrid optimization approach and Monte Carlo simulation to determine the hydrogen pipeline route. The study considers multiple criteria, including energy demand, energy potential, geographical suitability, and cost, to optimize the route. During the optimization process, the Particle Swarm Optimization (PSO) algorithm is employed to identify the most suitable route under predefined constraints. These constraints include ensuring that the total cost does not exceed the budget limit, meeting minimum energy demand and potential requirements, and selecting a specific range of provinces. Monte Carlo simulation is utilized to analyze the impact of uncertainties in the criteria and evaluate the likelihood of route selection under different scenarios. During the simulation, random variations are introduced to the cost, energy demand, energy potential, and geographical suitability values, and the selection frequency of each province is calculated.

Keywords: Hydrogen pipeline corridor, Optimization, Energy corridor estimation

1. INTRODUCTION

The rapid increase in global energy demand and the growing environmental impacts of fossil fuels have made renewable energy sources more critical than ever. Issues such as global warming, carbon emissions, and environmental sustainability necessitate a transition to renewable energy in production. Renewable energy sources such as solar, wind, biomass, and hydroelectric power are less harmful to the environment compared to fossil fuels and enhance energy security. However, the intermittent nature of these sources and challenges in energy storage and transmission processes require the development of innovative solutions for energy transformation. In this context, hydrogen emerges as the energy carrier of the future. With its high energy density, environmentally friendly characteristics, and compatibility with various energy production methods, hydrogen holds revolutionary potential in the energy sector. [1,2]. "Green hydrogen," produced from renewable energy sources, is becoming one of the cornerstones of sustainable energy systems by reducing carbon emissions to zero. Hydrogen has a wide range of applications in energy production, transportation, and industry, which has led to a steadily increasing demand for hydrogen over time. [3]. The increasing demand for hydrogen in the future highlights its critical role in energy systems, not only in production processes but also in transmission and distribution.

The safe, efficient, and economical transportation of hydrogen from production sites to consumption centers is of great importance for the sustainability of energy infrastructure. Various methods are available for hydrogen transportation, including liquefied hydrogen transport, compressed hydrogen transport in pressurized cylinders, and chemical carriers. However, these methods are often costly and have limited capacity. Therefore, the most suitable method for transporting large quantities of hydrogen at low cost and with minimal environmental impact is pipeline transportation. Pipelines are considered one of the most efficient and reliable methods for transporting hydrogen over long distances. This method offers significant advantages over other transportation methods, both economically and environmentally. Pipelines enable the continuous and uninterrupted transport of large volumes of hydrogen while minimizing carbon emissions. In particular, in countries like Türkiye, which serves as a strategic energy bridge between Asia and Europe, the development of hydrogen pipeline infrastructure can contribute to both regional and global energy transitions. Türkiye's geographical location, renewable energy potential, and proximity to energy demand centers provide a significant advantage for hydrogen pipeline projects.

In this study, a hybrid optimization approach and Monte Carlo simulation were applied to determine the hydrogen pipeline route among Türkiye's 81 provinces. The study considers multiple criteria such as energy demand, energy potential, geographical suitability, and cost, aiming to ensure the safe and efficient transportation of hydrogen. In this context, determining the hydrogen pipeline route is considered a significant step toward enhancing the sustainability of Türkiye's energy infrastructure and contributing to the global energy transition.

2. SYSTEM DESCRIPTION AND PROCEDURE

In this study, a hybrid optimization approach and Monte Carlo simulation were applied to determine the hydrogen pipeline route among Türkiye's 81 provinces. The study aimed to identify the most optimal route under defined constraints by considering multiple criteria such as energy demand, energy potential, geographical suitability, and cost. This section

provides a detailed explanation of the methods, algorithms, variables, and procedures used in the study.

2.1. Particle Swarm Optimization (PSO)

Optimization methods in the literature are generally designed to find the most suitable solution to a given problem. Numerous optimization algorithms have been developed, each with unique approaches. Among the commonly used algorithms are the bee algorithm, genetic algorithm, and Particle Swarm Optimization (PSO). Of these, PSO is one of the most widely preferred methods. Introduced in 1995 [4], PSO is inspired by the collective behavior of certain animals that live and move in groups. These behaviors include finding food sources and protecting themselves from external threats, achieved through communication within the group. In PSO, the group, or "swarm," consists of N particles moving in an n-dimensional space. The position of a particle at iteration t is represented as $x_i(t)$, which is used to evaluate the particle's state. To solve problems, PSO relies on information sharing among the particles in the swarm. Each particle updates its position by moving toward the best position in the swarm to avoid danger and locate resources. Additionally, particles use their own past experiences to guide their movements. Each particle maintains its personal best position (X_{pbest} and is also influenced by the global best position X_{gbest} of the entire swarm. The velocity and position of each particle in the next iteration are calculated using the following equations [5,6].

$$v_i(t+1) = wv_{i,j}(t) + c_1 r_1(t)\left(X_{pbest} - x_{i,j}(t)\right) + c_2 r_2(t)\left(X_{gbest} - x_{i,j}(t)\right) \quad (1)$$

$$x_i(t+1) = x_i(t) + v_i(t+1) \quad (2)$$

In this study, the PSO algorithm is used to optimize the hydrogen pipeline route. The algorithm works to select the most suitable provinces under the specified constraints.

2.2. Monte Carlo Simulation

Monte Carlo simulation is a method used to analyze the effects of uncertainties and evaluate the system's behavior under different scenarios. In this study, uncertainties in criteria such as cost, energy demand, energy potential, and geographical suitability were modeled by introducing random variations. During each simulation cycle, the values of these criteria were perturbed as follows:

$$M_{i+1} = M_i * (1 + \Gamma * \mathrm{W}) \quad (3)$$

Here M_i represents the original value, M_{i+1} denotes the new value, Γ is the standard deviation representing the level of uncertainty, and W refers to the noise. The Monte Carlo simulation was conducted in a 100-iteration loop, and in each simulation, the PSO algorithm was executed to calculate the selection frequency of the provinces. The constraints applied in the study are as follows:

Cost Constraint;

$$\sum_{i=1}^{n} x_i.cost_i \leq budget \quad (4)$$

Minimum Energy Demand Constraint:

$$\sum_{i=1}^{n} x_i.demand_i \geq minimum_demand \quad (5)$$

Minimum Energy Potential Constraint:

$$\sum_{i=1}^{n} x_i.potantial_i \geq minimum_potential \quad (6)$$

Number of Selected Provinces:

$$minimum\ number\ of\ cities \leq \sum_{i=1}^{n} x_i \leq maximum\ number\ of\ cities \quad (7)$$

Objective Function in the Study:

$$Objective_func. = 0.4 * potential + 0.3 * demand + 0.3 * geo_suitability \quad (8)$$

This system design and procedure offer a comprehensive approach to determining the hydrogen pipeline route by analyzing uncertainties and optimizing multiple criteria.

3. RESULTS AND DISCUSSION

The results obtained in this study for determining the hydrogen pipeline route have enabled a detailed analysis of both the optimization process and the effects of uncertainties. Using the PSO algorithm, baseline optimization was performed, and provinces were selected. These provinces were chosen from among those with the highest values in terms of energy potential, energy demand, and geographical suitability. The selected provinces did not exceed the budget constraint, which utilized 85% of the total cost, and met 25% of the total energy demand.

Monte Carlo simulation was conducted under 100 different scenarios by applying 10% random variations to the criteria. Based on the simulation results, the selection frequencies of the provinces were calculated and classified into three different ranges:
Very High Frequency Provinces (≥0.75): Ankara, Antalya, Diyarbakır, Elazığ, Gaziantep, Istanbul, Izmir, Kayseri, and Van.
Medium Frequency Provinces (0.55-0.75): Balıkesir, Erzurum, Eskişehir, Mersin, Kocaeli, Konya, Malatya, Manisa, Kahramanmaraş, Muğla, Sakarya, Samsun, Trabzon, and Şanlıurfa.
Low Frequency Provinces (0.30-0.55): Adana, Adıyaman, Artvin, Aydın, Bilecik, Çanakkale, Rize, Sivas, and Düzce.

This classification highlights the strategic importance of the provinces for the hydrogen pipeline route. The results obtained based on the calculated criteria are presented in Figure 1.

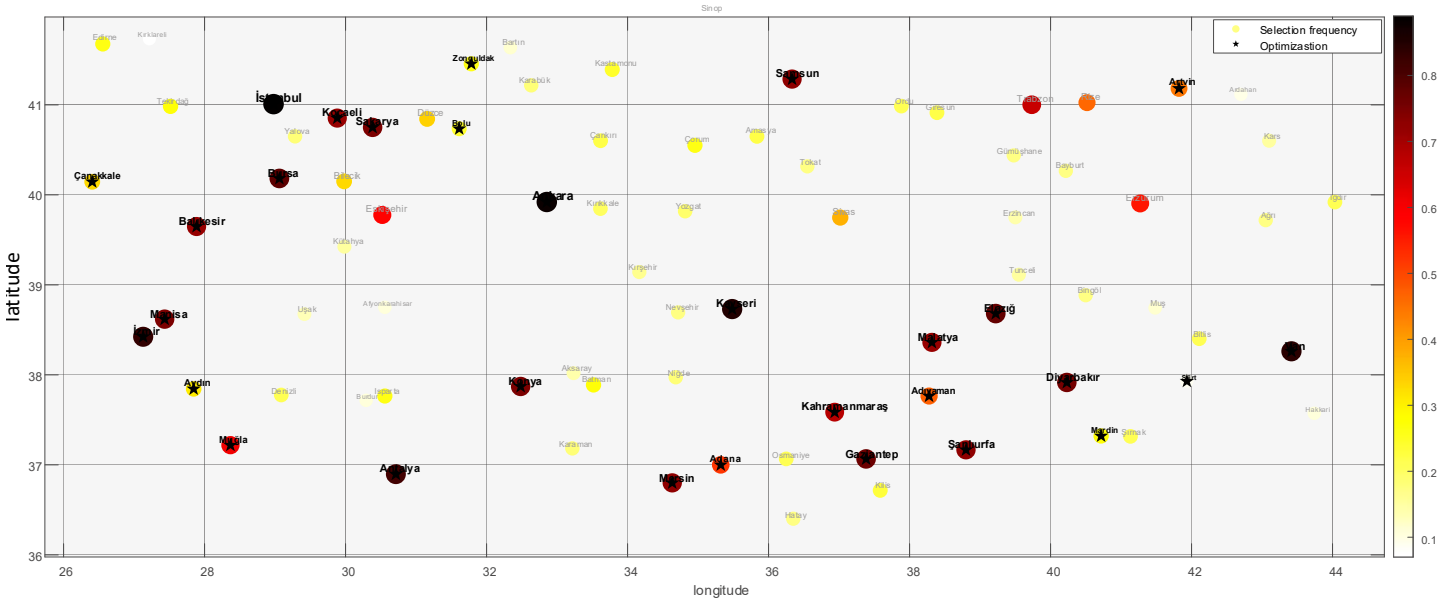

Fig. 1. Hydrogen Pipeline Route Optimization and Monte Carlo Simulation Results

Fig. 1 illustrates the results of hydrogen pipeline route optimization and Monte Carlo simulation for Türkiye's 81 provinces. The map visualizes the selection frequencies of the provinces and the provinces selected as a result of the optimization process. These results enable a detailed analysis of both the optimization process and the effects of uncertainties. The colors used on the map represent the selection frequencies of the provinces during the Monte Carlo simulation. The transition from white to black indicates the selection frequency of the provinces. Similarly, the black star symbol represents the provinces selected as a result of the optimization process. These provinces were chosen to form the most optimal route under the specified criteria (cost, energy demand, energy potential, and geographical suitability) and constraints (budget, minimum demand, and minimum potential). Provinces without a star symbol were not selected in the optimization process but may have been selected with a certain frequency during the Monte Carlo simulation. As a result, the proposed hydrogen pipeline corridor for Türkiye is presented in Fig. 2.

Fig. 2. Türkiye's hydrogen pipeline route between Asia and Europe.

As a result, some provinces, despite not being selected in the optimization process, exhibit high selection frequencies during the Monte Carlo simulation. This indicates that these provinces become more advantageous in certain scenarios due to the effects of uncertainties.

4. CONCLUSION

This study was conducted to determine the hydrogen pipeline route for Türkiye's 81 provinces using a hybrid optimization approach and Monte Carlo simulation. The study aimed to identify the most optimal route under specified constraints by considering multiple criteria such as energy demand, energy potential, geographical suitability, and cost. The results obtained allowed for a detailed analysis of both the optimization process and the effects of uncertainties. The uniqueness of this study lies in the hybrid use of Particle Swarm Optimization (PSO) and Monte Carlo simulation for hydrogen pipeline route planning. Unlike traditional methods in the literature, this approach analyzes the resilience of the route by taking uncertainties into account. The study provides decision-makers in energy infrastructure planning with the following contributions:

- Integrated evaluation of multiple criteria,
- Analysis and visualization of the effects of uncertainties,
- Numerical and visual presentation of the selection frequencies of provinces.

The optimization and simulation results reveal the selection frequencies and strategic importance of the provinces. The provinces selected as a result of the optimization process were determined based on their high values in terms of energy potential, energy demand, and geographical suitability. The selected provinces are Monte Carlo simulation was conducted under 100 different scenarios by applying a 10% random variation to the criteria. According to the simulation results, the three provinces with the highest selection frequencies are Istanbul (89%), Ankara (88%), and Kayseri (87%). As a result, a hydrogen pipeline route for Türkiye has been proposed to ensure a sustainable energy transition between Asia and Europe.

Future studies could further develop this method by incorporating additional criteria. Moreover, dynamic factors such as population growth and regional economic development could be included to enhance the model. However, as a pioneering study in this field, the current work provides a framework that can guide decision-makers in energy infrastructure planning.

ABSTRACT
The use of military microgrids plays a crucial role in ensuring energy security, achieving sustainability objectives, and providing operational independence in military operations. This study introduces a Load Frequency Controlled (LFC) stable power system to enhance the efficiency and robustness of microgrids used in military bases. In this paper, the Whale Optimization Algorithm (WOA) is employed to optimize the load frequency model of a military microgrid. The WOA, as a novel advanced control approach, is compared with traditional Proportional-Integral-Derivative (PID) controllers through simulations, employing an innovative two-degree-of-freedom proportional-integral-derivative (2DOF-PID) controller. The comparative analysis demonstrates that the WOA-optimized 2DOF-PID controller exhibits rapid response and precise targeting capability with an average square error of 0.00001. The results show that the microgrid frequency optimized by WOA is effectively controlled. Simulation results under low Renewable Energy Sources (RES) conditions reveal that the 2DOF-PID controller, optimized by WOA, reduces the ITAE and ISE values to 2.065 and 6.478, respectively, while maintaining system stability. This research enhances the resilience of microgrid systems, ensuring reliable performance, particularly when controlling frequency during military and emergency situations.

Keywords: Load Frequency Controlled, Whale Optimization Algorithm, Military Microgrids

1. INTRODUCTION
Military bases and emergency response centers are increasingly adopting microgrids due to their energy security and uninterrupted power requirements. These systems are designed to enhance the energy independence of military bases, ensure resilience against external grid outages, and improve operational efficiency. The ability to operate sustainably off-grid, provide uninterrupted power supply, and function silently offers critical advantages, such as reducing the risk of detection. Additionally, mobile microgrid systems enable rapid deployment and flexible usage, allowing them to quickly adapt to operational requirements.
Energy management in military microgrids is a critical factor for ensuring efficient and stable system operation. In this context, the integration of renewable energy sources (RES) emerges as a key strategy to enhance the sustainability of microgrids. However, the inherently variable nature of renewable energy sources can directly impact system stability and energy quality. Specifically, fluctuations in renewable energy generation and changes in consumption demand can lead to imbalances in system frequency, negatively affecting power quality. Therefore, the development of frequency regulation strategies in microgrids is of great importance.
Continuous fluctuations in the power output of renewable energy sources increase the imbalance between energy generation and consumption, causing oscillations in system frequency [1]. Frequency deviations from the nominal value reduce energy quality and system reliability. As a result, various control methods have been developed to ensure frequency regulation in microgrids [2-3]. Achieving this control in standalone microgrids requires a more complex process. In this regard, secondary controllers play a critical role in maintaining system stability and preventing frequency deviations [4].
In this study, a military microgrid consisting of diesel generators, wind turbines, solar panels, biomass energy systems, data monitoring and communication infrastructures, energy storage batteries, electric vehicles, fuel cells, electrolyzers, and unmanned aerial vehicles was modeled in MATLAB/SMILUNIK. To ensure energy security, maintain system stability, and achieve operational independence, an appropriate Load Frequency Control (LFC) is required. For this purpose, two different controllers were designed: Proportional Integral Derivative (PID) and Two-Degree-of-Freedom PID (2DOF-PID). The Whale Optimization Algorithm (WOA) was proposed to optimize the load frequency model of the microgrid. This allowed for fine-tuning the controllers' parameters more efficiently and accurately. The main contributions of this study are listed below:

- A Proposes a stable power system to ensure load frequency control in military microgrids.
- Tests and compares the use of the WOA algorithm with traditional PID controllers to optimize the load frequency model of microgrid systems.
- Introduces an innovative solution by employing the 2DOF-PID controller, differing from traditional PID controllers.
- Demonstrates that optimizing WOA and 2DOF-PID controllers for load frequency control can enhance the efficiency and reliability of military microgrids.
- Ensures more stable and consistent operation of microgrids against fluctuations in energy generation.

- Presents a model that improves microgrid performance even under low renewable energy conditions, contributing to energy security and sustainability goals.
- Highlights the importance of load frequency control in microgrids to ensure energy independence and security in military operations.
- Prevents energy losses caused by imbalances in generation and consumption, improving energy quality and increasing efficiency.

2. MATERIALS AND METHODS

Military Microgrid

The mathematical and dynamic model of a military-type microgrid (MMG) for load frequency control is presented in Fig. 1. The model consists of an integrated structure that includes diesel generators, wind turbines, solar panels, biomass energy systems, data monitoring and communication infrastructures, energy storage batteries, electric vehicles, fuel cells, electrolyzers, and unmanned aerial vehicles.

Fig. 1. Military microgrid model

Whale Optimization Algorithm

The Whale Optimization Algorithm (WOA) is an optimization algorithm inspired by the behavior of whales in nature. Specifically, it is designed based on observations of whales' hunting and social interaction behaviors. This algorithm mimics behaviors such as the "bubble-net" hunting technique and group movements of whales. WOA is an evolutionary algorithm that performs exploration and exploitation phases in parallel while searching the solution space.

Mathematical Model;

The mathematical model of WOA is derived by expressing the aforementioned behaviors through mathematical equations. Essentially, each whale represents a solution point, and the search process is shaped by the social and individual movements of the whales. The fundamental mathematical equations modeling whale behaviors are presented below as Equations (1)–(3).

1. Exploration Behavior (Bubble-Net):

The position of the whale is updated to find a new solution. The general form of this equation is as follows:

$$Xt + 1 = Xt + A \cdot | C \cdot Xg - Xt | \quad (1)$$

where: X_t represents the current solution, X_g represents the global best solution, A and C are algorithm parameters.

2. Exploitation Behavior (Targeted Swimming):

The swimming behavior allows the whale to reach the target in smaller steps within the solution space. This is mathematically expressed as:

$$Xt + 1 = Xt + B \cdot | D | \cdot Xg \quad (2)$$

where: B is a control parameter, D is the distance between two whales.

3. Position Update:
Whales approach each other in the solution space to discover new solutions. This process is modeled as:

$$Xt + 1 = Xt + (rand) \cdot (Xbest - Xt) \quad (3)$$

where: X_t is the current solution, *rand* is a random factor.
WOA performs exploration (global search) and exploitation (local search) phases sequentially in the solution space. In each iteration, the positions of the whales are updated, and the process continues until the best solution is found. This process progresses to minimize the objective functions that need to be optimized.

3. DOF PID CONTROLLER
The degree of freedom of a controller is defined as the number of closed-loop transfer functions that can be independently adjusted [5]. Studies have demonstrated the applicability of a two-degree-of-freedom PID (2DOF-PID) controller in load frequency control systems to improve system efficiency and stability [6-7]. 2DOF-PID controllers are widely used to detect and control disturbances and rapid shocks in electric power systems without symbolic setpoint tracking overshoot [8]. The control architecture of the 2DOF-PID controller is shown in Fig. 2.

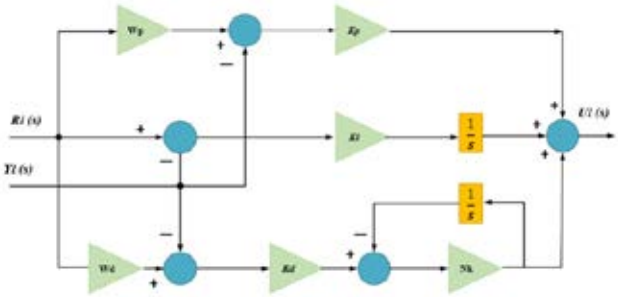

Fig. 2. 2DOF-PID control architecture

The transfer function of a 2-DOF PID controller can generally be expressed as follows:

$$C(s)= K_p+K_i/s+K_dNs/1+Ns \quad (4)$$

where: K_p Proportional gain, K_i Integral gain, K_d Derivative gain, N Derivative filter coefficient. The key difference from a classical PID controller lies in the two distinct weighting parameters (W_p and W_d) that determine the response to the reference input. The mathematical model used for the 2-DOF PID controller is shown in Equation (5):

$$U(s)=K_p[W_pR(s)-Y(s)]+K_i1/s\ [R(s)-Y(s)]+ K_d*Ns/1+Ns[W_dR(s)-Y(s)] \quad (5)$$

where: R(s) Reference input signal, Y(s) Output signal, Wp and Wd Weighting coefficients applied to the reference input. These equations are used to make the controller's behavior more flexible in response to reference changes and disturbances. Based on this model, the 2-DOF PID controller can provide superior performance compared to the conventional PID controller, enhancing system stability.

3. RESULTS AND DISCUSSIONS
Military microgrids are designed to provide uninterrupted energy without relying on external grids. These systems consist of various components, including diesel generators, wind turbines, solar panels, biomass energy systems, data monitoring and communication infrastructures, energy storage batteries, electric vehicles, fuel cells, electrolyzers, and unmanned aerial vehicles. In this study, the performance of a proposed controller for military microgrid systems was analyzed, particularly in terms of its load frequency control (LFC) capability. Accordingly, both proportional-integral-derivative (PID) and two-degree-of-freedom PID (2DOF-PID) controllers were integrated into the microgrid system. Subsequently, the specified controllers were optimized using the WOA model to evaluate system performance.

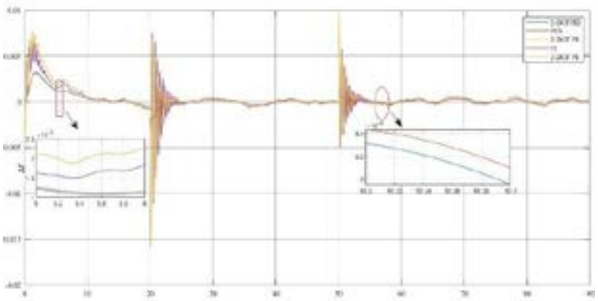

Fig. 3. The Frequency Response of the System

Implementing a robust controller to reduce oscillations and ensure stability in military microgrids is essential. For the two evaluated algorithms, the controller parameter limits were set between 0 and 10, with a maximum of 50 iterations and an initial population size of 50. Notably, the WOA model, proposed for the first time in this study, demonstrated superior performance compared to other algorithms under the same conditions. It was then compared with the designed PID and 2DOF-PID controllers. The oscillatory behavior of the PID controller, characterized by a long response time, is shown in Fig. 3. The 2DOF-PID controller exhibited the most optimal performance under load variations.

Table 1. Performance metrics

Controller	ITSE x 10^{-3}	ISE x 10^{-3}	IAE	ITAE
PID	0.26	3.32	0.027	0.0556
2DOF-PID	0.25	3.30	0.026	0.555

A more detailed comparison of the controllers optimized using the WOA model is provided in Table 1, which lists performance indices such as ITAE, ITSE, IAE, and ISE.

4. CONCLUSIONS

This study demonstrated that optimizing load frequency control systems can reduce the imbalance between energy generation and consumption, preventing oscillations in system frequency. In this context, it was shown that the proposed approach could enhance the energy quality and reliability of the system. The continuous fluctuations in the power output of renewable energy sources were mitigated by the proposed controller, which played a critical role in maintaining system stability and preventing frequency deviations. This study evaluated the performance of PID and 2DOF-PID controllers for load frequency control (LFC) in a military microgrid system. Simulation results proved that the proposed control scheme outperformed classical PID and 2DOF-PID controllers tuned using the WOA model in terms of performance metrics (ITAE, ISE, IAE, and ITSE). Among the tested controllers, the 2DOF-PID controller achieved the best results across all performance criteria. The proposed 2DOF-PID controller recorded the lowest values for ITSE (0.25×10^{-3}), ITAE (0.555), ISE (3.30×10^{-5}) and IAE (0.026), demonstrating its ability to provide precise and stable frequency regulation with minimal error and energy loss. It was the most consistent and effective controller.

In conclusion, the findings highlight the robustness and adaptability of advanced optimization techniques and controller designs in achieving efficient and reliable load frequency control for military microgrids. The 2DOF-PID controller combined with the WOA model, which outperformed all other controllers in terms of performance metrics, was identified as the best controller. This study serves as a reference point for advancing adaptive control strategies for enhanced energy infrastructures.

PARAMETRIC ESTIMATION AND PERFORMANCE ANALYSIS OF DIRECT ETHANOL FUEL CELLS AND LITHIUM BATTERIES FOR HYBRID ENERGY SYSTEMS

Meltem YAVUZ ÇELİKDEMİR
Bitlis Eren University, Tatvan Vocational School, Electronic and Automation, Bitlis, 13000, Türkiye

E-mail: meltem.ycd@gmail.com

ABSTRACT
Fuel cells and energy storage systems have become widely used in significant engineering applications today. However, one of the challenges faced in these applications is determining the exact values of unknown parameters. In this context, the use of Direct Ethanol Fuel Cells (DEFC) and lithium batteries in hybrid systems enhances the efficiency, sustainability, and longevity of energy storage and conversion systems, owing to the complementary characteristics of both technologies. This study aims to accurately estimate the parameters of the mathematical model of the DEFC and lithium battery hybrid system. For this purpose, the Starfish Optimization Algorithm, a contemporary algorithm with certain advantages in the literature, is applied for the first time. Additionally, a voltage-power-based objective function, recently proposed by researchers, is utilized. This approach ensures that the hybrid system operates within the maximum power region, thereby increasing its efficiency and operational lifespan. As a result, the absolute error sum for the DEFC is calculated as 4.2457, and the average absolute error sum for the lithium battery is 0.0469. Consequently, the parameters of the DEFC-lithium battery hybrid model are estimated with high accuracy. Furthermore, experimental data for the DEFC and lithium battery are used to improve the accuracy of the predictions.
Keywords: DEFC, The Starfish Optimization Algorithm, Objective Function

1. INTRODUCTION

In recent years, electrical power systems have undergone significant advancements. Parallel to these developments, the application areas of fuel cells have also expanded. Fuel cells offer several advantages in practical applications, such as low noise, low operating temperatures, high electrical efficiency, high current density, rapid start-up, excellent transient response, and high modularity [1-2]. These advantages have led to an increased focus in the literature on the development and optimization of fuel cells. Fuel cells are electrochemical devices that convert chemical energy into electrical energy using hydrogen gas as the fuel and oxygen/air as the oxidizer, while also producing heat as a byproduct. Among the various types of fuel cells, one of the most commonly used is the DEFC. DEFCs have been applied in numerous fields, including mobile devices, vehicles, transportation systems, industrial applications, and distributed residential energy production systems [3]. Due to their widespread use, the modeling and optimization of DEFCs have garnered significant attention in the literature. Another topic attracting significant attention in the literature is energy storage systems. These systems are developed to address the imbalance between energy production and consumption and to ensure the continuity of energy supply. By facilitating the integration of renewable energy sources, energy storage systems enhance energy efficiency and ensure energy security. Among energy storage technologies, lithium-ion batteries receive the most attention. They stand out as one of the most widely used and effective solutions due to their high energy density, long cycle life, and low self-discharge rate. These superior characteristics make lithium-ion batteries suitable for a wide range of applications, from portable electronic devices to electric vehicles and grid-scale energy storage systems. They play a critical role in accommodating the variable generation profiles of renewable energy sources. Furthermore, the decreasing costs and improving performance of lithium-ion batteries are driving their adoption on a larger scale.

Mathematical modeling and parameter estimation play a crucial role in the design and development of these two highly researched topics. In this study, for DEFCs: The literature provides various methods for modeling DEFCs, which can be broadly categorized into two groups. The first category, known as mechanistic modeling, focuses on describing the electrochemical processes occurring within fuel cells, as well as heat and mass transfer phenomena. The second category, empirical modeling, involves semi-empirical and non-linear equations to predict the effects of various parameters on the current-voltage relationship. Parameter estimation is crucial for optimizing the performance and extending the lifespan of lithium-ion batteries. Accurate parameter estimation enhances the effectiveness of battery management systems by preventing harmful conditions such as overcharging or overdischarging. Moreover, it enables the monitoring of performance metrics, such as energy density and power capacity, ensuring the safe and efficient operation of the battery.

In this study, the suitability of objective functions proposed in previous research was evaluated and compared. Unlike previous studies, the Starfish Optimization Algorithm (SFOA) is employed to optimize the proposed objective function. The results obtained were rigorously compared with a verifiable reference, and the performance of the proposed algorithm was thoroughly tested. The proposed objective function was applied to the same scenarios as previous studies, and the results are presented, demonstrating its effectiveness and potential for improving DEFC parameter estimation and performance. This study not only highlights the importance of accurate modeling and optimization of DEFCs but also introduces a new approach that could pave the way for further advancements in fuel cell technology.

2. MATHEMATICAL MODEL

Direct alcohol fuel cells convert the chemical energy of alcohol into electrical energy, heat, and other by-products. Direct ethanol fuel cells (DEFCs) have been studied in recent years due to ethanol being a non-toxic, renewable fuel that can be easily produced through the fermentation of sugar-containing raw materials. The electrochemical reaction equations of DEFCs are given below [3-4].

$$CH_3CH_2OH + 3H_2O \Leftrightarrow 2CO_2 + 12H^+ + 12e^- \quad (1)$$

$$3O_2 + 12H^+ + 12e^- \Leftrightarrow 6H_2O \quad (2)$$

$$CH_3CH_2OH + 3O_2 \Leftrightarrow 2CO_2 + 3H_2O \quad (3)$$

The mathematical model of DEFCs is given in Equation 4.

$$E_{cell} = E_{0_{cell}} - R_e j - \frac{RT}{F}\left(\frac{1}{\alpha_a} + \frac{1}{\alpha_c}\right) x \left[ln \frac{C_0^{ref}}{j_{0c}(C_0)^{N_0}} - N_0 ln\left(1 - \frac{j}{nFk_0C_0}\right)\right] - \frac{RT}{\alpha_a F} x \left[ln \frac{C_{Met}^{ref}}{j_{0a}(C_{Met})^N} - N ln\left(1 - \frac{j}{nFk_{eff}C_{Met}}\right)\right] \quad (4)$$

Here $E_{0_{cell}}$ is the standard potential for the DMFC overall reaction, which theoretically is given by the Nernst equation, j_{0a}, j_{0c} are the exchange current at reference concentration in the anode and cathode, α_a, α_c are the electronic transfer coefficients at the anode and cathode catalyst surfaces, respectively. C_{Met} is the methanol concentration, C_{Met}^{ref} is the reference methanol concentration, N and N_0 are the orders of reactions, k_0, k_{eff} are the mass transport coefficients for the cathode and anode, respectively [4]

Equivalent circuit models are a method frequently used in battery management systems to monitor and control lithium-ion batteries. For this purpose, the equations of the Thevenin model of lithium-ion batteries are given below.

$$V_t = V_{OC} - V_{Ri} - V_{RC} \quad (5)$$

$$V_{Ri} = I \; x \; R_i \quad (6)$$

$$\frac{dV_{RC}}{dt} = \frac{I}{C} - \frac{V_{RC}}{V_{RC}C} \quad (7)$$

Here V_t represents the terminal voltage, V_{OC} denotes the open-circuit voltage, V_{Ri} refers to the voltage drop across the internal resistance, and V_{RC} indicates the voltage drop across the capacitor. Additionally, I represents the battery current, and R_i denotes the internal resistance. The equation related to the state of charge (SOC) is given in Equation 8.

$$SOC(t) = SOC(0) - \frac{1}{C_n}\int_0^t I(\mathrm{r})d\mathrm{r} \quad (8)$$

Here $SOC(0)$ represents the initial state of charge, C_n denotes the nominal capacity, and $I(\mathrm{r})$ represents the current function. The open-circuit voltage is provided in Equation 9.

$$V_{OC} = f(SOC) \quad (9)$$

The expression for the effect of temperature is given in Equation 10.

$$V_t = V_t + k_T(T - T_{reff}) \quad (10)$$

Here k_T represents the temperature coefficient, T denotes the instantaneous temperature, and T_{reff} indicates the reference temperature. As a result, the mathematical model calculates the parameters V_r, R_i, C, R_{CH}, the time constant (r) and temperature-related variables.

3. THE STARFISH OPTIMIZATION ALGORITHM

Swarm-based algorithms are developed by drawing inspiration from the behavior of living organisms in nature. One such algorithm is the Starfish Optimization Algorithm (SOA). SOA is a novel bio-inspired metaheuristic method designed to solve optimization problems by simulating the behaviors of starfish, including exploration, foraging, and regeneration. It consists of two main phases: exploration and exploitation. The exploration phase mimics the exploratory behavior of starfish through a hybrid search pattern that combines five-dimensional and one-dimensional search strategies to enhance computational efficiency and search capacity. The exploitation phase simulates the foraging and regeneration behaviors of starfish using a bidirectional search strategy and specialized movements to ensure convergence during exploitation.

During the initialization phase of SFOA, the positions of the starfish are randomly generated within the boundaries of the design variables, which can be represented as a matrix. This process is provided in Equation 11 [5].

$$X = \begin{bmatrix} X_{11}X_{12} \dots X_{1D} \\ X_{21}X_{22} \dots X_{2D} \\ . \; . \; \dots \; . \\ . \; . \; \dots \; . \\ X_{N1}X_{N2} \dots X_{ND} \end{bmatrix}_{NxD} \quad (11)$$

To model the exploratory behavior of starfish, a new search pattern combining a five-dimensional search pattern for D>5 and a one-dimensional search pattern for D≤5 has been proposed. The dimensional threshold is determined based on the five arms (or eyes) of the starfish. The mathematical expressions are provided in Equations 12 and 13 [5].

$$Y_{i,p}^T = X_{i,p}^T + a_1\left(X_{best,p}^T - X_{i,p}^T\right) cos\emptyset, r \leq 0.5 \quad (12)$$

$$Y_{i,p}^{T} = X_{i,p}^{T} + a_1\left(X_{best,p}^{T} - X_{i,p}^{T}\right) sin\emptyset, r \geq 0.5 \quad (13)$$

4. RESULTS AND DISCUSSIONS

In this study, the model parameters are optimized using SOA to match the actual DEFC outputs. To achieve this, the parameters E_0, b, R_e, C_1 and C_2 must be determined to calculate the PEMFC outputs. Once these parameters are identified, the output voltage can be predicted for a given input current. Several objective functions, also known as cost functions, are used to determine the DEFC parameters. All of these cost functions are defined based on voltage. In the optimization processes using these cost functions, errors in the high-voltage regions are given priority. Specifically, the activation voltage drop region holds the highest priority, the ohmic voltage drop region is given lower priority, and the concentration voltage drop region is considered non-prioritized. Considering the power curve of fuel cells, it is more appropriate for these regions to have opposite priorities. This approach aligns with real operating conditions. In this study, the current literature uses voltage- and power-based cost functions to determine DEFC parameters [6]. The objective function used for this purpose is provided below.

$$J = \sum_{i=1}^{N}\left(\left[V_{exp.} - V_{est.}\right]^2 + \left|P_{exp.} - P_{est.}\right|\right) \quad (15)$$

In this study, only data that can be definitively validated were used. For this purpose, the experimental data employed in the works of Blanco-Cocom et al. have been provided numerically [3]. The results of these studies were examined as reference works for objective comparison. The unknown parameters of the DEFCs examined in this study, determined as a result of SOA, are presented in Table 1.

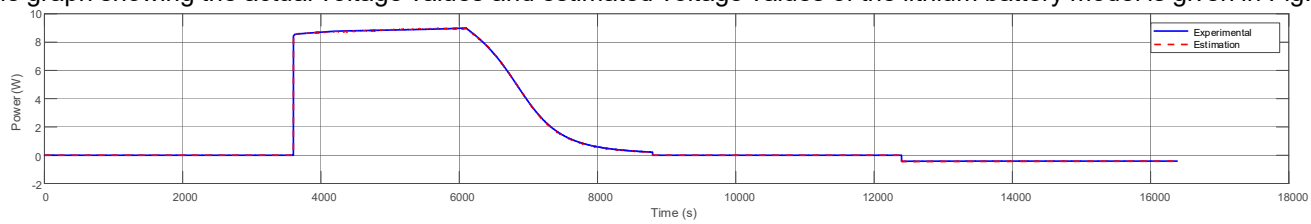

Fig. 2. Comparative results

Here, the data of the experimental study are shown in blue and the estimated voltage values are shown in red. 16384 current-voltage data were used in the experimental study. As a result, the mean absolute error sum was calculated as 0.0469 using the voltage and power based objective function.

5. CONCLUSIONS

In this study, the parameters of the DEFC and lithium battery hybrid model were determined. For this purpose, the Starfish Optimization Algorithm was applied for the first time as a novel algorithm for estimating the unknown parameters of DEFC. This demonstrated that predictions were made with high convergence, as observed in the literature. Unlike voltage-based objective functions recommended by most researchers, a hybrid objective function was used. This resulted in an absolute error sum of 4.24 for the DEFC model. Additionally, the average absolute error sum for the lithium battery model was calculated as 0.0469. This indicates that predictions with high convergence were achieved using the hybrid objective function, as demonstrated by the literature. Furthermore, the use of the proposed hybrid objective function led to a reduction in the total power error for PEMFCs, thereby ensuring more efficient operation of the fuel cells. The use of experimental data in such studies is crucial for objective evaluation.

ABSTRACT
The primary objective of this study is to identify the key variables influencing voltage prediction in Polymer Electrolyte Membrane Fuel Cells (PEMFC). For this purpose, 22 variables from an 80 W PEMFC dataset containing 33,899 recorded entries were analyzed using 25 different regression models through machine learning techniques. Among these models, the Bagged Trees method was selected as the most suitable model due to its lowest RMSE value. Using this model, the five most influential variables (voltage, current, temperature, time, cell temperature) were identified. These variables were then re-applied as input features in the Bagged Trees model to perform voltage prediction, achieving a minimum RMSE value of 4.131×10^{-3}. Another aim of this study was to investigate the impact of these variables on voltage. For this purpose, 4,000 external test data points were used, where four variables were kept constant while the value of the remaining variable was incrementally increased to observe its effect on voltage. The results revealed that an increase in power, temperature (3), and cell temperature variables led to an increase in voltage, whereas an increase in current and time variables caused a decrease in voltage. These findings provide significant insights into optimizing PEMFC performance and understanding the system dynamics.
Keywords: PEMFC, Voltage Estimation, Bagged Trees, Regression, Identified Variables

1. INTRODUCTION

In recent years, the use of fuel cells has become increasingly widespread due to their numerous advantages, such as high energy efficiency, fast startup, low operating temperature, and minimal noise. These features have made them a focus of research in the literature [1]. The importance of parameter tuning for the design and performance improvement of Polymer Electrolyte Membrane Fuel Cell (PEMFC) models has been emphasized to expand their use in clean energy applications [2]. For instance, variants of the Grey Wolf Optimization (GWO) algorithm have been applied to evaluate unknown parameters of PEMFCs [3]. However, one of the disadvantages of PEMFCs, which are alternative energy sources that generate electricity without causing adverse effects, is their short lifespan and the non-linear relationship between load current and voltage. To address this, a novel method based on a semi-empirical model using a transient search optimization algorithm has been proposed to predict PEMFC voltage under varying ambient conditions [4].
Operational faults such as water flooding and membrane drying during PEMFC operation can lead to performance degradation and reduced lifespan. Studies have been conducted to examine various fault indicators for PEMFC fault diagnosis, including stack voltage, pressure drops, membrane resistance, flow rate, stack temperature, oxygen excess ratio, compressor speed, hydrogen mass, and oxygen mass [5].
In this study, regression learning algorithm models were used to determine the importance ranking of parameters affecting the voltage value, which is a critical criterion for PEMFC fault diagnosis. The algorithms used gaussian process, support vector machines, neural networks, decision trees, linear regression, ensemble methods, and GLM. The dataset used in this study contains 22 variables and 33,899 recorded entries from an 80 W PEMFC. Of these, 33,799 entries were used for model training, while 4,000 entries were reserved for external testing. Additionally, internal testing was performed during model training, and the performance metrics were compared.

2. SYSTEM DESCRIPTION AND PROCEDURE

This study utilized experimental data from an 80 W PEMFC. The experimental data included 22 different PEMFC variables, including voltage information. A voltage drop of 5% in PEMFC output voltage is considered water flooding [6]. To observe PEMFC voltage drops, the feasibility of voltage prediction was first evaluated. For this purpose, 25 different regression models were trained. Among these models, the Bagged Trees model was identified as the most suitable based on the RMSE performance metric. The five variables that caused the most significant changes in voltage were determined through testing on this model. The variable importance ranking and graph for the Bagged Trees model are shown in Fig. 1. These results help identify which variables the model assigns more "importance" to and which variables contribute less to the model's accuracy. The importance ranking of the identified variables is as follows:

- Power: 3.9×10^{-5}
  This is the most critical variable contributing to the model's prediction performance.
- Current: 1.9×10^{-5}
  The second most important variable, significantly contributing to the model's accuracy.
- Temperature (3) and Time: 2×10^{-6}
  These two variables contribute minimally to the model's accuracy but have a non-zero importance level.

- Cell temperature: 1×10^{-6}
  This variable has a very low contribution to the model's accuracy.
- Other variables (e.g., hydrogen inlet temperature, air supply pressure, etc.): 0×10^{-6}
  These variables do not contribute to the model's accuracy.

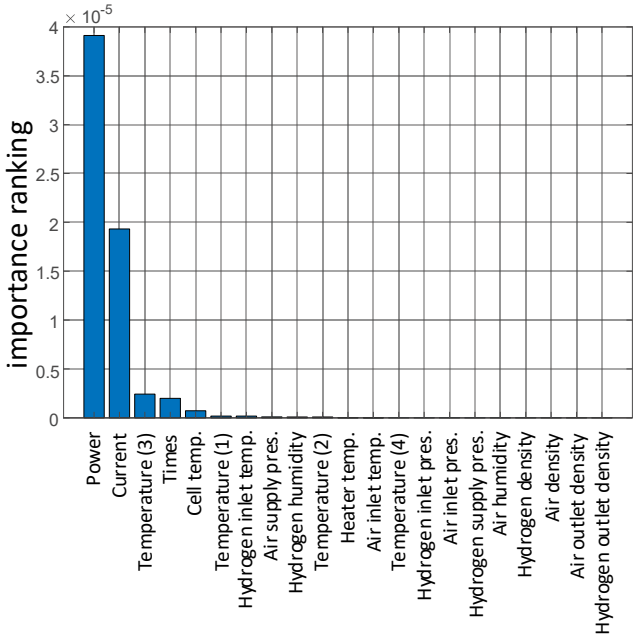

Fig. 1. Importance ranking of variables

Fig. 1 illustrates the variable importance ranking. The variables 'power' and 'current' have significantly higher importance levels compared to all other variables. This indicates that these two variables play a dominant role in the model's prediction performance. Other variables have importance levels close to zero, indicating that they do not contribute meaningfully to the model's prediction performance. Consequently, the critical variables power, current, time, temperature (3) and cell temperature are essential for the model's prediction performance and are observed to define the system's fundamental dynamics. Therefore, by focusing on these variables and excluding variables with zero importance (e.g., hydrogen inlet temperature, air supply pressure etc.), a simpler and faster model was obtained. The Bagged Trees model was retrained with the new variable set, achieving a high-performance voltage prediction with an RMSE value of 5.7368×10^{-3}. The model's accuracy, based on this variable importance ranking, explains the system's fundamental dynamics.

3. MODEL EVALUATION

Supervised machine learning algorithm models were trained on the available data. Supervised learning teaches the algorithm to memorize the expected outcomes. In the dataset, the voltage variable was evaluated as the output. The supervised machine learning algorithm models used in this study are shown in Fig. 2.

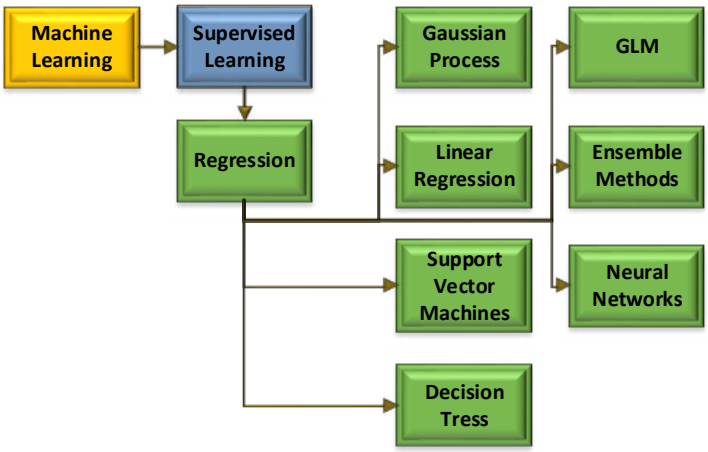

Fig. 2. Regression algorithm models

The dataset, containing 22 variables and 33,899 recorded entries, was trained using 25 different regression learning models, and the results were compared. Ten percent of the dataset was reserved for testing. The RMSE error values and training times for different algorithms are shown in Fig. 3.

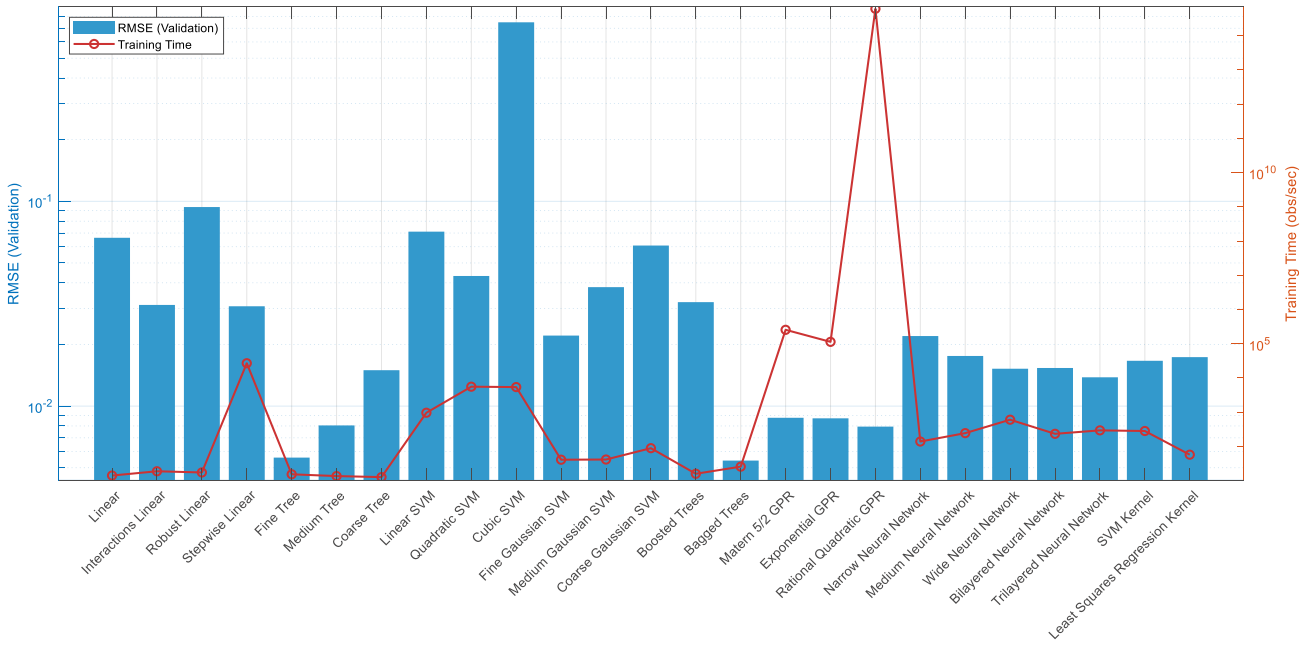

Fig. 3. RMSE error values and training times for 25 algorithm models

According to the results, the Bagged Trees regression learning model had the lowest RMSE value. The RMSE validation value for this model was 5.421×10^{-3}, with a training time of 25.59759 seconds. To improve the best-performing Bagged Trees model, the 22 input variables were ranked by importance, and five key variables were identified. When the model was trained with these five variables, the RMSE validation value was 4.131×10^{-3}, and the training time was 5.342 seconds. The voltage prediction and error graph for the 4,000 external test data points are shown in Fig. 4-a. Additionally, the graph in Fig. 4-b shows the results of the analysis conducted to determine the effects of the identified variables on voltage.

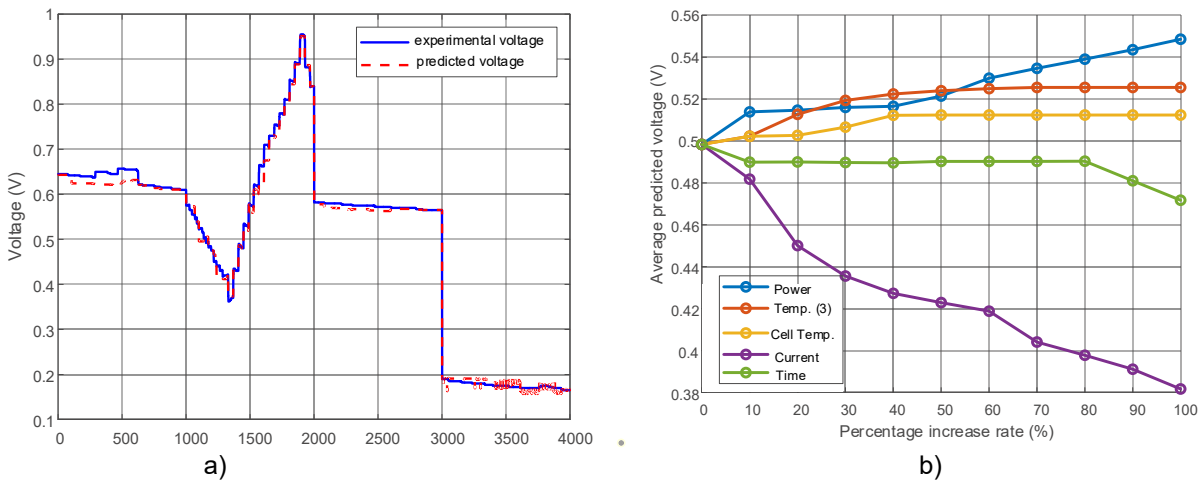

Fig. 4. a) Voltage prediction b) Identified variables

According to the results, based on the graph showing the 10% changes in the variables, the parameters affecting the voltage are ranked in the following order: current, power, temperature (3), cell temperature, and time information. Since a 5% change in voltage is considered a fault condition, it is anticipated that the importance ranking of these variables will contribute to the literature in this regard.

4. CONCLUSIONS

In this study, 22 variables from an 80 W PEMFC dataset containing 33,899 recorded entries were trained using regression models. To improve the model with the lowest RMSE value, variable importance ranking was performed. A new dataset with five variables was created, and the model was retrained. The results showed better performance metrics. The variables affecting PEMFC voltage were supported by both quantitative and qualitative graphical results. The proposed algorithm's performance was tested, and the Bagged Trees regression model achieved the lowest RMSE validation value of 4.131×10^{-3} and an RMSE test value of 5.7368×10^{-3}. The training time for this model was 5.342 seconds. Changes in the values of the variables were shown to affect PEMFC voltage, which is critical for fault evaluation and ensuring the continuous and efficient operation of fuel cells.

ABSTRACT
A theoretical investigation, based on density-functional calculations, was carried out to evaluate the feasibility of storing hydrogen molecules in doped and functionalized two-dimensional tin carbide (2D-SnC) nanostructures. The monolayer with substitutional doping X (X = B, Al Ga) is more stable when the X atom replaces the Sn one. The doped monolayer is also functionalized with transition metal atoms such as Sc, Ti, Ni, Pd, and Pt, where six adsorption sites for the metal atoms were tested , finding that these metal atoms have adsorption energies between 3.60 eV and 6.9 eV. The formation energy results indicate that the structures functionalized with Ni, Pd, and Pt atoms are unstable, whereas those decorated with Sc, and Ti, are stable and also they can adsorb hydrogen molecules. In particular, boron-doped 2D-SnC decorated with Sc and Ti atoms may be suitable as solid-state hydrogen storage materials.

Keywords: Hydrogen storage, DFT, Energy, 2D materials, doping – functionalization.

1. INTRODUCTION

Hydrogen is a sustainable energy source capable of replacing fossil fuels and reducing carbon dioxide (CO_2) emissions, thereby mitigating global warming [1]. It can be used as a fuel in nearly all applications that currently rely on fossil fuels. When produced from renewable resources, hydrogen offers immediate advantages over conventional fuels [2]. Despite its potential, hydrogen storage remains a challenge. Nanostructured materials, with their unique surface properties, are promising candidates for hydrogen storage due to their ability to adsorb hydrogen on their surfaces, form inter- and intragrain boundaries, and absorb significant amounts of hydrogen [3]. Additionally, they enable the development of lightweight hydrogen storage systems with enhanced capacity. Considerable research has focused on utilizing 2D materials for hydrogen storage, as they exhibit exceptionally large surface areas, high carrier mobility, and stability. Several effective 2D materials have been identified, including transition metal dichalcogenides (TMDs), lithium-modified $B_3C_2P_3$ monolayers, carbide monolayers, MXenes, and 2D boron. Doping plays a crucial role in modifying the electronic structure, introducing defects, and enhancing hydrogen adsorption and retention, thereby increasing storage capacity [4,5]. Furthermore, the adsorption of transition metals on 2D materials can significantly improve their ability to capture and release hydrogen. This study explores the impact of transition metal functionalization on doped 2D-SnC (with B, Al, and Ga) for hydrogen storage. To date, no studies have investigated the functionalization of doped 2D-SnC with transition metals such as Sc and Ti for this purpose. Here, we assess the feasibility of decorating doped 2D-SnC with transition metals (Sc, Ti, Ni, Pd, Pt) based on stability criteria, finding that only Sc and Ti form stable configurations. Additionally, we analyze the hydrogen adsorption properties of TM_XSnC systems (TM = Sc, Ti; X = B, Al, Ga) and their storage capacities. The results reveal that Sc- and Ti-decorated 2D-SnC can store up to three and four hydrogen molecules per adsorption site, respectively.

2. METHODOLOGY

In this study, the SIESTA code [6] based on Density Functional Theory (DFT) was used and a 50-atom SnC supercell was considered, where a dopant atom substitutes an atom of the former pristine lattice and a metal atom was added. To optimize the structures of the SnC-based materials and to address their energetic and electronic properties, the Perdew–Burke–Ernzerhof (PBE) exchange-correlation functional [7] was employed in conjuction with norm-conserving Troullier-Martins pseudopotentials and doubly-ζ polarized basis sets. The van der Waals interactions were accounted for through the semi-empirical Grimme DFT-D2 method [8], and the cutoff energy that defines the real-space grid for numerical integration was set at 320 Ry. Also, the Monkhorst-Pack scheme [9] was used with a 5×5×1 k-point grid to sample the Brillouin zone for geometric optimization and a 24×24×1 k-point grid for electronic calculations. After geometric optimization, it was obtained that the primitive lattice constant of the honeycomb SnC nanosheet is 3.64 Å with a C-Sn distance β=2.1 Å, and the calculations indicate that the distance between the dopant atom and the neighboring C is lower than the former Sn-C distance, as illustrated in **Fig. 1**. Also, the calculations indicate that two-dimensional SnC is an indirect bandgap semiconductor with a GGA bandgap of 0.81 eV [10], and by doping with B, Al and Ga, the SnC nanosheet becomes a p-type semiconductor. The binding energy (E_b) of a transition metal atom bound to the X-doped SnC nanosheet (X= B, Al, and Ga) is given by:

$$E_b = E_{X_2DSnC} + E_{TM} - E_{X_2DSnC+TM} \quad (1)$$

where E_{X_2DSnC} is the energy of SnC doped with B, Al, or Ga; E_{TM} is the energy of an isolated transition metal atom (TM = Sc, Ti, Ni, Pd, Pt); and $E_{X_2DSnC+TM}$ is the total energy of the optimized system of 2DSnC doped and functionalized with transition metal atoms. These binding energies were compared with the theoretical cohesion energies of metals (E_{coh}) to

determine whether metals can bind better to X_2DSnC instead of forming clusters. The cohesion energy of the metals was obtained from:

$$E_{coh} = \frac{n_{Bulk}E_{TM} - E_{Bulk}}{n_{Bulk}} \quad (2)$$

where n_{Bulk} is the number of metal atoms in the bulk unit cell, and E_{Bulk} is the energy of the bulk unit cell. Likewise, the formation energy (E_f) of the system was evaluated to determine the stability of the X_2DSnC+TM systems (X=B, Al, Ga; MT= Sc, Ti, Ni, Pd, Pt), and it is given by [11]

$$E_f = E_{X_2DSnC+TM} - (E_{X_2DSnC} + \mu_{TM}) \quad (3)$$

Here, $E_{X_2DSnC+TM}$ represents the energy of the TM-functionalized X-doped 2DSnC supercell, E_{X_2DSnC} is the energy of the doped 2DSnC supercell, and μ_{TM} is the chemical potential of the transition metal. A more negative the formation energy indicates a more stable system.
The interactions of hydrogen molecules on doped and functionalized SnC monolayers were analyzed through the adsorption energies of the H_2 molecules (E_{ads}) [10] given by:

$$E_{ads} = \frac{(E_{X_2DSnC+TM} + n\mu_{H_2}) - E_{MT_XSnC+H_2}}{n} \quad (4)$$

Here μ_{H_2} and $E_{MT_XSnC+H_2}$ are the chemical potential of the hydrogen molecule and the total energy of the doped-functionalized 2DSnC supercell with *n* hydrogen molecules adsorbed, respectively.

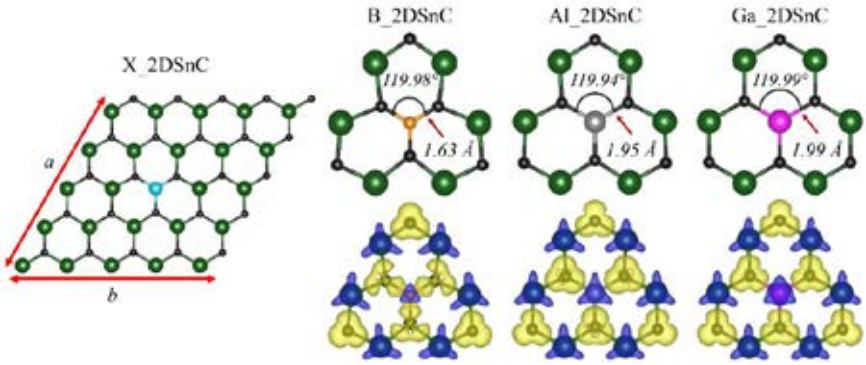

Fig. 1. Geometrical structure of a 50-atom SnC supercell with a dopant atom (left panel). Optimized structures of doped 2DSnC and their respective charge densities (right panel). Orange, gray, magenta, black and green spheres symbolize B, Al, Ga, C and Sn atoms, respectively. The accumulation (depletion) of electron charge density is represented in yellow (blue).

3. RESULTS AND DISCUSSION

The analysis of the results is divided in two parts. The first part analyzes the results regarding the functionalization of doped 2DSnC with transition metal atoms (Sc, Ti, Ni, Pd, and Pt), while in the second part, their capacities to store molecular hydrogen are discussed.

3.1. TRANSITION ADSORPTION ON DOPED 2DSnC

After optimizing the geometries of the doped nanosheets, they are decorated with transition metal atoms in six different sites, above a C atom, above a Sn atom, above the dopant X atom (X=B,Al,Ga), at the Sn-C bond, at the dopant-C bond and at the middle of a lattice hexagon. After relaxing each decorated doped monolayer, the configuration with the highest binding energy (E_b) between each metal atom and the doped nanosheet was chosen. The results indicate that the 5 metal atoms have a large binding energy, which makes them difficult to be removed from the system, being Sc, Ti and Pt the metal atoms with a more strong bond. The cohesion energy (E_{coh}) was calculated to evaluate the tendency of the added metal atoms to form clusters rather than maintaining individual bonds with the nanosheet. To ensure that the metals remain uniformly dispersed and bonded to the nanosheet, it is essential that the cohesion energy be lower than the binding energy. This condition prevents the aggregation of metal atoms into clusters and promotes stable, isolated metal adsorption on the nanosheet surface. Another criterion that determine the stability of these metal-decorated monolayers is their formation energy (E_f) given by Eq. 3. The more viable metal adatoms are Sc and Ti (see **Table 1**).

Table 1. Binding energy (E_b) of the metal atom in doped 2DSnC, formation energy of the X_2DSnC+TM system, calculated cohesion energy (E_{coh}) and distance from the adatom to the nanosheet ($d_{X_2DSnC-MT}$).

Doping	Transition Metal	E_b (eV)	E_f (eV)	E_{coh} (eV)	$d_{X_2DSnC-MT}$ (Å)
	Sc	6.79	-2.65	4.13	2.18
	Ti	6.62	-2.04	4.57	2.07
B	Ni	4.59	0.41	5.01	2.70
	Pd	3.96	0.11	4.07	2.77
	Pt	5.23	0.58	5.81	2.72
	Sc	6.88	-2.74	4.13	2.18
	Ti	6.69	-2.11	4.57	2.08
Al	Ni	4.61	0.39	5.01	2.01
	Pd	3.59	0.48	4.07	2.08
	Pt	5.10	0.71	5.81	2.05
	Sc	6.90	-2.76	4.13	2.18
	Ti	6.71	-2.13	4.57	2.07
Ga	Ni	4.66	0.34	5.01	2.01
	Pd	3.61	0.46	4.07	2.07
	Pt	5.34	0.47	5.81	2.10

3.1. HYDROGEN ADSORPTION ON DOPED AND DECORATED 2DSnC

To investigate the adsorption of molecular hydrogen on the doped and functionalized 2DSnC, hydrogen molecules were systematically located, one by one, close to the metal adatom and the system was further relaxed until no more hydrogen molecules were adsorbed. The average adsorption distance between the adsorbed hydrogen molecules and the metal adatom and the charge excesses on the hydrogen molecules were also calculated (see **Table 2**).

As shown in **Fig. 2** and **Table 2**, a maximum of three H_2 molecules per adsorption site can be adsorbed by the 2DSnC doped with Al and Ga and functionalized with Sc Sc and Ti, while the B-doped 2DSnC decorated with Ti can adsorb four hydrogen molecules per adsorption site. Also, this system has an average adsorption energy of 0.26eV, which is suitable for reversible hydrogen storage.

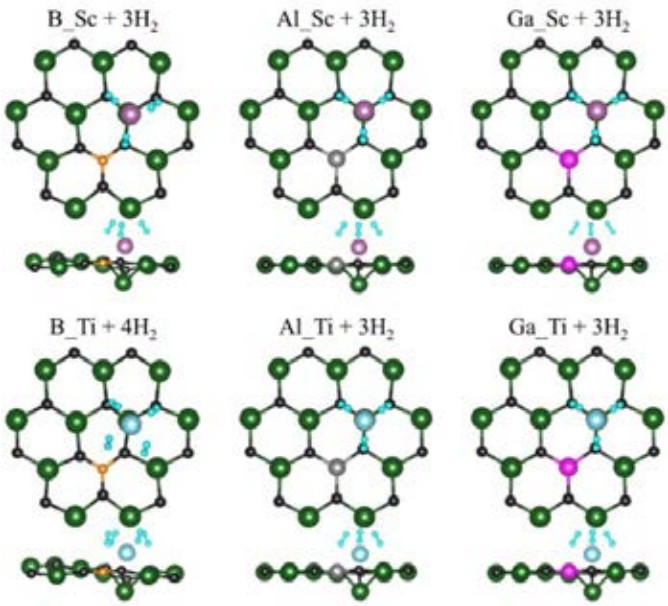

Fig. 2. Optimized structures of X-doped 2DSnC decorated with TM atoms (X=B, Al, Ga; TM=Sc, Ti) with the highest amount of H_2 molecules adsorbed. Cyan, Light Blue and Purple spheres represent H, Ti and Sc atoms respectively.

Table 2. Maximum amount of adsorbed hydrogen molecules (n_{H_2}), average adsorption energy (E_{ads}) and Hirshfeld charge excess on hydrogen molecules (δQ_H)

Doping	Transition metal	n_{H_2}	E_{ads} (eV)	$d_{MT_BSnC-H_2}$ (Å)	δQ_H (|e|)
B	Sc	3	0.34	2.32	0.067
	Ti	4	0.26	2.05	0.017
Al	Sc	3	0.41	2.14	0.070
	Ti	3	0.31	1.98	0.020
Ga	Sc	3	0.41	2.13	0.061
	Ti	3	0.31	1.98	0.012

4. CONCLUSIONS

DFT calculations were performed to study hydrogen storage in transition-metal-decorated doped SnC nanosheets. Sc and Ti, the lightest metals, have a very strong bond with 2DSnC doped with B, Al and Ga atoms. This confirms that Sc and Ti adatoms do not tend to form clusters on the doped nanosheet because their binding energies are higher than their cohesion ones. Likewise, formation energies indicate that 2DSnC decorated with Ni, Pd, and Pt atoms are not as stable as those monolayers decorated with Sc and Ti. Adsorption energy results indicate that hydrogen molecules are physisorbed on Sc- and Ti-functionalized doped 2DSnC. In particular, doped nanosheets decorated with Ti atoms show adsorption energies suitable for reversible hydrogen storage and also have the largest hydrogen storage capacity among the studied which are estimated to reach a hydrogen-storage capacity of 5.5 wt%, as required by the US Department of Energy (DOE), when the coverage of Ti reaches 68%. These results suggest that B-, Al-, and Ga-doped SnC nanosheets decorated with Ti are potential solid-state materials for hydrogen storage.

ABSTRACT
A shift towards sustainable transportation is necessary to reduce the sector's environmental footprint, particularly in countries like Qatar that rely heavily on personal hydrocarbon-based vehicles. While the country has battery electric vehicle goals, the dependence on natural gas power plants translates into emissions; hence, the deployment of hydrogen fuel cell vehicles (HFCVs) can be considered as an alternative. However, one of the major issues with this technology is the lack of infrastructure; for this reason, the present study deploys a maximum coverage location model (MCLM) to determine the required number and location of hydrogen refueling stations (HRSs) to meet a potential HFCV demand. Population density and vehicle registration data are used to develop the model alongside 107 potential HRS sites and a 10% fleet penetration assumption. As a result, 49 HRSs with a capacity of 1200 kgH_2/day are required to meet the demand; moreover, these stations are mainly located in the east, where the nation presents the highest population density and infrastructure development.

Keywords: Hydrogen Mobility, Maximum Coverage Location Problem, Hydrogen Refueling Station

1. INTRODUCTION
Increased awareness of environmental impacts originating from using conventional fuels has enhanced the necessity to seek solutions to decrease their dependency. Although the power sector is widely targeted in this regard, the transport sector is not being overlooked, and for a good reason, considering that it is the third highest CO_2 emitter after industry and power [1]. More so, road transport attracts attention since it represents up to 74% of the sector's emissions; a value that presents higher relevance in Qatar and the rest of the GCC countries since private cars represent 67% of the modal split and taxis add an additional 5%, making car use 72% of the share [2] For this reason, countries and regions have set targets and established strategies to transition away from conventional hydrocarbon-based vehicles. Qatar, in particular, has its green car initiative, which aims to have electric vehicles (EVs) representing 10% of the nation's vehicle fleet; however, with this approach, one issue remains, which is the dependency on natural gas-based power plants that supply roughly 96% of the nation's electricity [3]. Due to this, other alternatives like hydrogen fuel cell vehicles (HFCVs) must be considered.
From a vehicle technology perspective, HFCVs are not new since they were first commercialized in 2014 [4]; however, one issue remains in the form of infrastructure readiness. Qatar, in particular, has the H2 production know-how since it consumes roughly 1.3% of the globe's hydrogen demand for oil refining, as well as ammonia, methanol, and steel production [5–7]. Conversely, the country's refueling infrastructure is non-existent and it should be developed to enable HFCV adoption. For this reason, the present study develops a maximum coverage location model (MCLM) to determine the optimum location for hydrogen refueling stations (HRSs).

2. CASE STUDY
Accounting for Qatar's H_2 know-how and EV strategy, Qatar can target the deployment of HFCVs fueled by blue hydrogen obtained by steam methane reforming with carbon capture to complement the use of battery electric vehicles (BEVs). However, the potential H_2 demand must be estimated to determine the refueling station requirements. To do so, this study assumes that the HFCVs will represent 10% of the total vehicle stock and combines population density and registered vehicles to determine the projected demand for each of the country's eight municipalities (see Table 1).

Table 1. HFCV allocation based on population distribution

Municipality	Population Eligible to Drive	Distribution (%)	HFCV allocation based on population distribution
Al Daayen	58,337	2.17%	2,639
Al Khor	246,387	9.15%	11,146

Umm Salal	96,049	3.57%	4,345
Total	**2,694,076**	**100%**	**121,873**

Given that personal gasoline-fueled vehicles is Qatar's main mean of transport, existing gasoline fuel stations are used as a benchmark for potential HRS locations. With this approach, a total of 107 potential locations are obtained, while the demand points per municipality is placed based on the population's dencity as shown in Fig. 1.

Fig. 1. Potential HRS locations

3. MATHEMATICAL FORMULATION

The present study seeks to select the minimum number of locations to solve a maximum coverage location problem. Todo so, equations (1) to (5) are used; (1) represents the objective function, (2) and (3) are constraints that ensure that the demand is met and that it does not exceed the capacity, while (4) and (5) represent decision variables that enable refueling stations selection per region.

$$minimize \sum_{r \in R} \sum_{f \in F} d_{rf}\, x_{rf} \tag{1}$$

Subject to:

$$\sum_{f \in F} x_{rf} = Dem_r \; ; \; \forall r \in R \tag{2}$$

$$\sum_{r \in R} x_{rf} \leq capy_f \; ; \; \forall f \in F \tag{3}$$

$$x_{rf} \geq 0; \; \forall f \in F \tag{4}$$

$$y_f = (0,1); \; \forall f \in F \tag{5}$$

Where:
R = Region
F = Refueling station
d_{rf} = Distance between the refueling station and the demand point
Dem = Demand
Cap = Refueling station capacity in kg
x_{rf} = Decision variable based on demand availability per refueling station.

y_f = Binary decision variable set to 1 if refueling station is available and 0 otherwise.

Moreover, the refueling stations' capacities are set at 1200kgH_2/day, and d_{rf} is determined by applying the Haversine Formula.

4. RESULTS AND DISCUSSION

Table 2 shows how out of the 107 potential locations, 49 are chosen to install HRSs to meet the demand, meaning that roughly 46% of the possible locations are selected. Moreover, the results reflect how the regions with the highest density require the most HRSs.

Table 2. Maximum Coverage Location Problem Results

#	Municipality's Name	Required HRSs
1	Al Daayen	3
2	Al Khor	3
3	Al Rayyan	14
4	Al Shamal	1
5	Al Shahaniya	3
6	Al Wakra	6
7	Doha	17
8	Umm Salal	2

From a geographical perspective, Fig. 2 shows how most of the selected refueling stations are located in the east of the country, aligning with its current infrastructure development. However, since Al Rayyan's municipality extends from the country's south-west region to the east and its demand point, due to the population and infrastructure density is located closer to the east, not all of the country's surface is covered, and to ensure it, considerations must be done; like locating an additional station in the south-west region of the country. Similarly, for Dukhan (east Qatar), where no refueling station is selected, however, in this case, the distance between the city and the closest HRS does not require, initially, the deployment of a forced refueling station in that sector.

Fig. 2. Selected Hydrogen Refueling Stations

It is imperative to indicate that the development of the refueling station infrastructure must be linked with the HFCV adoption rate to align the necessary investment with the actual size of an evolving market. Especially considering that,

with the current approach, a total of eight refueling stations are underused; specifically, the results reflect a 7% overestimation.

5. CONCLUSIONS

The present study carries out a maximum coverage location model to determine the number of HRSs required to meet the potential HFCV demand, which is estimated to be the equivalent of Qatar's vehicle stock. Based on this approach, 49 HRSs of 1200 kgH_2/day must be deployed, most of which are located in the eastern part of the country, aligning with its population density and infrastructure development.

ABSTRACT
This study involves optimizing the parameters of a multi-layer perceptron (MLP) to predict fuel cell stock prices over the last five years. This aims for better stability and aligns with recent trends. The model is trained under different conditions, and the best model is chosen based on the lowest root mean squared error (RMSE). The forecasting is performed for varying time spans (5, 7, 30, 180, and 360 days) and separately for specific predictions on a given day (1:1:360, 5:5:360, and 30:30:360 days). The RMSE values are also scaled and represented in a format that is better understood. Secondly, since this is an under-resourced segment, the comparison has been drawn from lithium-ion battery and pack information over the last 15 years, highlighting where this study can be related to other analogous technologies. The results offer insightful conclusions regarding fuel cell price forecasts for the next days. When the minimum batch size is 64 and the maximum epoch size is 200, the best RMSE value is 0.004987. It is recommended that future work be conducted to extend the optimization process to include deeper models of learning for longer and more detailed forecasting. This research adds to achieving accurate stock forecasting models with innovative machine learning methods.

Keywords: Fuel cell stock data, Stability, MLP hyperparameter optimization

1. INTRODUCTION

Fuel cells are the most promising technological advances in the renewable energy sector, providing a clean and efficient method of producing electricity [1]. In contrast to conventional energy sources, fuel cells operate based on converting chemical energy directly into electrical energy, resulting in negligible emissions, and thus are a perfect option for lowering the carbon footprint in most industries [2]. Fuel cell technology has the potential to become a valuable key to a sustainable energy system in the future, particularly in applications such as transportation, power generation, and industry [3]. As we increasingly use variable renewable energy sources such as sun and wind, fuel cells offer a stable way of storing energy and backup power, thus enabling the efficient incorporation of variable renewable energy into the power grid. One of the key drivers of the extensive use of fuel cells is their cost factor [4]. Fuel cell technology is relatively expensive, mainly due to the exorbitant price of materials like platinum and the intricacy of production processes [5]. Nevertheless, these expenses are bound to decrease with technological improvement over the years. Effective forecasting of fuel cell cost can yield extremely valuable information on market forces, thereby assisting investors and producers in making informed decisions [6]. A drop in the price of fuel cells will probably stimulate more investments in the field, causing more research and development activities [7]. This development will likely continue improving fuel cell technologies' performance and efficiency. Therefore, analyzing fuel cell stock data makes price prediction possible and can be used as a pointer to more investments and technological development in the field. This study aims to tune MLP hyperparameters to predict fuel cell stock prices using the latest data to increase stability and performance and provide insights for future investments and fuel cell technology advancement.

2. MATERIALS AND METHODS

In the study, the prediction of fuel cell stock prices using the optimization of MLP hyperparameters from current data is considered, and the prediction is made for different time horizons to obtain better prediction stability and accuracy.

2.1. Data Used in the Study

The data used in this research is historical fuel cell stock price data for 30 years [8], emphasizing the last 5 years for more recent and similar results. The data consists of daily stock prices processed to find patterns and trends. This research also uses MLP models to optimize hyperparameters and forecast stock prices. A comparison with lithium-ion battery statistics for the last 15 years is also provided to contextualize fuel cell technology in energy storage developments.

2.2. MLP

MLP is one of the feed-forwards artificial neural network types and is considered one of the most widely used deep learning models. MLP is a fully connected neural network model with at least one hidden layer and has a wide range of uses due to its ability to learn nonlinear complex functions.

2.3. MLP Structure

The MLP model usually consists of three essential components:
1. Input Layer: Represents the data received by the model. The number of neurons in the input layer equals the number of features used.

2. Hidden Layers: These are the layers that determine the essential learning capacity of the MLP. The neurons in each hidden layer learn complex relationships from the input data. Activation functions (ReLU, Sigmoid, Tanh, etc.) enable the model to make non-linear transformations.
3. Output Layer: This is the section where the model makes predictions or classifications. The number of neurons in the output layer is determined depending on the type of problem (for example, there may be a single neuron for regression and multiple neurons for multi-class classification).

2.4. MLP Mathematical Model

The essential mathematical components of MLP are:

• Weights and Bias Values: MLP learns by multiplying the inputs of neurons in each layer with weights and bias values added.

• Activation Function: The output of each neuron is passed through a specific activation function, applying a nonlinear transformation as in Eq. (1):

$$h = f(Wx + b)h = f(Wx + b)h = f(Wx + b) \quad (1)$$

where *W* represents the weight matrix, *x* represents the input vector, *b* represents the bias value, and *f*(.) represents the activation function (ReLU, Sigmoid, etc.).

• Forward Propagation: Forward propagation is performed by multiplying the input data with weights and passing them through activation functions.

• Backpropagation and Weight Update: The error function is calculated, and the weights are updated with the Gradient Descent method.

2.5. Error Function and Performance Measurement Metrics

RMSE is calculated by taking the square root of the mean of the squared differences between the model predicted values $(\hat{y}_i)$ and the actual values (y_i) as given in Eq. (2):

$$RMSE = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{y}_i)^2} \quad (2)$$

Where, y_i represents the real values, $\hat{y}_i$ represents the values predicted by the model. The closer the RMSE value is to zero, the higher the model's prediction accuracy.

Loss function determines how the weights will be updated during the training process of the model. Since this study is a regression problem, the mean squared error (MSE) loss function is defined in Eq. (3):

$$Loss = \frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{y}_i)^2 \quad (3)$$

MSE penalizes significant errors more by squaring the errors, therefore allowing the model to learn better.

3. RESULTS AND DISCUSSION

Future predictions are obtained using the MLP model, and the Adam optimizer is used. The best results in the scanned space were obtained for the following hyperparameters; MLP-based models obtained different prediction results for [5 7 30 180 360] days and [1 7 30] days intervals. The analysis shows the minimum batch size is 64, and the maximum epoch size is 200. In the study, space scanning was performed for different hyperparameters of MLP, as given in Table 1, and the best model was created by determining the best hyperparameters depending on the RMS values, as seen in Table 1. For the selected model, the best RMSE = 0.004987 was obtained. The visual of this training process is given in Fig. 1. As can be understood from Fig. 1, RMSE and loss functions converge to 0, which shows that the model is robust.

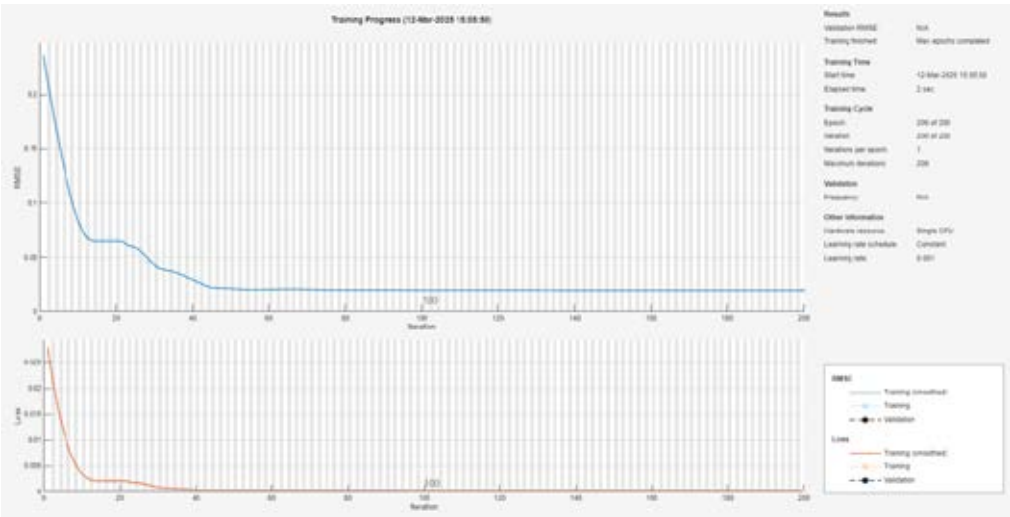

Fig. 1. Training Progress for MLP

It was then used to estimate different time intervals. This model based on MLP yielded different estimation results for [5

7 30 180 360] days later and [1 7 30] days later. The numerical results obtained for these other areas are given in Table 2 below. In addition, visual results are shown in Fig. 3.

Table 1. Hyperparameters search space, and best hyperparameters

Hyperparameters	Space	Best Hyperparameters
Optimizers	{'adam', 'sgdm', 'rmsprop'}	'adam'
MiniBatchSizes	[8, 16, 32, 64, 128]	64
MaxEpochsList	[50, 100, 150, 200]	200

Table 2. Future forecasts

Time Points	Forecast Values
5 days later	0.0134 ± 0.0001
7 days later	0.0214 ± 0.0001
30 days later	0.0143 ± 0.0001
180 days later	0.0201 ± 0.0002
365 days later	0.0194 ± 0.0013

The results obtained for the forecasts made with different day intervals, such as [1:1:360], [5:5:360], and [30:30:360], are given in Figs. 3a, b, and c, respectively.

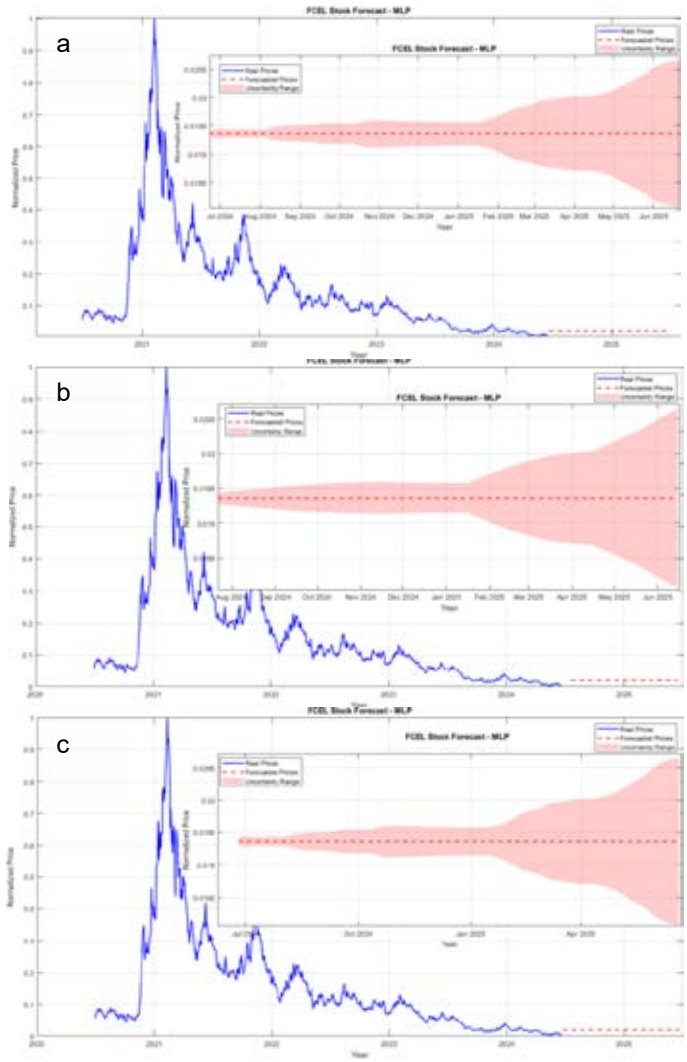

Fig. 2. Results obtained for different time intervals a) 1:1:360 b) 30:30:360 c) 5:5:360

Fig. 3 shows lithium-ion battery pack prices hit a record low of $139/kWh [9]. It is emphasized that lithium-ion batteries,

which have widespread and efficient use in terms of environment, economy, and energy, are available at very low prices.

Fig. 3. Volume-weighted average lithium-ion battery pack and cell price split, 2013-2023 [9]

The visuals obtained from the stock market dataset in Figs. 2a, b, and c, along with the estimates made for different time intervals, show that this fact given in Fig. 3 for lithium-ion can also be compatible with fuel cells.

4. CONCLUSIONS

Both fuel cell technology and lithium-ion batteries exhibit a clear downward price trend over time. The lithium-ion battery market has been experiencing a steady price decline, primarily driven by economies of scale, advances in material technology, and increasing demand for electric vehicles and energy storage devices. Fuel cell prices have been less predictable, with a peak followed by a gradual decline. This uncertainty stems from the yet-to-be-established hydrogen infrastructure and relatively smaller production scale. While lithium-ion batteries have already achieved the mass market, fuel cell technology will continue to decrease in price as mass production scales up and hydrogen infrastructure is established. Both technologies will likely be significant parts of hybrid energy systems in the future, playing different roles in various applications. In future studies, a detailed optimization study will be conducted for the fuel cell stock market data with the best deep learning model by scanning a broader space to obtain the best model for LSTM, Deeper LSTM, 1D CNN, and transformer models. In addition to this data set and related estimations, a study that includes energy and environmental effects will be conducted.

ABSTRACT
This study analyzes the wind and solar energy potential in the İzmir region and designs a hybrid energy system supported by hydrogen production and utilization. One-year hourly wind speed, solar radiation, and temperature data estimate renewable energy generation. The annual average wind speed in the region is 5.7 m/s, and the average solar radiation is 210 W/m². Using 600 kW solar panels with 18% efficiency and a 600-kW wind turbine with a 30% capacity factor, the total annual renewable energy generation is approximately 3.2 GWh. While wind energy production exceeds demand in winter, solar energy production increases significantly in summer. Excess energy is utilized for hydrogen production via electrolysis, while hydrogen fuel cells compensate for energy deficits. The system produces approximately 42,000 kg of hydrogen annually, requiring 2.1 GWh of electricity for electrolysis with 65% efficiency. When converted back into electricity via fuel cells with 50% efficiency, hydrogen contributes around 1.05 GWh to the system. Hydrogen storage requirements for both liquid and gaseous storage methods are also analyzed. The results indicate that integrating renewable energy with hydrogen storage ensures energy continuity. Future studies will focus on cost analysis, hydrogen production optimization, and storage strategy efficiency.

Keywords: Hybrid energy system, wind energy, solar energy, hydrogen production, electrolysis, fuel-cell

1. INTRODUCTION
The increasing global energy demand and environmental concerns have accelerated the shift towards renewable energy sources. Wind and solar power have gained significant attention due to their sustainability and minimal environmental impact. However, the intermittent nature of these energy sources poses a challenge to maintaining a stable and continuous power supply. The variability in wind speed and solar radiation throughout different seasons affects energy generation, leading to periods of excess production and energy deficits. To overcome this challenge, energy storage technologies are crucial in ensuring grid stability and reliable energy supply [1-2].
Hydrogen storage has emerged as a promising solution for integrating renewable energy sources into the energy system. By utilizing excess wind and solar power for hydrogen production through electrolysis, surplus energy can be stored and later converted back into electricity using hydrogen fuel cells during peak demand periods. This approach enhances energy security and contributes to developing a sustainable hydrogen economy. Compared to conventional battery storage, hydrogen offers a high energy density and long-term storage capabilities, making it an ideal choice for large-scale energy management [1-2].
This study examines the feasibility and efficiency of a hybrid wind-solar-hydrogen energy system in the İzmir region. The region is well known for its high wind potential and solar radiation, making it a suitable location for renewable energy integration. The research focuses on energy generation patterns, hydrogen storage requirements, and the role of hydrogen fuel cells in balancing seasonal variations. The findings provide insights into the potential of hydrogen-based energy storage in hybrid systems and contribute to the ongoing efforts to develop sustainable and resilient energy solutions.

2. MATERIALS AND METHODS
The İzmir region, favorable for wind and solar energy, has been selected as the application region. One year of hourly wind speed, solar radiation, and temperature data for İzmir province have been used [3].

2.1. The Analysis of Solar Generation of the Paper
Solar radiation and temperature data for the region are required to calculate solar energy. Using this information, the amount of power generated from a PV panel is given in Eq (1) [4].

$$P_{pv} = N_{pv} * P_r * \eta_{pv} * \left(\frac{G}{G_{ref}}\right) * \left[1 + \beta(T - T_{ref})\right] \quad (1)$$

$P_{pv} = N_{pv} * P_r *$Solar power (P_{pv}) depends on the number of panels (N_{pv}), rated power (P_r), efficiency (η_{pv}), radiation (G), and reference radiation (Gref, 1000 W/m²). The reference temperature (T_{ref}) is 25°C, with a temperature coefficient (β) of -3.7×10⁻³/°C for monocrystalline and polycrystalline silicon. Panel temperature (T) is calculated using Eq. (2). Here, T_a and T_{NOC} are the ambient and normal operating cell temperatures, respectively [4].

$$T = T_a + \left(\frac{T_{Noc} - 20}{1000}\right) * G \quad (2)$$

2.2. The Analysis of Wind Energy Potential

Equation 3 calculates the power obtained from the wind turbine [4].

$$P_{wt} = N_{WT} * \begin{cases} v(t) \prec v_{cutin} or v(t) \geq v_{cutoff} \Rightarrow 0 \\ v_{cutin} \leq v(t) \prec v_{cutoff} \Rightarrow v(t)^3 \left(\frac{P_r}{v_r^3 - v_{in}^3}\right) - P_r \left(\frac{v_{in}^3}{v_r^3 - v_{in}^3}\right) \\ v_r \leq v(t) \prec v_{cutout} \Rightarrow Pr \end{cases} \quad (3)$$

2.3. The Analysis of Hydrogen Energy

Hydrogen production is achieved by separating water into hydrogen and oxygen through electrolysis, as in Eq.(4). The electrical energy required for this process is calculated with Eq. (5) [5].

$$2H_2O \rightarrow 2H_2(g) + O_2(g) \quad (4)$$

$$H_p = \frac{P_E * t * \eta_e}{E_H} \quad (5)$$

The energy required for hydrogen production is calculated with Eq. (6), and electricity production in the hydrogen fuel cell is calculated with Eq. (7). To produce 1 kg of hydrogen, approximately 50 kWh of electricity is required. This efficiency is usually between 60-80%. When 1 kg of hydrogen is burned, it can produce approximately 33 kWh of electricity. The efficiency of this conversion is usually between 45-55% [5].

$$E_{H_2} = \frac{m_{H_2} * 50}{\eta_{electrolysis}} \quad (6)$$

$$E_{H_2,fuelcell} = m_{H_2} * 33 * \eta_{fuelcell} \quad (7)$$

3. RESULTS AND DISCUSSION

Monthly averages of wind speed, solar radiation, and temperature data obtained from NASA for Izmir province are given in Table 1.

Table 1. Monthly wind speed, solar radiation, and temperature data

Months	Wind Speed (m/sec)	Solar Radiation (Wh/m2)	Temperature (C°)
January	5.80	96.20	10.26
February	6.81	140.96	7.77
March	6.10	171.39	12.03
April	5.41	209.59	14.54
May	4.94	235.68	18.40
June	5.11	294.96	23.59
July	6.48	337.74	28.56
August	5.21	290.75	28.64
September	6.15	233.99	25.24
October	4.93	168.79	20.31
November	6.41	93.95	16.70
December	5.28	80.08	13.05

According to various studies, a house's average daily energy consumption is 20 kWh. Especially in the morning between 07.00-09.00 and in the evening between 18.00-22.00, higher consumption occurs. Accordingly, the daily load information of an average house is given in Fig. 1.

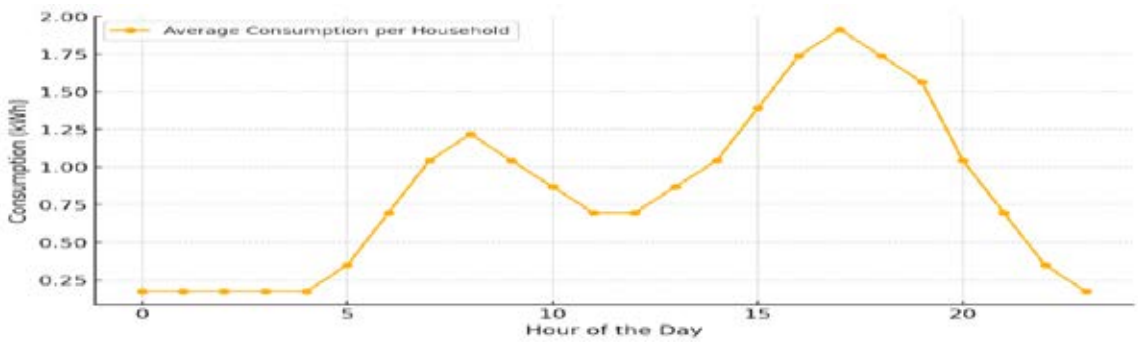

Fig.1. Hourly load profile

The energy consumption data for a site with 1,000 residences, covering 12 months, is presented in Fig. 2. While calculating the monthly consumption, the relevant values are determined based on the assumption that the region requires more energy during the summer months due to air conditioning.

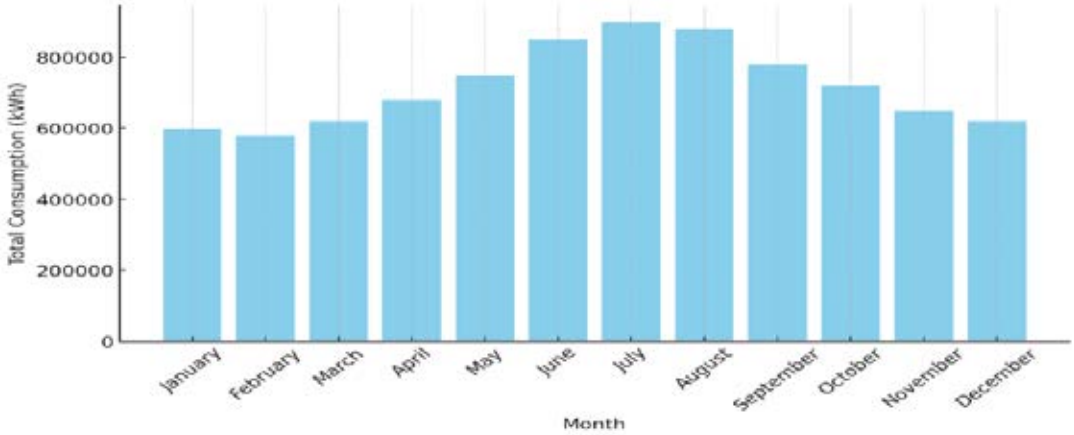

Fig. 2. Monthly electric load profile

The monthly solar energy obtainable using the region's data is presented in Fig. 3a. In contrast, wind energy is shown in Fig. 3b. The wind turbine and solar panel installed capacity is 600 kW. The efficiency of the solar panel is 18%, and the capacity factor of the wind turbine is taken as 30%.

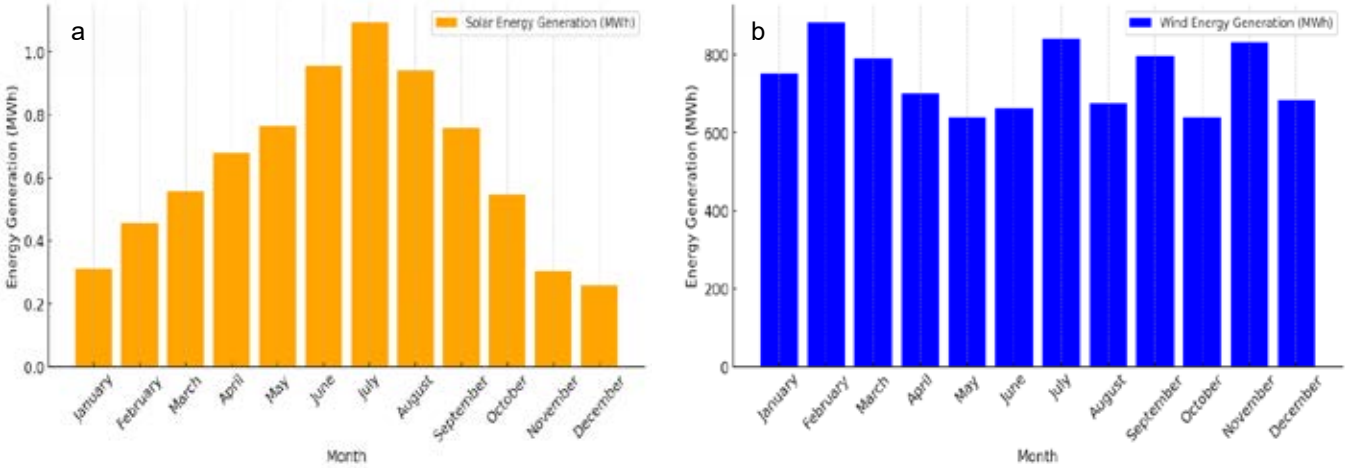

Fig.3. Monthly a) solar, b) wind energy generation

The aim is to supply the electrical load using the hybrid system. If wind and solar energy production exceeds the load, the surplus energy will be used for hydrogen production. Conversely, if the generated energy is insufficient, the deficit will be compensated by hydrogen fuel energy. In this context, the cases where excess and deficient energy occur, based on the monthly loads, are illustrated in Fig. 4. Fig 4. illustrates the balance between a 600-kW solar and 600 kW wind energy capacity and the total energy demand, highlighting seasonal variations in renewable energy production and the resulting surplus and deficit energy levels throughout the year.

Fig. 4. Monthly excess and deficit energy balance

During the winter months (January–March), there is a surplus of energy production, primarily due to higher wind speeds, which enhance wind turbine output. In spring and early summer (April–June), energy deficits emerge, particularly in May, when increased energy consumption coincides with a decline in renewable generation. This shortfall necessitates using hydrogen fuel cells to compensate for the energy deficit. In autumn (September–November), energy production and consumption become more balanced, although excess energy levels rise again in certain months. Based on these variations, Fig. 5a presents the monthly hydrogen production derived from excess energy and the hydrogen demand that must be met using fuel cells during energy shortages. Additionally, in response to these values, the required number of hydrogen storage tanks, both in liquid and gas form, has been calculated, and these values are displayed in Fig. 5b.

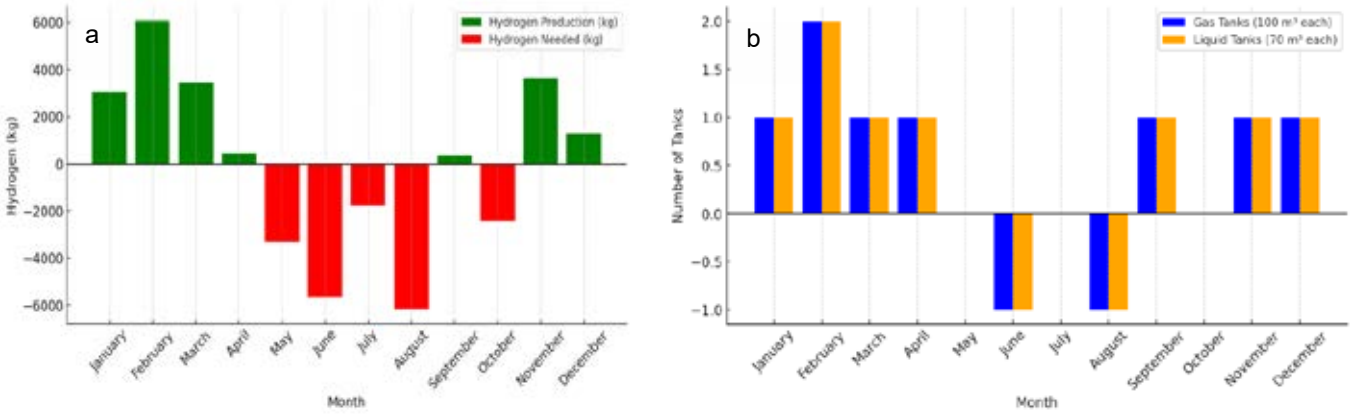

Fig. 5. Monthly a) hydrogen production and utilization, b) required hydrogen tanks

4. CONCLUSIONS

This study evaluates the efficiency of a hybrid energy system for the İzmir region and the effectiveness of hydrogen storage in ensuring energy continuity. The results show that wind energy production is high during the winter months, leading to excess energy generation, while in the summer months, increased energy demand requires hydrogen fuel cells. Hydrogen storage emerges as a critical solution for addressing seasonal imbalances. The data indicate that maintaining a balance between hydrogen production and consumption enables sustainable energy management. Future studies focus on the effectiveness of different storage methods and the development of the hydrogen economy.

ABSTRACT
Molecular hydrogen (H_2) is a renewable energy carrier, however, its practical applications are limited due to the challenges of developing safe and efficient H_2 storage devices. Hydrogen sulfide (H_2S), on the other hand, is a highly toxic chemical commonly found in petroleum, natural gas, and biomass synthesis gas. Even at low concentrations, it causes severe corrosion in pipelines and equipment. H_2S is also present in synthesis gases used for H_2 production and it deactivates catalysts as well as electrode catalysts in fuel cells. For these reasons, we theoretically investigated H_2 and H_2S adsorption capacities of the Zeolitic Imidazolate Framework, namely ZIF-71, applying Grand Canonical Monte Carlo (GCMC). We also examine the response of ZIF-71 to various electric field strengths to evaluate its behavior under electric field stimuli using ab initio Molecular Dynamics simulations.

Keywords: Physisorption, H_2 adsorption, H_2S adsorption, Grand Canonical Monte Carlo, ab initio Molecular Dynamics

1. INTRODUCTION

Metal-organic frameworks (MOFs), which consist of metal atoms and organic ligands linking these metal atoms, were introduced into the literature by Yaghi et al. [1]. MOFs are highly porous coordination compounds containing transition metal ions such as Co, Cu, and Zn. Zeolitic imidazolate frameworks (ZIFs) are a sub-class of MOFs named for their structural similarity to zeolites. By functionalizing imidazole (IM) linkers, ZIFs with a wide range of structural properties can be synthesized. ZIF-71 material, shown in Fig. 1, was synthesized by linking Zn metals using 4,5-dichloroimidazolate ligands and was introduced into the literature by Banerjee et al. [2].ZIF-71 ($Zn(dcIM)_2$) has surface area of 1004.7 m²/g and void fraction of 0.5. The smallest pore size is measured at 5.41 Å, while the largest pore size is 17 Å. The performance of ZIF-71 has been investigated in various applications, including CO_2 storage [3], biofuel purification [4], xylene diffusion [5], and ethanol and water adsorption [6]. ZIF-71 can potentially be used as gas storage system.

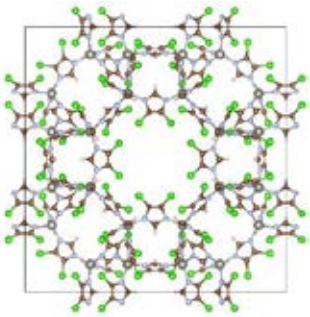

Fig. 1. ZIF-71: Zn metals are connected to each other through 4,5-dichloroimidazolate ligands.
H: white, N: blue, Cl: green, C: brown.

In the literature, modified ZIF-71 nanorods have been used for the adsorption of certain gases, and in one study, modified ZIF-71 exhibited high selectivity for H_2 [7]. Department of Energy (DOE) aims for hydrogen storage systems to achieve a volumetric capacity of 40 g H_2/L under conditions of 233 to 333 K and 5 to 12 bar pressure [8].Considering these findings and the high adsorption capacity of ZIF-71, research has been conducted on its H_2 adsorption properties.Hydrogen sulfide (H_2S) is highly toxic chemical commonly reside in petroleum, natural gas, and biomass synthesis gas [9]. Since H_2S is also present in synthesis gases used for hydrogen production, it deactivates catalysts and electrode catalysts in fuel cells [10]. For these reasons, the separation of H_2S is important for safe production and environmental protection. Zhou et al. [11] modeled MOFs with different ligands and topologies for H_2S adsorption and demonstrated that ZIF-71, ZIF-69, and ZIF-97 exhibited the best performance, adsorbing H_2S from an air mixture at room temperature and atmospheric pressure at a rate of 0.01 mmol/g. Apart from gas storage potentials, recent theoretical and experimental studies have shown that controlled and reversible structural changes occur in MOFs under externally applied electric field stimuli. Ligand rotation within the MOF structure, as well as pore opening/closing mechanisms in the presence of an electric field, have been investigated. ZIF-71, containing dichloroimidazolate ligands, is predicted that the H atoms in H_2S and H_2 could potentially adsorb onto the Cl groups. Additionally, Cl

halogens attached to the imidazolate ligands in ZIF-71 may trigger ligand rotation under an electric field.

This study aims to theoretically examine the controlled and reversible structural transformations, such as ligand rotation, that may take place in the ZIF-71 framework when subjected to external stimuli like electric fields and chemical agents. To achieve this, *ab-initio* Molecular Dynamics (AIMD), Density Functional Theory (DFT), and Grand Canonical Monte Carlo (GCMC) will be utilized. The primary goal is to determine whether the structural properties of materials can be manipulated under these external influences and to assess whether this control remains effective in the presence of industrially relevant gases, providing a foundation for smart material design research.

2. MATERIALS AND METHODS

The adsorption of H_2S and H_2 in ZIF-71 has been modeled using GCMC simulations at temperatures of 193 K, 233 K, 273 K, and 298 K for H_2S, 193 K, 233 K, and 298 K for H_2, with pressures ranging from 0.1 bar to 50 bar for H_2S and 0.1 bar to 100 bar for H_2. Adsorption isotherms of the materials have been obtained. The GCMC method is widely used in the literature to predict the gas adsorption capacities of nanoporous materials. GCMC simulations conducted using the open-source RASPA simulation package [8]. During these simulations, the MOF structures were kept fixed, and their initial configurations have been obtained from geometry optimizations using DFT. Gas-gas and gas-MOF dispersion interactions modeled using Lennard-Jones (LJ) interactions. The adsorption of H_2S and H_2 molecules into MOF pores calculated by considering both dispersion and electrostatic interactions.The force field parameters for H_2 utilized from previous studies [12]. For sulfur representation, a single Lennard-Jones (LJ) site was used, while partial charges placed at the centers of hydrogen and sulfur atoms were employed to account for electrostatic interactions. We applied the H_2S potential which was successfully used by Hamon et al. [13] to predict the H_2S adsorption capacities of MIL-53 and MIL-47. DFT simulations conducted to calculate the electronic density, and the atomic charges of the ZIF-71 were determined using the DDEC6 method [14]. An external electric field was applied in the x-direction to the cubic-symmetric ZIF-71 at strengths of 1 and 2 V/nm for a simulation duration of 40 ps using AIMD.

3. RESULTS

H_2 adsorption capacity of ZIF-71 was evaluated under various temperature and pressure conditions. Fig.3 presents the adsorption capacities at 298 K, 233 K, and 193 K as a function of pressure(bar) The results demonstrate a significant increase in adsorption capacity with decreasing temperature and increasing pressure. At 298 K, the adsorption capacity ranged from 0.0214 g/L at 0.1 bar to 11.63 g/L at 100 bar. A similar trend was observed at 233 K, where the adsorption capacity increased from 0.0714 g/L at 0.1 bar to 20.4057 g/L at 100 bar. The highest adsorption capacity was recorded at 193 K, where the values covered a range from 0.24 g/L at 0.1 bar to 29.33 g/L at 100 bar. Compared to DOE, which specifies a volumetric capacity of 40 gH_2/L under conditions of 233–333K and 5–12 bar, ZIF-71 exhibits promising adsorption behavior. Particularly at 233 K and elevated pressures, the material approaches the DOE target range, suggesting its potential applicability for hydrogen storage under optimized conditions.[8]

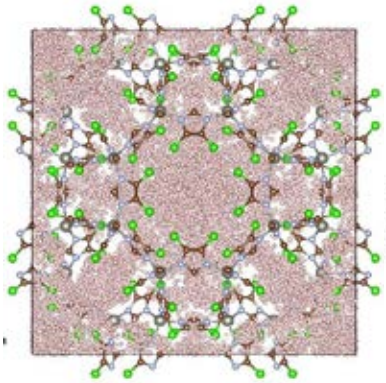

Fig. 2. ZIF-71 with adsorbed H_2 molecules, H: white, N: blue, Cl: green, C: brown.

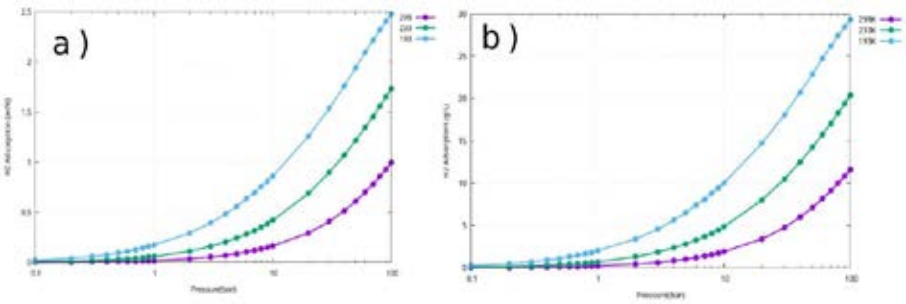

Fig. 3. H_2 adsorption values of ZIF-71 a) in g/L, b) in wt% unit.

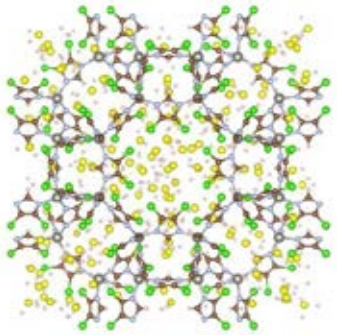

Fig. 4 . ZIF-71 with adsorbed H_2S molecules, H: white, N: blue, Cl: green, C: brown, S: yellow

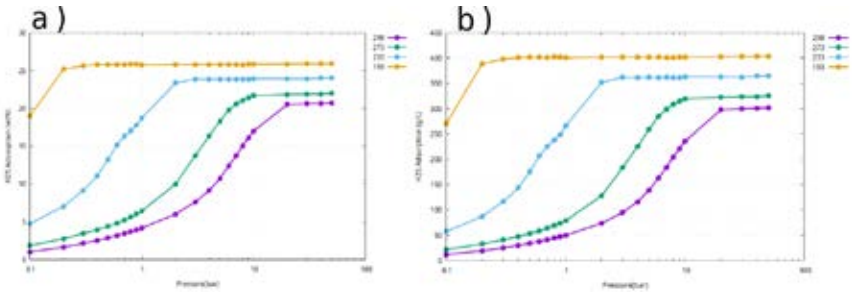

Fig. 5 . H_2S adsorption values of ZIF-71 a) in wt%, b) in g/L unit.

H_2S adsorption capacity of ZIF-71 was analyzed at different temperatures (298 K, 273 K, 233 K, and 193 K) as a function of pressure (bar). The results, summarized in Fig.5, indicate a strong dependence on both temperature and pressure.At 298 K, the adsorption capacity values covered a range of from 0.98 mg/g at 0.1 bar to 20.71 mg/g at 50 bar. As the temperature decreased to 273 K, adsorption capacity increased, reaching 21.98 mg/g at the highest recorded pressure. A more pronounced increase was observed at 233 K, where the adsorption values covered a range of from 4.75 mg/g at 0.1bar to 23.99 mg/g at 50 bar. The highest adsorption capacity was recorded at 193 K, where the values ranged from 18.97 mg/g at 0.1 bar to 25.88 mg/g at 50 bar. When compared to previous studies, such as the work of Zhou et al. [11], which demonstrated H_2S adsorption in ZIFs at 0.01 mmol/g(0.34 mg/g) under ambient conditions, the adsorption capacity of ZIF-71 under the examined conditions appears significantly higher. Furthermore, the results suggest that ZIF-71 could be a promising candidate for gas adsorption applications, particularly at lower temperatures and elevated pressures. These findings highlight the strong dependence of adsorption capacity on both temperature and pressure. The adsorption capacity significantly improves as the temperature decreases, which can be attributed to the enhanced van der Waals interactions at lower thermal energy levels. Additionally, increasing the pressure promotes higher adsorption, as more gas molecules interact with the porous structure of ZIF-71.

In Fig.6 simulations revealed that under a 1V/nm electric field, the ligand dihedral angles exhibited a slight increase, suggesting that moderate electric fields induce minor adjustments in ligand orientation. However, when the electric field strength was increased to 2V/nm, a moderate shift in ligand dihedral angles was observed. These findings indicate that the structural response of the MOF can be modulated by varying the electric field strength, which should be further investigated.

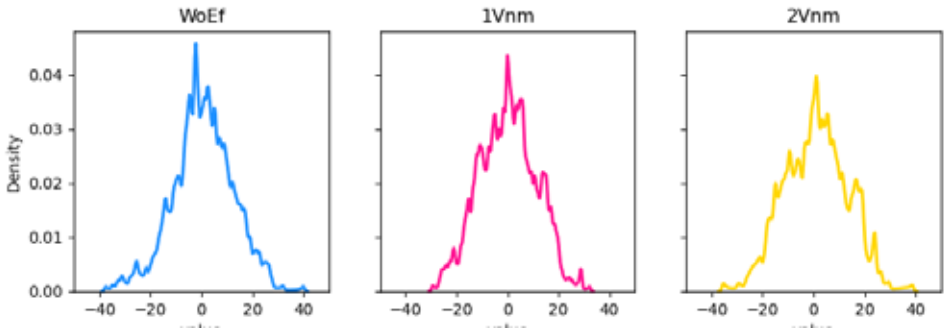

Fig. 6. The distribution of dihedral angles in the ZIF-71 exposed to an electric field strengths of 1 and 2 V/nm in the x-direction.

4. CONCLUSIONS

In this study, the adsorption performance of ZIF-71 was evaluated for both hydrogen (H_2) and hydrogen sulfide (H_2S) under various temperature and pressure conditions. The results demonstrated that adsorption capacity significantly increased with decreasing temperature and increasing pressure.For H_2 adsorption, ZIF-71 exhibited a maximum volumetric adsorption capacity showing its potential for hydrogen storage applications. ZIF-71 approaches the required performance under optimized conditions but may require further structural modifications to fully meet required specifications. Regarding H_2S adsorption, ZIF-71 showed a significantly higher capacity under ambient conditions. The highest recorded adsorptions indicate that ZIF-71 is a highly effective sorbent for hydrogen sulfide capture, especially under low-temperature conditions. Results confirm that ZIF-71 is promising material for gas storage and separation applications, particularly for H_2S removal and potential hydrogen storage. However, further studies are needed to optimize its structural properties, enhance adsorption capacity at ambient conditions, and evaluate its long-term

stability in practical applications. Electric field simulations conducted on ZIF-71 demonstrated that ligand rotations have a potential to obtain controlled behavior under external stimuli. This suggests that external fields may serve as a tunable mechanism for influencing the structural properties of the MOFs.

ACKNOWLEDGEMENT

ABSTRACT

Photoelectrochemical (PEC) water splitting is a highly promising approach for sustainable hydrogen production, utilizing on semiconductor materials as photoanodes. Among semiconductors, tungsten oxide (WO_3) stands out for its chemical stability in acidic environments, resistance to photocorrosion, and effective charge transport properties. Despite these advantages, the wide bandgap of WO_3 limits its ability to absorb visible light, reducing its overall efficiency. This study presents kinetic modeling of transient photocurrent (TPC) behaviors in WO_3 photoanodes, aiming to understand the dynamics of electron-hole generation, separation, recombination, and charge transfer processes. TPC experiments at various applied potentials revealed significant variations in charge carrier behavior. The developed kinetic model accurately matches these experimental observations. These insights provide valuable insights for optimizing PEC systems and can be extended for further research and improve other semiconductor systems for efficient hydrogen production.

Keywords: Photoelectrochemical water splitting, Tungsten oxide (WO_3), Semiconductor, Transient photocurrent, Kinetic modeling

1. INTRODUCTION

Photoelectrochemical (PEC) water splitting is a sustainable and promising technology for producing hydrogen through light-driven water splitting. PEC water splitting produces hydrogen and oxygen without any undesired pollutants. It relies on semiconductor materials as photoelectrodes that absorb sunlight, generating electron-hole pairs, which then drive chemical reactions to split water molecules into oxygen and hydrogen. Semiconductors suitable for this process must demonstrate high chemical stability, suitable electronic properties for efficient charge transport, and robust resistance against corrosion under operational conditions. Typically, PEC systems use an n-type semiconductor as a photoanode, which captures photons to generate those crucial electron-hole pairs. Electrons move towards the external circuit, while holes move to the photoanode surface, helping to drive the oxygen evolution reaction (OER). However, the recombination of these generated charges can significantly limit efficiency.

Among various semiconductor types, tungsten oxide (WO_3) is significant due to its high stability under acidic conditions, resistance to photocorrosion, good charge carrier mobility, and cost-effectiveness. However, WO_3 possesses a relatively wide bandgap, which limits absorption light range thus its efficiency under the visible light illumination. the photo response under visible light can be enhanced by optimizing annealing conditions or doping by means of extending the light absorption range and the formation of oxygen vacancies which are acting as active sites for redox reactions. WO_3 with elements like carbon, sulfur, and nitrogen can significantly boost its performance under visible light. Among these, nitrogen (N) doping using NH_3 is the most promising, as it effectively reduces the band gap.

Kinetic modeling is a way to describe the dynamic behavior of chemical systems. It focuses on the rates of the reactions, providing insights into how various factors such as temperature, concentration, pressure affects the mechanism of a reaction to understand and enhance semiconductor performance.

The goal of this research is to optimize the conditions for high-performance PEC cells for hydrogen production by utilizing a kinetic model of WO_3 photoanodes that provide insights into charge carrier dynamics and photo response behavior.

2. REACTION KINETICS IN PEC WATER SPLITTING

When WO_3 is exposed to light, it absorbs photons that have energies greater than its band gap energy. This absorption occurs within the bulk of the semiconductor. Photon absorption creates electron-hole pairs. The electric field within the

space charge region at the semiconductor-electrolyte interface helps to separate these electron-hole pairs efficiently. Holes move toward the photoanode surface, while electrons move towards the cathode via an external circuit. The photogenerated holes that migrate to the surface of WO_3 interact with water molecules, driving the Oxygen Evolution Reaction (OER). At the same time, electrons moved to the cathode reduce protons (H^+) in the electrolyte, forming hydrogen gas.

The concentration of holes at the photoanode surface is influenced by how quickly they are generated and how fast they are removed through recombination and oxidation reactions. The surface hole concentration reaches steady state when generation and removal rates balance. The hole current density represents the generation of holes within the semiconductor due to photon absorption. This current density is always considered positive because it indicates the generation and initial movement of holes toward the semiconductor surface, initiating the water oxidation reaction. The charge transfer current density relates to how effectively the photogenerated holes are used at the semiconductor/electrolyte interface for the OER Specifically, this current describes how holes at the WO_3 surface oxidize water molecules. As holes are consumed for oxidizing water, this process contributes positively to the measurable photocurrent, indicating a productive use of created charges. The recombination current density describes losses that occur due to the recombination of electrons and holes within the semiconductor material or at its surface. Electron-hole recombination hinders the effective use of charge carriers for water splitting, thus reducing overall system efficiency. High recombination rates suggest lower overall PEC performance, as fewer holes remain available for water oxidation. The total photocurrent density at any moment is the sum of holes generated and losses due to electrons recombining with holes before they can participate in chemical reactions. The kinetics of PEC water splitting reactions are governed by the rates of electron-hole pair generation, separation, transfer, and recombination which will simulate the transient photocurrent response under different experimental conditions.

3. KINETIC MODELLING OF WO_3 PHOTOANODES

TPC measurements on WO_3 photoanodes annealed at different temperatures such as 500°C, 600°C, and N-doped WO_3 at 425°C were conducted. These measurements revealed differences in photocurrent behavior associated with crystallinity changes depending on annealing and doping conditions. It is possible to show these measurements in the kinetic model by changing certain parameters.

(a) (b)

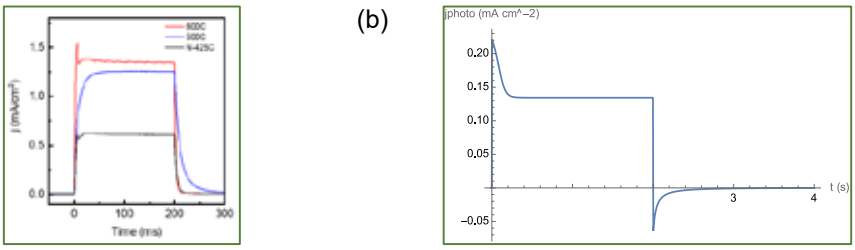

Fig. 1 (a) TPC of WO_3 photoanodes annealed at different temperatures , (b) Kinetic model of photocurrent transient behavior.

For WO_3 photoanode, potential dependence of total photocurrent response has been modeled. The results and the kinetic model are matching in showing significant variations in photocurrent dynamics at different potentials. The model of WO_3 photoanode needs to be developed to explain all the behaviors such as the instantaneous decay right after the hole accumulation. The kinetic model for N-doped WO3 photoanode will be further modeled. It will be helpful to make comparisons with N-doped WO_3 (N-WO_3) photoanodes since they revealed significantly different transient behaviors due to newly introduced surface states and enhanced oxygen vacancy concentrations.

(a) (b)

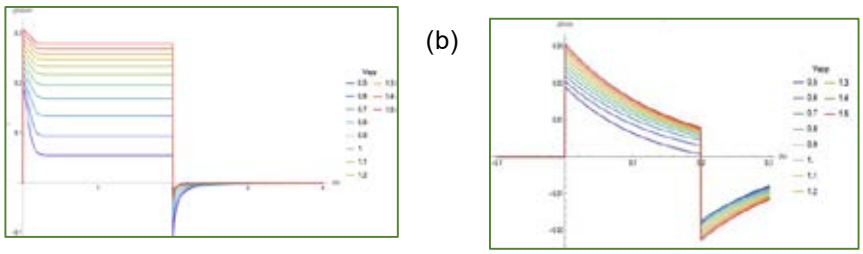

Fig. 2 (a) Kinetic model of total photocurrent transients at different applied potentials, (b) Kinetic model of total photocurrent transients at different applied potentials including charge carrier trapping.

It is possible to observe not only the total photocurrent response but also multiple behaviors such as the time-dependent surface hole concentrations of photoanodes and the variations in charge transfer and recombination rate constants with different applied potential.

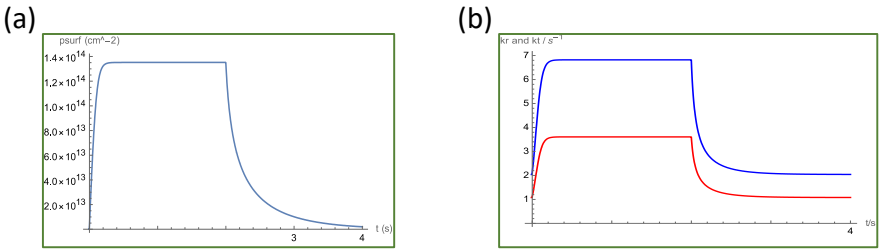

Fig. 3 (a) Kinetic model of surface hole concentration, (b) Kinetic model of charge transfer and recombination rate constants at different applied potentials

4. DISCUSSION

The annealing temperature significantly affects PEC performance by changing WO_3 crystallinity. Usually, solution-based methods yield hydrated WO_3 requiring annealing to get rid of water and enhance crystallinity. Annealing around 400°C forms stable monoclinic WO_3 with improved crystallinity, while further increasing the temperature to 600°C reduces PEC activity.

For the total photocurrent transient behavior, upon illumination, a rapid initial spike results from electron-hole separation within the space-charge region. Holes move toward the electrolyte interface, charging the space-charge capacitance, while electrons travel. Subsequent photocurrent decay arises from accumulated holes at the interface, causing increased recombination. A steady state is eventually reached when hole arrival equals their consumption by recombination and charge transfer. Turning off illumination interrupts hole flow, causing a negative current overshoot due to recombination with residual surface holes.

WO_3 photoanode results showed significant differences in photocurrent dynamics at different potentials. The total photocurrent increases with the applied potential due to enhanced charge separation facilitated by increased band bending and expansion of the space charge layer.

For N-doped WO_3, transient photocurrent behavior has been experimentally observed but is not yet fully modeled. Additional work is needed to account for N-induced surface states and oxygen vacancies, which influence charge transport and recombination dynamics.

5.CONCLUSION

The developed kinetic model successfully described the transient photocurrent behaviors observed in WO_3 photoanodes, enhancing understanding of the fundamental kinetics behind PEC water splitting. Further studies should extend this approach to other semiconductor systems. These studies will contribute significantly toward developing efficient PEC technologies for sustainable hydrogen production.

ABSTRACT
Integrating renewable energy sources into hybrid microgrid (MG) systems presents a sustainable solution for meeting modern energy demands. This study investigates the performance of a hybrid energy system designed to supply uninterrupted and environmentally friendly electricity to a sample town. The system operates in island mode and incorporates four primary renewable energy sources: a 50-kW hydrogen fuel cell stack, a 100-kW photovoltaic (PV) system, a 6-kW wind turbine, and a 6-kW wave energy system. A fuzzy logic (FL)-based load management (LM) algorithm is proposed to optimize energy distribution and prevent wastage by dynamically adjusting to the system's production capacity. The PV system generates substantial energy during daylight hours, while the wind turbine complements energy production during low-light conditions. The fuel cell ensures high efficiency and reliability, particularly when renewable generation is insufficient. Wave energy also supports the system with the energy that is produced. By combining these components, the system achieves enhanced flexibility and sustainability. Furthermore, an energy storage system (ESS) is integrated to improve reliability and balance supply-demand dynamics. This study highlights the importance of intelligent load management strategies in achieving optimal energy utilization. The proposed model demonstrates the potential of hybrid MGs to provide continuous and sustainable energy, addressing the challenges of rural and urban electrification.

Keywords: Hybrid microgrid, Load management, Fuzzy logic control, Renewable energy, Wave energy

1. INTRODUCTION

The increasing demand for sustainable energy has made conventional energy sources a critical issue worldwide. Traditional energy production, primarily reliant on fossil fuels such as coal, oil, and natural gas, leads to significant environmental concerns, including carbon dioxide emissions, global warming, and climate change [8,9-14]. The depletion of fossil fuel reserves also poses challenges for energy security, driving the necessity for alternative energy solutions [4]. As a response, renewable energy sources such as solar, wind, and biomass have gained prominence due to their sustainability and lower environmental impact. These energy sources provide a viable solution for reducing dependence on fossil fuels while enhancing energy security and economic stability. In Türkiye, renewable energy has been integrated into national energy policies to decrease reliance on fossil fuels [13]. Hybrid MG systems, which integrate multiple renewable sources with ESSs, offer a promising approach to ensuring a continuous and stable energy supply. These systems can function in grid-connected and island modes, improving energy management through advanced control strategies. This study proposes a hybrid MG model incorporating solar, wave energy, wind, and hydrogen fuel cell technologies to address the energy needs of a specific town in Türkiye. The proposed system enhances energy resilience by integrating multiple renewable sources and storage solutions, making it viable for addressing energy access challenges in remote areas.

2. MATERIALS AND METHODS

An efficient MG has been designed to supply loads in the circuit and support battery storage systems. The system integrates fuel cells, wave, wind, and PV systems. An ESS has been implemented to store excess power generated within the MG. This design considers the flexibility between energy supply and demand and the connection with the ESS. After determining the total power generated, a fuzzy logic controller has been developed to optimize the operating mode of the MG. In the proposed system, loads are managed based on their priority, allowing unnecessary loads to be deactivated when not needed using fuzzy logic. The schematic diagram of the designed MG is shown in Fig. 1.

2.1. The Structure of The Wave Energy System

Wave energy will also be present in the system, unlike many MG structures. Wave energy is the energy obtained from wind waves formed by water movement in oceans and seas. A machine that can collect wave energy is called a Wave Energy Converter (WEC). The purpose of WECs is to convert the kinetic energy of incoming waves into electrical energy [10]. In this way, it can be one of the structures included in the total energy produced in the system. This study included a coastal oscillating water column system called land installed marine powered energy transformer in the simulation [2]. The " column " structure in these systems has seawater at the bottom and air at the top. The movement of the waves changes the water level inside the column and compresses the air above. The compressed air rotates a turbine and produces electrical energy [6]. Sea waves have a sinusoidal structure; therefore, the sine wave curve was used in simulation studies. While creating the sine wave, it was assumed that the waves came regularly. The wave height and period were constant. While designing the wave energy system, a place on the Aegean Sea coast in Türkiye was taken

as the basis for the input information. These values were used to calculate the total energy that was contained in wave (ΔP) in Eq. (1) [5], speed of the air (v_{air}) in Eq. (2), and the torque (T_{Nm}) Eq. (3), that rotates the turbine wheel.

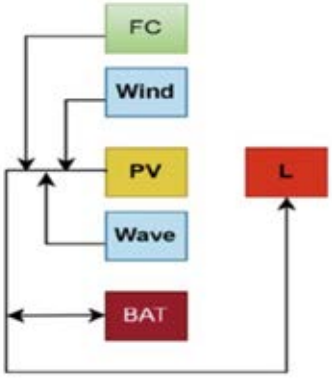

Fig. 1. Island MG diagram

This system can produce 6-kW of energy. System parameters can be seen in Table 1.

$$\Delta P = \frac{1}{8} \times p_{water} \times g \times H^2 \times \sin\left(\frac{2\pi}{T} \times t\right) \quad (1)$$

$$v_{air} = \frac{((\Delta P / p_{air}))}{A_{turb}} \quad (2)$$

$$T_{Nm} = C_t \times p_{air} \times A_{turb} \times {v_{air}}^2 \times R_t \quad (3)$$

Table 1. Parameters of The Proposed Energy System

Wave Energy Parameters	**Value**	**Units**	**PV Energy Parameters**	**Value**	**Units**

2.2. The Structure of PV System

Solar panels are components that capture solar energy and convert it into electricity [3]. These panels consist of solar cells. Solar cells are usually made of silicon-based semiconductor materials. Electrons are activated when sunlight hits these cells, and an electric current is created. When cells are connected sequentially in solar panels, the voltage (tension) increases. When cells are connected in parallel, the current capacity increases. This collected energy is transmitted to consumers (homes, businesses, factories, etc.) and made available with devices such as inverters (DC-AC converters).

In this way, the light energy from the sun is directly converted into electrical energy and becomes usable for people. This system is the main energy source of the MG system. 100-kW of energy can be produced by this system. The parameters of the PV system used in Simulink design can be seen in Table 1.

2.3. The Structure of the Fuel Cell Energy System

Proton Exchange Membrane Fuel Cells (PEMFCs) are critical among environmentally friendly energy solutions [12]. They provide efficient energy conversion by directly converting the chemical energy of hydrogen into electricity. In traditional methods, fuel and oxidizer react in the same environment, while in fuel cells, these components are kept in different compartments. In this way, their direct mixing is prevented, and energy production occurs by ions and electrons moving in a controlled manner [11].

The hydrogen fuel electrochemical equation is defined in Eq. (4) [1].

$$2H_2 + O_2 = 2H_2O + electricitiy + heat \quad (4)$$

The output voltage of a PEMFC can be calculated with Eq. (5).

$$V_{FC} = n_{cell}(V_{nernst} - V_{con} - V_{act} - V_{ohm}) \quad (5)$$

Here, V_{nernst} represents the unprocessed electrical potential generated by the chemical reaction. Meanwhile, V_{act} denotes the activation overvoltage, while V_{con} and V_{ohm} indicate voltage drops due to resistance and concentration losses. The Nernst voltage is detailed in Eq. (6).

$$V_{nernst} = V_o - (0.85 \times 10^{-3})(T - 298.15) - (4.3085 \times 10^{-5})Tln(P_{H_2}{P_{O_2}}^{1/2}) \quad (6)$$

The proton exchange membrane fuel cell (PEM) system, including the buck converter, is modeled in MATLAB/Simulink. A simplified PEM model parameter is given in Table 1.

2.4. The Structure of the Wind Energy System

The input to a wind turbine is the wind, while its output is the mechanical power that drives the generator rotor. In a variable-speed wind turbine, the mechanical output power obtained from the turbine can be expressed by Eq. (7) [7].

$$P_m = \frac{1}{2}pAC_p(\lambda, \beta){V_w}^3 \quad (7)$$

Here, p represents the air density, and A represents the area swept by the turbine blades. V_w is the wind speed (m/s), C_p is called the power coefficient and is expressed as a nonlinear function of the tip speed ratio (TSR) λ. This function is defined as Eq. (8).

$$\lambda = \frac{w_r r}{V_w} \quad (8)$$

The wind turbine, including its PMSG (Permanent Magnet Synchronous Generator), boost converter, and control system, was modeled in MATLAB/Simulink. The MG system was simulated based on a 6.5 kW small wind turbine, with its parameters provided in Table 1.

2.5. The Structure of the Load Management System

The loads are prioritized according to their importance and integrated into the system accordingly. The main purpose is to feed critical loads by using the available power most efficiently and include other loads in the system if the energy status allows. Loads are divided into four different categories according to their importance. Tertiary load is of minor importance and is connected to the system whenever there is excess energy. It needs 30 kW of power and is disconnected first during a lack of energy. It can be commercial appliances or comfort equipment. The quarterly load has the lowest priority in the system. It needs 50 kW of power. It operates only if there is enough power. It shuts down as soon as there is low energy. Examples include large lighting systems or non-essential appliances. The FL-based load management system takes the total generated power as an input and calculates how to switch the loads on and off. It has a single input (total power input) and three outputs, which control load connections based on priority. These outputs ensure critical loads are connected while others are adjusted according to the available power.

3. RESULTS AND DISCUSSION

The proposed system is designed to generate high efficiency and quality line voltage. Operating in island mode, the system manages variable loads based on fuzzy logic outputs. Loads are dynamically added or removed depending on the available power, directly influencing the system's voltage and current. Furthermore, power generation has been analyzed under various operating conditions to evaluate system performance. The battery charge decreases rapidly when the system is operated without load management. This is because the loads in the system are constant even if the power generated decreases. In the system without load management, the battery is separated from the charging mode to provide sufficient energy, and its charge begins to decrease rapidly. This situation is seen in Fig. 2a.

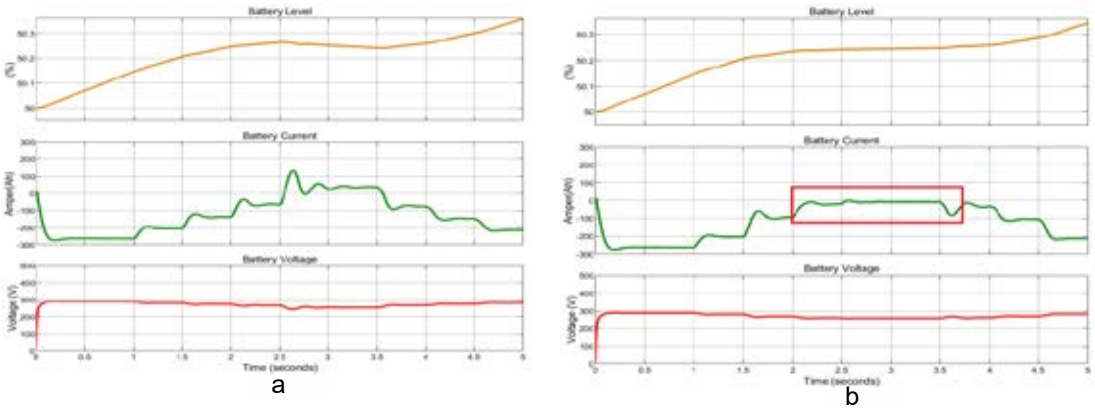

Fig. 2. a) Change of charge level without load management, b) Change in charge level after load management is applied.

When load management based on the fuzzy logic method is applied in the system, the insensitive secondary loads are separated from the system if there is not enough power. In this case, since the power drawn from the system will decrease, the battery charge level will decrease less or will switch to the charging state. In this way, the MG will continue to operate in a controlled manner. The load-shifting process ensures that there is less charge loss in the system. Fig. 2b shows the changes in battery charge levels after the load management is applied to the system.

4. CONCLUSIONS

This study presents an innovative energy solution for remote areas with renewable energy resources but struggles to utilize them efficiently. The proposed system has been introduced and thoroughly examined for the first time in this research. It has been evaluated under two different scenarios: with and without load management (LM), and the battery status has been analyzed in detail. The performance of critical, non-critical, and secondary loads has been tested under various conditions using load management and FL control. Additionally, the system has been adapted for a sample region and is supported by a storage infrastructure that provides uninterrupted energy for 24 hours. This study aims to enhance energy supply in remote areas by making it more sustainable and efficient while serving as a foundation for future innovations. In future research, load classification methods and the battery management system could be further expanded, incorporating a wider range of energy sources. Additionally, ESSs could be scaled up to support more extensive and complex power systems. These advancements would play a crucial role in improving the efficiency and sustainability of global energy infrastructure.

ABSTRACT

In this study, SiC Schottky barrier diode production was carried out by DC sputtering method. Different types of Schottky barrier diodes were produced by coating Al on the one side of the 4H-SiC wafer and Ti or Ni or Pt on the other side. The DC and AC electrical properties of the Al/4H-SiC/Metal Schottky barrier diodes were measured depending on the temperature. Inferences were made on the character of the metal-semiconductor SiC Schottky barrier diode in the I-V graphs obtained as a result of the measurements. In addition, gas measurements of SiC Schottky diodes were made and the obtained data were discussed. Al/4H-SiC/Ti and Al/4H-SiC/Ni device showed Schottky behavior but Al/4H-SiC/Pt device showed memristive behavior.

Keywords: SiC, Schottky barrier diode, Gas sensors, Metal-semiconductor contacts

1.INTRODUCTION

Since the 19th century, the interest of mankind in electronics has become an inseparable part of life today, with the development of the field of electrical and electronics. The electrical industry is currently one of the largest industries in the world. The differentiation of human needs every passing day further develops technology. In these studies, the investigation of the electrical properties of solids and the findings obtained have made great contributions to electronics. The first systematic research on metal-semiconductor rectifier systems was made by Braun in 1874. Point contact rectifiers in various forms found practical applications. In 1931, Wilson formulated the transport theory of semiconductors. This theory, based on the band theory of solids, was later applied to metal-semiconductors. In 1938, Schottky suggested that there could be a potential barrier. He stated that the chemical layer was caused only by stable space charges in the semiconductor without the existence of an entity. The model resulting from this evaluation is known as the Schottky barrier [1]. In 1938, Mott also designed a more suitable theoretical model for the swept-away ones. This model, known as the Mott barrier, takes place in metal-semiconductor contacts. These models were further developed by Bethe in 1942 and became the thermionic emission model [2]. When a metal comes into contact with a semiconductor, a barrier is formed in the metal-semiconductor. This barrier is responsible for controlling the current conduction. The energy band diagrams that lead to the formation of the barrier height and some effects can change the value of this barrier. The energy band diagrams of metal-semiconductor contacts before and after the contact are given in Figure 1 [2] (Sze et al., 2021). The work function is the energy difference between the vacuum level and the Fermi level. Here, the work function is denoted by $q\phi_m$ for a metal and is equal to $q(\chi + \phi_n)$ for a semiconductor. The $q\chi$ given for a semiconductor is the electron affinity measured from the bottom of the conduction band (E_C) to the vacuum level. Here $q\phi_n$ is the energy difference between the E_C and the Fermi level [2].

Since the realization of high-performance power devices provides high energy saving, conservation of fossil fuels and less environmental pollution, interest in devices using semiconductors is increasing. Currently, the technology of Si power devices used in most fields is experiencing difficulties in innovative breakthroughs in applications. Silicon carbide (SiC), one of the newly emerging semiconductors, has attracted considerable attention due to its superior physical properties. SiC is an extremely wide bandgap semiconductor, and its use is increasing day by day. Due to the significant development of SiC wafer quality and advancement in device technology, high voltage SiC Schottky barrier diodes (SBDs) and field effect transistors (FETs) have been proven to perform significantly better than their Si counterparts. Components that provide significant reduction of power loss will be used in various power converters in the future, indicating that SiC power devices will become the key [3].

SiC is a material that shows polytypism. Polytypism expresses different crystal structures in one-dimensional variation while preserving the same chemical structure. The change of occupied sites along the c-axis gives more than 200 SiC polytypes different crystal structures. While expressing polytypes, the number of layers in the unit cell and the crystal system (cubic for C, H for hexagonal and R for rhombic) are taken into consideration. 3C-SiC, 4H-SiC and 6H-SiC are the most common and also the most technologically important ones . In general, 3C-SiC shows a stable structure at low temperatures, while 4H-SiC and 6H-SiC are known as high-temperature resistant polytypes [3].

SiC is resistant to high-energy radiation compared to semiconductors such as GaAs and Si, which allows it to be used in space technologies. SiC is used in high voltage, high frequency, and high temperature resistant devices. SiC is found in UV photodiodes, blue light emitting diodes, and detector diodes [4].

SiC Schottky diodes were used in microwaves, radio, and radar detectors in the past, but today they are used in many areas in the semiconductor industry due to their unique properties. The main areas of these areas are MESFET elements, solar cells, varactors, high-energy detectors, switching circuits, etc. Since it is a type of diode that is open to development, it is foreseen that it will be used in many more areas in the future [5].

One of the needs of the increasing world population is undoubtedly the need for energy. In today's world where fossil resources are rapidly depleting, the demand for renewable energy is rapidly increasing. There has been an increase in the studies carried out to meet this demand from hydrogen in recent years. In the face of the challenges faced by the world in producing clean energy, it has become generally accepted that hydrogen will be a sustainable resource. In addition, the fact that hydrogen is used in many areas of space studies and industry also contributes greatly to scientific studies [6].

2.METHOD

2.1. SiC Schottky Barrier Diode Fabrication

SBD production was performed using commercially produced and ready-made 4H-SiC wafers. The ohmic and Schottky contacts of the SBDs to be created were made by coating Al, Ti, Ni, and Pt metals. In Figure 1, the upper part of the 4H-SiC was coated with Ti or Ni or Pt metals and the other side with Al metal to obtain a SBD.

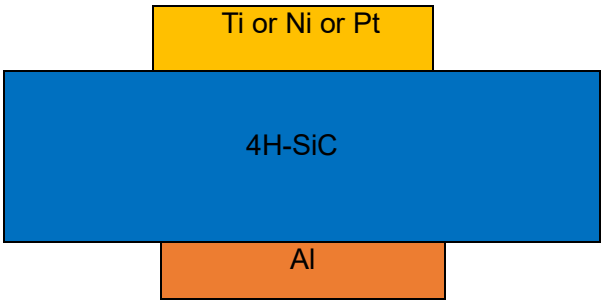

Fig. 1. Al/4H-SiC/metal SBD schematic diagram

2.2. Electrical characterization

The DC and AC electrical behaviors of the different Schottky diodes obtained were measured with the Source Measure Unit and LCR meter. The electrical characteristics of these diodes were measured depending on the temperature, frequency and ambient conditions. During the measurement, the temperature were changed between 25 - 200 ^{0}C and electrical measurements will be made in different gas environments.

2.3. Gas sensor tests

Within the scope of this study, the sensor devices produced by our group were measured in the sensor test system located in the sensor laboratory. The measurement system includes a measurement cell where the temperature of the sensor devices can be changed, a gas flow control device to obtain the desired concentration of gas mixture, a temperature control device to precisely control the temperature of the sensor device, a multimeter to measure the resistance of the sensor device, and a computer to control these devices, collect and record data from the devices. Sensor tests were performed against hydrogen gas on the produced sensor devices. The sensors were tested between room temperature and 200 ^{o}C. In order to check the repeatability of the measurements, same sensor device were taken at different times under the same conditions and their comparisons were made.

3. RESULTS AND DISCUSSION

Figure 2a and b shows the I-V and semi-logarithmic I-V graphs of the SBD we produced from Ti metal at room temperature and Al/4H-SiC/Ti device has seen Schottky behavior. The semi-logarithmic I-V graphs of the Al/4H-SiC/Ni device at different temperatures is given in Figure 2c. It is seen that the Al/4H-SiC/Ni device behaves like a diode at low temperatures and exhibits ohmic behavior at high temperatures. Figure 2d shows the semi-logarithmic I-V graph of the Al/4H-SiC/Pt device that measured in the range of -/+5V at room temperature in a dry air environment for three cycles. It is seen that Al/4H-SiC/Pt device exhibits memristive behavior in the forward bias. The I-V graph of the Al/4H-SiC/Ni device in dry air and 1% hydrogen environment at room temperature was given in Figure 2e. It is seen that the current decreases in the hydrogen environment. The semi-logarithmic I-V graph of the Al/4H-SiC/Ni device in dry air and 1% hydrogen environment at room temperature was given in Figure 2f. While the difference in current was seen clearly in dry air and 1% hydrogen environments in the forward bias, almost the same current values were seen in the reverse bias.

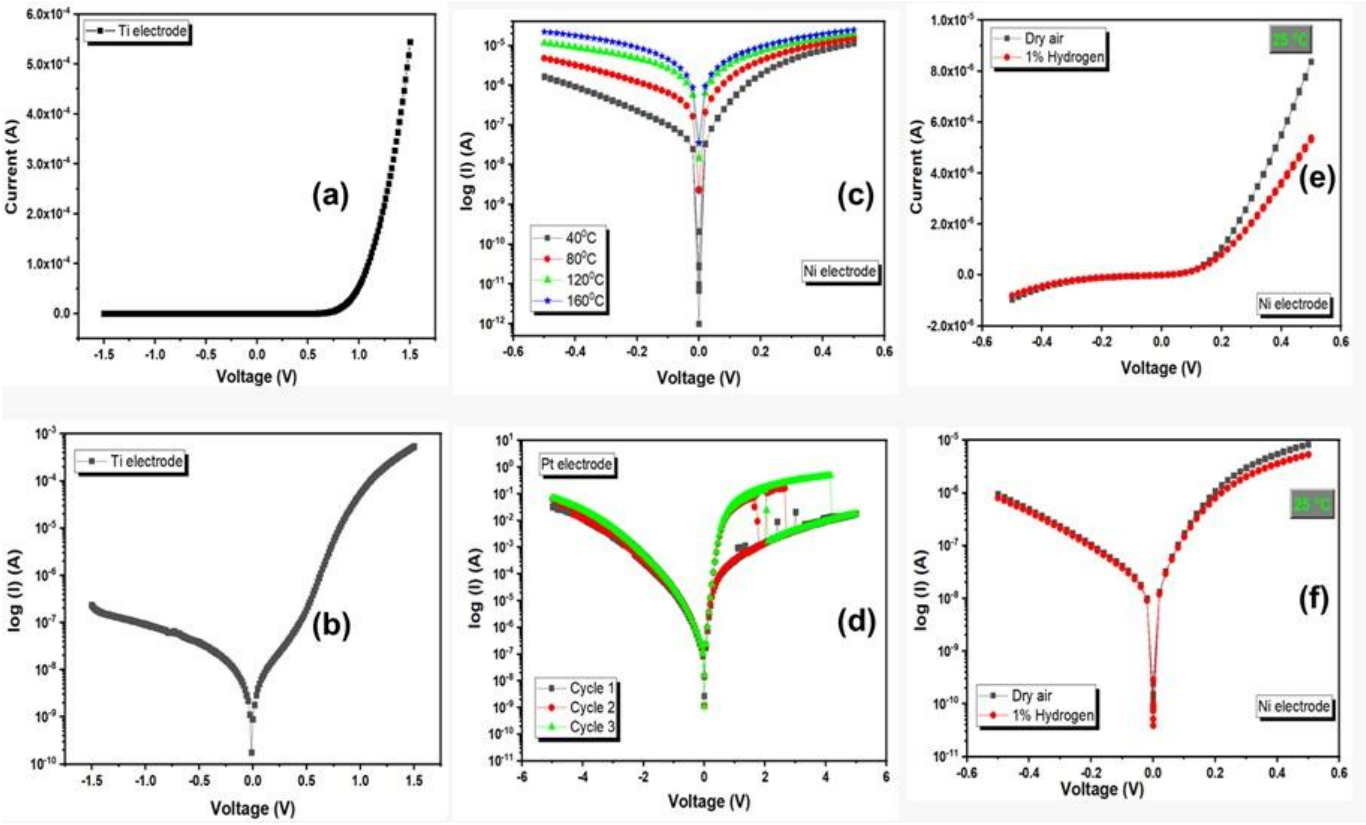

Fig. 2. (a) Al/4H-SiC/Ti I-V graph and **(b)** Al/4H-SiC/Ti semi-logarithmic I-V graph. **(c)** Al/4H-SiC/Ni semi-logarithmic I-V graph and **(d)** Al/4H-SiC/Pt semi-logarithmic I-V graph. **(e)** Al/4H-SiC/Ni I-V graph and **(f)** Al/4H-SiC/Ni semi-logarithmic I-V graph.

4. CONCLUSIONS

As a result, DC sputtering method was used to produce Al/4H-SiC/Metal Schottky barrier diodes. Different types of Schottky barrier diodes were produced by coating Al on one side of 4H-SiC wafer and Ti or Ni or Pt on the other side. DC and AC electrical properties of Al/4H-SiC/Metal Schottky barrier diodes were measured depending on temperature and I-V characteristics were investigated. In addition, hydrogen gas sensor tests of SiC Schottky diodes were performed. Al/4H-SiC/Ti and Al/4H-SiC/Ni devices showed Schottky behavior, while Al/4H-SiC/Pt devices showed memristive behavior.

ABSTRACT
Zeolitic Imidazolate Frameworks (ZIFs), as a subclass of Metal-Organic Frameworks (MOFs), have gained significant attention for their potential in hydrogen storage and separation applications. This study investigates the adsorption properties and structural characteristics of ZIF-3 and ZIF-90, which exhibit high thermal and chemical stability, thus they are potential candidates for hydrogen-related technologies. The hydrogen adsorption capacities of these materials have been computed using Grand Canonical Monte Carlo (GCMC) simulations, allowing for an in-depth evaluation of adsorption, interaction energies, and pore structures under different pressure and temperature conditions. The results highlight the impact of pore size distribution, functional groups, and framework topology on hydrogen adsorption efficiency. The results add to the current research on ZIFs as potential sustainable hydrogen storage solutions and provide fresh insights into the development of advanced porous materials for clean energy purposes.

Keywords: Hydrogen storage, ZIFs, Adsorption, Grand Canonical Monte Carlo (GCMC)

1. INTRODUCTION

As a subtype of Metal-Organic Frameworks (MOFs), Zeolitic Imidazolate Frameworks (ZIFs) have significant potential in hydrogen storage and separation applications due to their high porosity and chemical resilience, which has garnered considerable interest. ZIFs are characterized by their strong porosity, large surface area, and exceptional thermal and chemical stability, which makes them highly promising for hydrogen storage applications. [1]

ZIFs are promising materials for use as adsorbents and membranes in the separation of noble gas mixtures. Due to their high porosity and selective gas adsorption properties, ZIFs can effectively separate gases such as carbon dioxide (CO_2) and methane (CH_4), as well as noble gases like neon (Ne) and argon (Ar). The structural flexibility and pore size of ZIFs allow for selective gas capture and release. Additionally, ZIFs have potential applications in membrane technology, where their properties can enhance the efficiency of noble gas separation processes. Moreover, ZIFs hold great potential for environmentally friendly gas separation and energy production applications. Specifically, the separation of methane and other gases from natural gas can contribute to reducing the carbon footprint. ZIFs are highly promising materials for adsorption and separation technologies, and their potential can be more efficiently harnessed through further exploration. [2]

Among the various ZIF structures, ZIF-3 and ZIF-90 have been extensively studied for their unique properties. ZIF-3, for instance, exhibits a sodalite (SOD) topology, which contributes to its high porosity and stability [1]. ZIF-90 is notable for its aldehyde functional groups, rendering it hydrophilic and allowing for post-synthetic modifications to enhance gas adsorption properties [3].

The hydrogen storage capabilities of these ZIFs are influenced by factors such as pore size, surface area, and functionalization. Studies have shown that ZIF-8, a structurally similar framework, can adsorb hydrogen molecules up to 4.2 wt% at high loading concentrations [4]. This suggests that ZIF-3 and ZIF-90 may also exhibit comparable hydrogen storage capacities, contingent upon their structural attributes and functional groups.

To accurately assess the hydrogen adsorption performance of these materials, computational methods such as Grand Canonical Monte Carlo (GCMC) simulations were employed. GCMC simulations enable the evaluation of adsorption isotherms, pore size distributions, and the impact of functional groups on gas uptake under various conditions. In this study, we have analyzed the hydrogen adsorption behavior of ZIF-3 and ZIF-90 under different temperature and pressure conditions using GCMC simulations. By investigating the relationship between their structural features and hydrogen storage capacities, this work aims to provide guidance for the development of advanced porous materials for clean energy applications. Theoretical insights gained from this study are crucial for optimizing the design and synthesis of ZIFs tailored for efficient hydrogen storage applications.

2. COMPUTATIONAL DETAILS

The Grand Canonical Monte Carlo (GCMC) simulation is a method based on statistical mechanics, designed to model adsorption processes at the molecular level. This method is commonly employed to study adsorption equilibrium because it has the ability to directly calculate the number of moles of molecules within the pore. [5]

The grand canonical ensemble is defined by thermodynamic variables such as chemical potential (μ) and absolute temperature (T). Additionally, it depends on mechanical parameters like volume (V), which determine the system's internal states. Since these three quantities remain constant in this ensemble, it is commonly referred to as the μVT ensemble.

2.2. Simulation Details

Grand Canonical Monte Carlo (GCMC) simulations were performed to compute the H_2 adsorption isotherms of the selected ZIF materials, namely ZIF-3 and ZIF-90, under varying temperature and pressure conditions. The open-source RASPA simulation package [6] was used to obtain H_2 adsorption isotherms at 193 K, 233 K, and 273 K with pressures ranging from 1 bar to 40 bar.

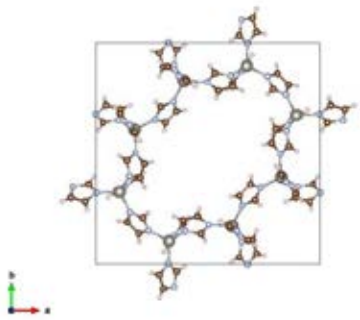

Fig. 1. Image of ZIF-3

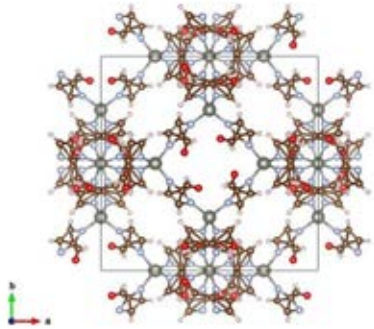

Fig. 2. Image of ZIF-90

The frameworks were kept rigid throughout the GCMC simulations.The Lennard-Jones potential was used to calculate dispersive interactions, and the force field parameters of the ZIF atoms were taken from the Universal Force Field (UFF) [7]. Lorentz–Berthelot mixing rules were applied to determine the force field parameters between different atomic pairs [8]. We applied the five-site Belof-Stern-Space (BSS) model to simulate the H_2 molecule. Table 1 displays the parameters of the BSS model, where q denotes charge and ε and σ denote Lennard-Jones force field parameters of energy and size.

Simulation cells are sufficiently replicated and a Van der Waals cut-off distance of 12 Å was employed in simulations. The Coulomb cut-off was set to 18 Å. Various Monte Carlo moves, including translation, reinsertion, and rotation, were incorporated during the simulations. The GCMC simulations consisted of a total of 500,000 cycles, including 10,000 initialization cycles, followed by 490,000 production cycles.

Following the GCMC simulations, the adsorption capacities of ZIF-3 and ZIF-90 were analyzed to determine their efficiency in hydrogen storage applications. The results provide insights into the relationship between the structural properties of ZIFs and their hydrogen adsorption performance under different temperature and pressure conditions.

Table 1. Parameters of the BSS model applied in this work.

3. RESULTS AND DISCUSSION

In this study, ZIF-3 and ZIF-90 materials were used to evaluate hydrogen adsorption performance, and these materials were thoroughly examined due to their structural stability and potential in hydrogen storage capacity. Grand Canonical

Monte Carlo (GCMC) simulations were carried out at temperatures of 193 K, 233 K, and 273 K, with pressures ranging from 1 bar to 40 bar.

The adsorption results indicate that ZIF-3 exhibited the highest hydrogen uptake across all investigated temperatures. As shown in Fig. 3, the highest performance was observed at 193 K, followed by 233 K and 273 K. In both ZIF-3 and ZIF-90, an increase in pressure led to an enhancement in adsorption, confirming the pressure-dependent nature of hydrogen storage in porous materials. This trend is clearly observed in Fig. 3. The highest adsorption capacities were recorded at 193 K, where ZIF-3 showed the best performance.

A comparative analysis of ZIF-3 and ZIF-90 revealed an average difference of approximately 0.3 in adsorption capacity across all conditions, with ZIF-3 consistently outperforming ZIF-90. This difference was particularly noticeable in Fig. 3, where ZIF-3 exhibited the highest adsorption capacity at 193 K. These findings suggest that ZIF-3's structural properties are more favorable for hydrogen adsorption, making it a stronger candidate for storage applications under cryogenic conditions.

The structural stability and high hydrogen storage capacity of ZIF-3 make it a key material for efficient energy storage and transport systems. While ZIF-90 shows lower performance than ZIF-3, it still demonstrates significant hydrogen storage capacity under certain conditions, highlighting its potential for optimization in specific applications. ZIF-3's high performance is especially prominent in low-temperature environments, while ZIF-90 may be more suited for high-pressure conditions.

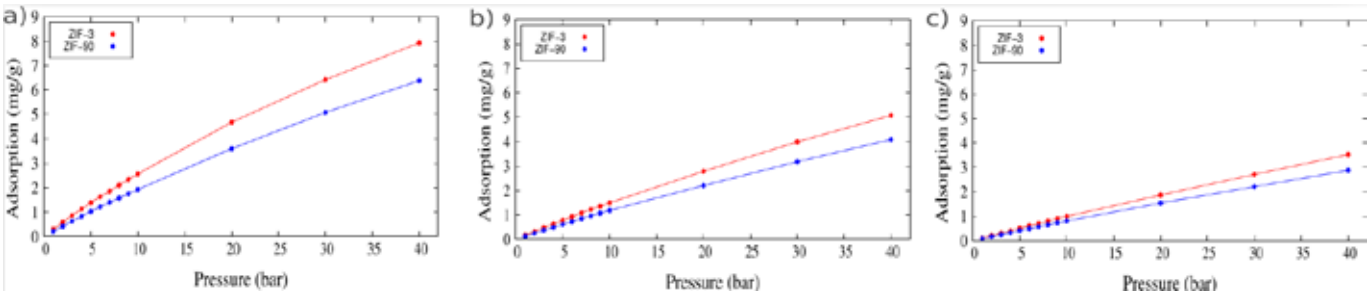

Fig. 3. H2 adsorption isotherms of ZIFs calculated at (a) 193 K, (b) 233 K and (b) 273 K

The ZIF structures remained rigid throughout the geometry optimization process. The geometry-optimized structures of the H_2/ZIF systems for ZIF-3 and ZIF-90 are presented in Fig. 4(a–d), respectively. H_2 molecules predominantly adsorb near the metal ions, and the measured distances are highly comparable. The adsorption distances observed for ZIF-3 are significantly shorter than those measured for ZIF-90. This finding further supports the higher adsorption capacity of ZIF-3, as demonstrated in Fig. 3.

4. CONCLUSIONS

This study investigated the hydrogen adsorption performance of ZIF-3 and ZIF-90 under varying temperature and pressure conditions using GCMC simulations. The results demonstrated that adsorption is significantly influenced by both pressure and temperature. The highest adsorption capacities were observed at 193 K, as shown in Fig. 3**,** confirming the superior hydrogen storage potential of these materials at low temperatures. Additionally, the pressure-dependent nature of hydrogen uptake was confirmed, as adsorption increased with rising pressure.

Among the two studied frameworks, ZIF-3 consistently outperformed ZIF-90, with an average adsorption capacity difference of 0.3 across all conditions. These findings highlight ZIF-3 as a more effective material for hydrogen storage applications, particularly in low-temperature environments. Future work could explore structural modifications, functionalization strategies, and optimization for higher temperatures to further enhance adsorption capacities and make these materials more suitable for practical hydrogen storage applications.

ABSTRACT
Hydrogen energy is a sustainable carrier that enables fossil fuel replacement and long-term storage for renewable energy. This study evaluates the annual hydrogen production capacity of the Sivas region using its wind and solar potential. For a realistic model, one year of hourly data is analyzed using the Weibull and Gamma distributions for wind and solar energy, respectively. Based on these analyses, wind turbines and solar panels (300 kW–450 kW) are selected, and monthly/annual energy production potential is calculated. A PEM electrolyzer is then used to estimate hydrogen production. For a comprehensive evaluation, five scenarios assessed wind and solar energy in individual and hybrid configurations. In contrast, the sixth and seventh scenarios analyzed hydrogen production using grid electricity from fossil fuels and renewables. The levelized cost of hydrogen (LCOH) is determined, showing that hydrogen costs $4.15–7.77/kg with renewables and $8.59–10.3/kg with grid power, highlighting the economic benefits of local resources. Besides, the effects of CAPEX, government incentives, and hydrogen production on LCOH are investigated. Hydrogen production is found to reduce CO_2 emissions by 1,357–1,727 tons annually, generating $19.25–25.91 million in carbon revenue, making it both an economical and sustainable energy solution.
Keywords: Hydrogen production, renewable energy, Weibull& Gama statistical method, Economic feasibility, Carbon reduction

1. INTRODUCTION

Hydrogen, abundantly available in nature, is a key energy carrier with high energy density and eco-friendly properties. It reduces carbon emissions, enhances energy security, and stabilizes energy systems by balancing fluctuations in renewable sources. Since hydrogen does not exist freely, it must be produced and is classified as grey, blue, or green based on its energy source. Grey hydrogen comes from fossil fuels, blue hydrogen captures emissions, and green hydrogen—produced via renewable-powered electrolysis—is the most sustainable. The global adoption of hydrogen energy is accelerating, making it a key part of energy policies worldwide. The EU, Japan, South Korea, and China lead the hydrogen economy with national strategies. Germany is investing €9 billion in hydrogen infrastructure, while Japan focuses on hydrogen-based transportation. Research on hydrogen energy is growing in Turkey, especially in renewable-based production. However, large-scale production, storage, and distribution costs remain significant challenges. Research on integrating hydrogen into sustainable energy systems is advancing rapidly. Some notable studies are outlined: Aziz et al. examined biomass and organic waste conversion into hydrogen, assessing economic feasibility [1]. Berrada and Laasmi analyzed green hydrogen costs in Morocco, finding prices between $3.49–5.96/kg, with variations across regions [2]. Razi and Dinçer compared solar hydrogen production methods, concluding that high-temperature processes are more efficient but environmentally harmful, while photonic and biochemical methods are greener but less efficient [3]. Ayodele et al. assessed a wind-powered hydrogen refueling station in South Africa, with costs ranging from $6.34–8.97/kg, making it globally competitive [4]. Rezai et al. evaluated offshore wind-based hydrogen production in Australia, showing that input power significantly affects electrolysis energy consumption [5]. This study evaluates Sivas's hydrogen production potential using wind and solar energy. A realistic modeling approach assesses renewable capacity, estimates energy output, and compares hydrogen production feasibility with grid-based alternatives. Economic and environmental impacts are also examined.

2. MATERIALS AND METHODS

Sivas's province is selected as the study area, located between 35° 50'–38° 14' E longitude and 38° 32'–40° 16' N latitude. Hourly wind speed, solar radiation, and temperature data from 2023–2024 NASA datasets are used. [6].

2.1. The evaluation of Wind Potential

Accurate wind energy assessment relies on analyzing wind speed distribution. For this, the two-parameterWeibull distribution defined in the Eq. (1) is widely used.

$$f(v) = \frac{k}{c}\left(\frac{v}{c}\right)^{k-1} e^{-\left(\frac{v}{c}\right)^{k}} \tag{1}$$

Here, *e* represents the Euler function, k (shape parameter) defines wind speed variability, and c (scale parameter) indicates its overall magnitude. k and c are determined using Eqs. (2) and (3), respectively [7].

$$k = \left(\frac{\sigma v}{\bar{v}}\right)^{-1.086} \tag{2}$$

$$c = \frac{\bar{v}}{\Gamma\left(1+\frac{1}{k}\right)} \tag{3}$$

Here, σ represents the standard deviation, $\bar{v}$ is the mean wind speed, and Γ denotes the gamma function. The average

power generated by the wind turbine using the Weibull distribution is calculated with Eq. (4) [7].

$$P_{avgw} = \frac{1}{2}\rho A C_P \int_{v_{cut-in}}^{cut-out} v^3 f(v) dv \quad (4)$$

Here, P_{avgw} represents average wind power, ρ is air density, C_p is the turbine's power coefficient, and A is the rotor swept area. v_{cut-in} is the minimum wind speed required for turbine operation (m/s), while $v_{cut-out}$ is the maximum wind speed at which the turbine shuts down (m/s).

2.2. The evaluation of Solar Potential

The gamma statistical method models the variability of solar radiation, with its probability density function given in Eq. (5) [8].

$$f(G) = \frac{G^{\alpha-1} e^{-G/\beta}}{\beta^{\alpha}\Gamma(\alpha)} \quad (5)$$

where G is the solar radiation. α and β denote shape and scale parameters. Using solar radiation data modeled with the gamma distribution, the average power output of a pv panel can be estimated using Eq. (6) [8]:

$$P_{avgs} = \eta A \int_0^{\infty} G f(G) dG \quad (6)$$

where η represents efficiency of pv panel. A denotes the surface area of the solar panel (m²).

2.3. The evaluation of Hydrogen Production

Hydrogen is produced via water electrolysis (Eq.7) using renewable energy [9].

$$2H_2O \rightarrow 2H_2(g) + O_2(g) \quad (7)$$

Eq. (8) is used to calculate the amount of hydrogen production.

$$H_p = \frac{P_E * t * \eta_e}{E_H} \quad (8)$$

where H_p and E_H represent the mass of hydrogen produced and energy required to produce one gram of hydrogen, respectively. P_E is the total electric power, t is the time of operation. η_e denotes efficiency of the electrolyzer [9].

2.4 Economic Analysis and Cost Evaluation of Hydrogen Production

The two most important basic formulae for the economic analysis of hydrogen production are the total cost and the levelised cost of hydrogen (LCOH). The main components that constitute the total cost of hydrogen production (C_{TOTAL}) are capital cost (C_{CAPEX}), operating cost (C_{OPEX}), and energy cost (C_{ENERGY}):

$$C_{TOTAL} = C_{CAPEX} + C_{OPEX} + C_{ENERGY} \quad (9)$$

The unit cost of hydrogen (LCOH) is found using Eq. (10):

$$LCOH = \frac{C_{TOTAL}}{H_P} \quad (10)$$

2.5. Carbon Quota and Emission Analysis of Hydrogen Energy

Hydrogen's emissions depend on its energy source; renewables produce **zero-emission green hydrogen**, while fossil fuels generate CO_2. In this study, wind and solar energy are used, and emission reduction is calculated via Eq. (11) [10]

$$\Delta_{E_{CO_2}} = \left(C_E^{fossil} - C_E^{renewable}\right) * E_{TOTAL} \quad (11)$$

Here, $\Delta_{E_{CO_2}}$ represents the reduced CO_2 amount, C_E^{fossil} while and $C_E^{renewable}$ are the carbon emission factors for electricity from fossil fuels and renewable energy, respectively. E_{TOTAL} denotes the total energy produced. In carbon markets, systems that reduce emissions earn carbon credits, which can be traded for revenue. Carbon revenue is calculated using Eq. (12). Here, R_{Carbon} , p_c represents the total revenue from carbon credits and unit price of carbon credit

$$R_{Carbon} = \Delta_{E_{CO_2}} * p_c \quad (12)$$

3. RESULTS AND DISCUSSION

This study evaluates Sivas' wind potential using the Weibull distribution. Monthly k and c values are calculated, with annual k = 2.1429 and c = 5.8577, validated by R² = 0.9821 and MAE = 0.001234 (Fig. 1). Two optimal wind turbines, Enercon E-30 (300 kW) and Vestas V27 (450 kW), are identified. The Enercon E-30 produces 900 MWh/year (34.24% capacity factor), while the Vestas V27 generates 1,487.4 MWh/year (37.27% capacity factor) (Table 1).

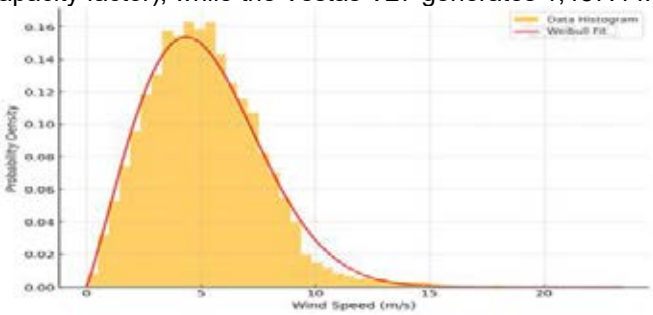

Fig.1. Weibull probability density function

Table 1. The results of wind energy analysis

k	2.1429
c	5.8527
R2	0.9821
MAE	0.001234
Energy generation (E30)	900 MWh
Capacity factor (E30)	%34.24
Energy generation (V27)	1,487.400 MWh
Capacity factor (V27)	%37.27

The Gamma distribution is applied to model solar energy data, with shape and scale parameters of 4.86 and 0.86,

respectively. The goodness of fit is evaluated using the Kolmogorov-Smirnov (KS) test and Pseudo R^2, yielding a *p*-value of 0.95 and a Pseudo R^2 of 0.85. These results confirm the Gamma distribution's suitability for representing the region's solar energy potential, though alternative distributions may also be applicable. The Gamma probability density function is shown in Figure 2. Annual energy production for PV panels with 300 kW capacity and 21% efficiency is 482.481 MWh, while 450 kW panels produce 723.722 MWh. The related results are summarized in Table 2.

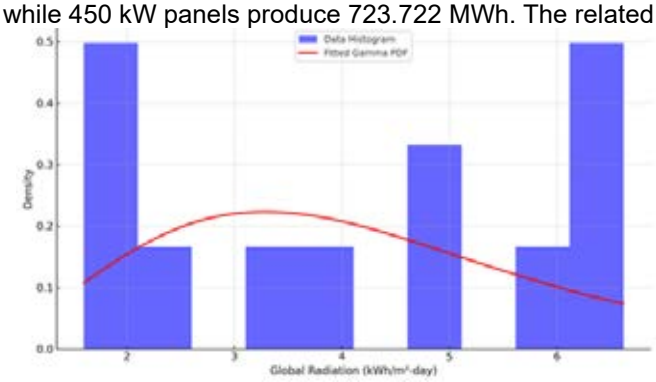

Fig.2. Gama probability density function

Table 2. The results of solar energy analysis

α	4.86
β	0.87
KS	0.27
p	0.95
Pseudo R^2	0.85
Energy production/year (300 kW-PV panel)	482.481 MWh
Energy production/year (450 kW-panel)	723.722 MWh

The monthly hydrogen production obtained using a PEM electrolyzer with 75% efficiency from wind turbines and solar panels of varying capacities is presented in Figure 3. The results indicate that wind turbines produce more hydrogen, particularly during winter, while solar energy reaches peak hydrogen production in May and June. The Vestas V27 (450 kW wind turbine) achieves the highest hydrogen output, whereas the 450 kW solar PV system approaches wind turbine performance during summer.

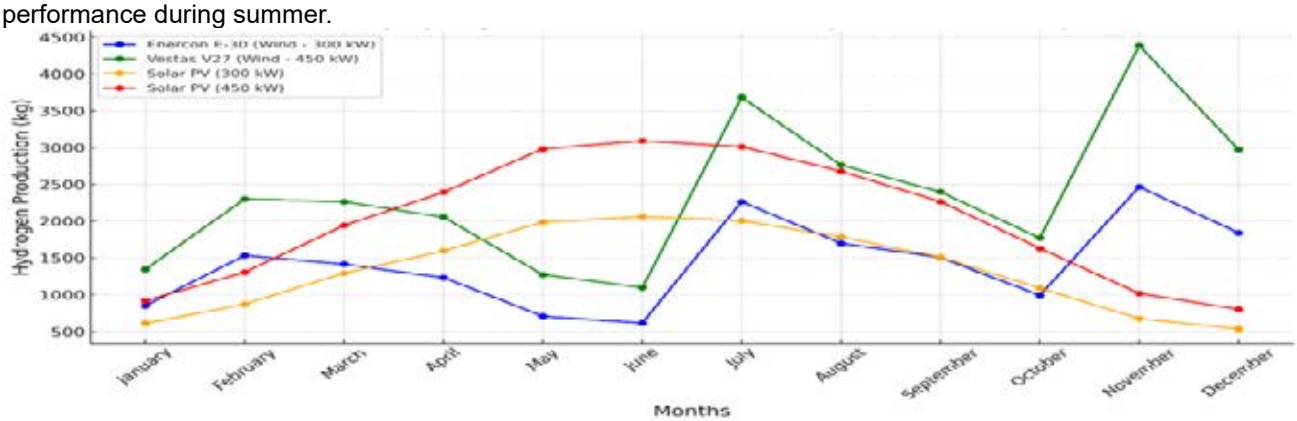

Figure 3. The monthly hydrogen production amount

Eight scenarios for hydrogen production are set up for real-world practical applicability. Scenarios one to five are based on regional solar and wind energy, either individually or as a hybrid mix. Scenario six uses grid electricity obtained from fossil fuels, and scenario seven uses only renewable grid electricity. Hydrogen production, cost, CO_2 savings, and carbon revenue are calculated for the scenarios. CAPEX for wind turbines and solar PV is $1,300/kW and $1,044/kW, respectively, while the OPEX is $16/kW-year for wind and $20/kW-year for solar. The 1 MW electrolyzer is used with CAPEX of $1,280,000/year and OPEX of $39,680/year. The emission factor is 0.6261 tons CO_2 avoided per each 1 MWh, and the carbon credit value is $15 per ton CO_2 equivalent.

Table 3. The results of economic and environmental analysis determined different scenarios

Scenarios	Contents	The amount of hydrogen production (kg)	LCOH ($/kg)	Reduced carbon emission (ton $C0_2$/year)	Carbon credit value ($/year)
1	%100 wind	54534	4.15	1727660	25914905
2	%50 wind-%50 solar	41044	5.37	1357447	20361711
3	%40 wind-%60 solar	38346	5.71	1283405	19251072
4	%60 wind-%40 solar	43742	5.06	1431490	21472440
5	%100 solar	27567	7.77	987234	14808517
6	Purchase from grid (Fossil sources)	41044	10.30	1357447	20361711
7	Purchase from grid (renewable sources)	41044	8.59	1357447	20361711

Finally, the effects of CAPEX and OPEX values and hydrogen production on the LCOH value are investigated in the

study. The graphs related to this are given in Fig. 4. An increase in CAPEX increases LCOH, while a decrease reduces costs; the effect of OPEX is more limited. Higher incentive levels reduce LCOH, increasing the competitiveness of hydrogen.

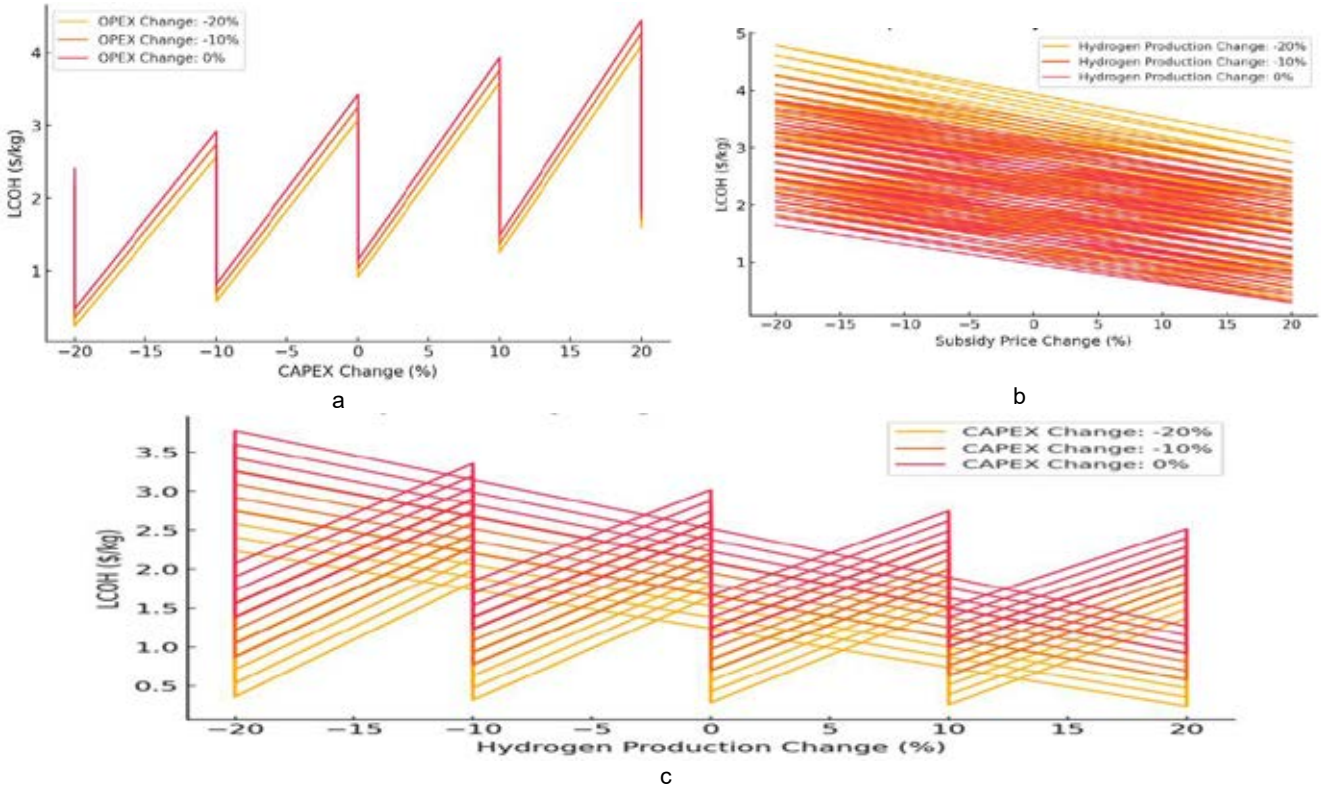

Fig.4. The effects of a) CAPEX, b) subsidy price, c) hydrogen production on LCOH

4. CONCLUSIONS

Utilizing the Sivas region's wind and solar potential for hydrogen production is more economical than purchasing on-grid electricity, reducing LCOH from $8.59–10.3/kg to $4.15–7.77/kg. Local renewable resources not only lower costs but also cut CO_2 emissions by 1,357–1,727 tons annually, generating $19.25–25.91 million in carbon revenue. This highlights regional renewable energy integration's economic and environmental advantages for sustainable hydrogen production.

ABSTRACT
Recent studies have been focusing focused on the mixed transition metal-based oxide electrocatalysts such as (CoFe, NiFe, MnNi, or FeCoNi) and layered double hydroxides (LDH) due to better performance and stability rather than pure forms for oxygen evolution reaction. Most NiFe-based electrocatalysts undergo structural and compositional self reconstruction under applied anodic potential; usually result in a dynamic activity in OER. In this study the catalytic properties of mesoporous thin film $NiFeO_x$ compounds are shown through cyclic voltammetry, and they were characterized through Raman, TEM/STEM, and XPS.
Keywords: NiFe oxides, OER, water splitting, LDH

1. INTRODUCTION

Developing abundant and cheap electrocatalysts for the electrolysis of water that minimize overpotential and Tafel slope is a challenge standing over against the efficient electrolyzers. Recent studies have focused on the mixed transition metal-based oxide electrocatalysts such as (CoFe, NiFe, MnNi, or FeCoNi) and layered double hydroxides (LDH) due to better performance and stability rather than pure forms [1]–[4]. Among them, NiFe oxide electrocatalysts have come into prominence owing to superior long-standing activity [5]. An enhanced OER activity obtained by incorporating Fe at even very low concentrations into nickel oxide had been demonstrated [6].

NiFe-based electrocatalysts with several structures, various morphologies, adjustable stoichiometries, modified electronic structures, abundant active sites, and long-range order can be synthesized in many synthesis protocols [7], [8], [9]–[12]. Mesoporous metal oxide thin film electrodes can satisfy many requirements for the next generation electrolyzer technology and the understanding of triangle among the structure-stability-activity relations. In addition, creating more surface area with interconnecting conductive networks increases the number of active sites and improves charge transfer kinetics and reagent/product diffusion as their mesoporous analogues [13], [14]–[16], [12]. Herein, we applied the liquid crystal templating method to produce mesoporous more durable flat NiFe oxide thin film electrodes. The mesoporous $NiFeO_x$, $NiFe_2O_4$, and Fe_2O_3 thin film electrodes on FTO having tunable compositions and a high surface area were successfully synthesized and comprehensively characterized. OER activities and stabilities of the electrodes were compared by numerous electrochemical tests in both Fe-free and non-purified electrolytes. Uniform and highly porous nano-sized metal oxide framework allowed the understanding of the OER mechanism of NiFe based electrocatalysts in which insertion of an infinitesimal number of Fe atoms in NiO lattice boosts the OER activity of Ni sites by altering its electronic structure.

2. MATERIALS AND METHODS

2.1. Preparation of Solutions of Nickel and Iron Precursors and Surfactants for Mesoporous NiFe Oxide Thin Films

In a typical solution preparation, CTAB, $C_{12}EO_{10}$, nickel nitrate hexahydrate, and iron nitrate nonahydrate are mixed in a 25 ml vial with deionized water. The solution is stirred for one day in order to make sure that it is homogenous and clear. Deionized water was kept constant in all solutions, 5 g. As CTAB/$C_{12}EO_{10}$ mole ratio was kept being 1.0 and total transition metal (iron and nickel nitrate)/CTAB mole ratio was kept being 9.0 for all solutions, nickel/iron salt mole ratios were altered. The nickel to iron salt mole ratios were used for labeling the solution.

2.2. Preparation of Lyotropic Liquid Crystalline (LLC) Mesophase for Mesoporous NiFe Oxide Thin Films

Spin coating was applied to prepare LLC and further mesoporous NiFe oxide thin films. An adequate amount of the solution was placed on the FTO or glass lamels and it was spun for 20 s at 1000 rpm by a spin coater. To obtain thicker mesophase, drop-cast coating on the microscopic slides was also applied. Drop-casting was applied by placing solution and aged for evaporation of deionized water. The spin-coated samples were used for XRD analysis.

2.3. Synthesis of Mesoporous NiFe Oxides

Mesoporous NiFe oxide thin films were prepared via calcination of LLC prepared by spin coating or drop-casting coating. The calcination procedure was carried out starting from room temperature up to 300 ℃ with a ramp of 2℃/min and keeping at 300 ℃ for 2 hours. The samples were annotated as mesoporous Ni_x/Fe_y, where x and y are the mole ratios

of nickel nitrate and iron nitrate to CTAB, respectively.

3. RESULTS AND DISCUSSION

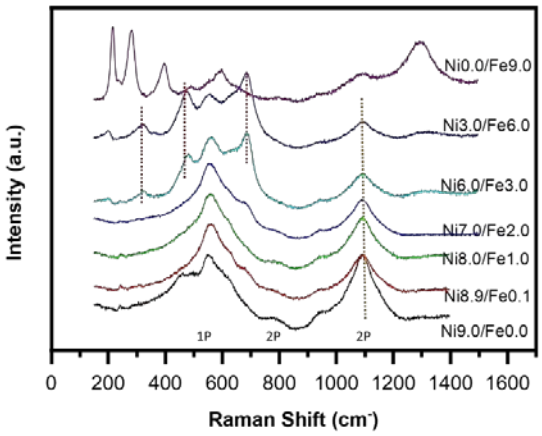

Fig. 1. Raman spectrum of the calcined samples of various Ni/Fe salt mole ratio mesophases

Raman spectroscopy analysis was conducted to figure out the oxide phases present in critical synthesized mesoporous samples, (Fig. 1). When the sample content becomes Ni6.0/Fe3.0, three new peaks appear at 320, 467, and 688 cm^{-1}, belonging to spinel structured $NiFe_2O_4$. At Ni3.0/Fe6.0, the NiO peak at 1100 cm^{-1} has low intensity compared to other peaks. The sample of pure Fe directly matches with α-Fe_2O_3. In conclusion, Up to Ni/Fe ratio, 7/2, iron atom are mixed in the rock salt type NiO, and then the formation of spinel $NiFe_2O_4$ structures starts at higher iron contents until the main oxide phase becomes spinel mixed oxide structure at Ni3.0/Fe6.0.

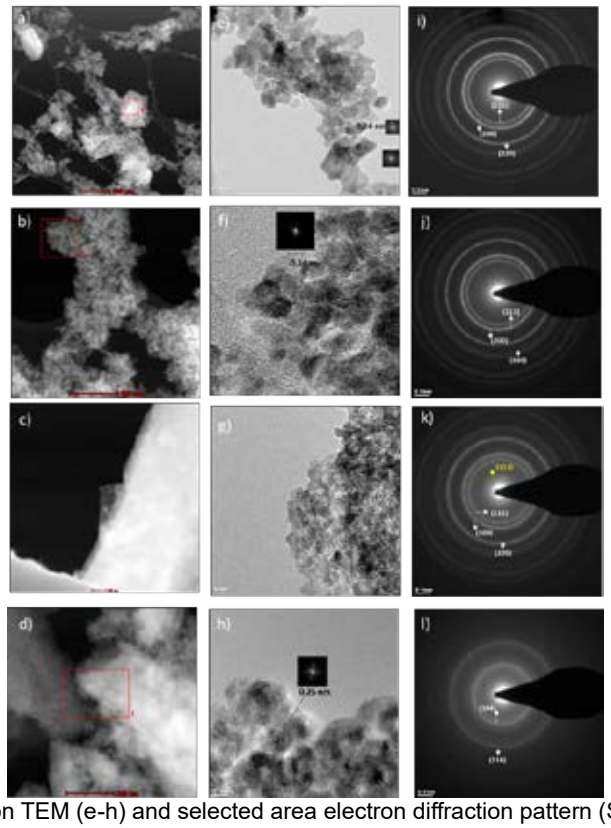

Fig. 2. STEM (a-d), high resolution TEM (e-h) and selected area electron diffraction pattern (SAED) (i-l) of calcined samples of Ni9.0/Fe0.0, Ni8.9/Fe0.1, Ni60/Fe3.0 and Ni0.0/Fe9.0, respectively

TEM/STEM experiments were performed to examine the more detailed structural and morphological analysis in selected samples at the nanoscale, (Fig. 2). Pure and mixed samples show a sponge-like mesoporous framework as seen in STEM images. High-resolution TEM images and selected area electron diffraction patterns (SAED) of Ni9.0/Fe0.0 and

Ni8.9/Fe0.1 samples are consistent with Raman analysis. Iron atoms substitute with nickel atoms in cubic NiO crystalline structure with particle sizes around 5-10 nm. At Ni6.0/Fe3.0 sample, electron diffraction pattern differs from other mixed oxide phases with the circle indexed as (111) lattice plane of spinel $NiFe_2O_4$ with a yellow arrow as detected in Raman analysis. The pure iron sample displays an α-Fe_2O_3 nanocrystalline structure, having a particle size smaller than 5 nm.

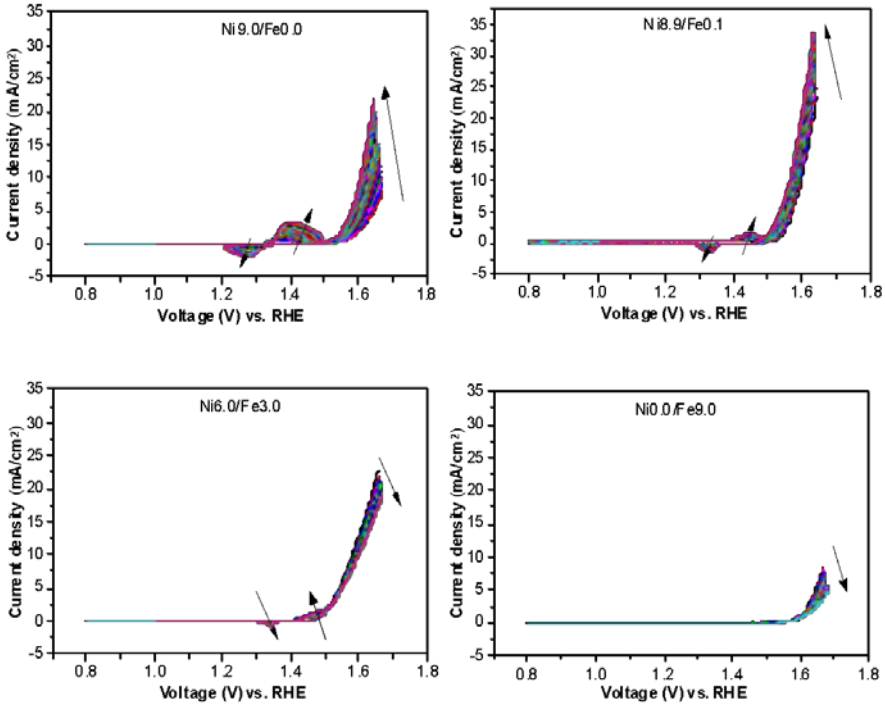

Fig. 3. Consecutive CV plots for mesoporous NiFe oxide electrodes having various compositions in alkaline electrolyte, 1.0 M KOH.

In order to verify the compositional change which is responsible for $Ni(OH)_2$/NiOOH and Fe impurities in KOH, cyclic voltammetry plots were recorded for selected electrodes in Fig.3. The observed oxidative peak is reversible due to appearing opposite reductive peak at lower potentials in the reverse cycle, evidence for the change of $Ni(OH)_2$/NiOOH. Interestingly, the OER activity of mesoporous pure nickel electrode increases with CV scans intenser than the observations in LSV measurements. Another abnormality is that the steady activities in LSV measurements of mesoporous NiFe oxide electrodes present the enhancing or diminishing trends with CV cycles accompanying alterations of oxidation/reduction potentials nickel in even pure NiO. CA tests of selected electrodes display mild changes as their LSV tests. In order to reveal the activity-structure relations regarding composition, the electrochemical tests should be conducted in Fe-free KOH electrolyte.

Fig.4 shows the XPS results of the samples before and after electrochemical measurements in the clean electrolyte. Studying the Fe 2p and Ni 2p spectra of these samples reveals no significant difference between them and the samples measured after immersing inside electrolyte. The observations for the Br/Ni content, and the nickel hydroxide/oxide peaks in the Ni 2p spectra can be observed here too. It is important to point out that the Br 3d peak intensity decreases for all of the samples and it has a shift towards lower binding energies.

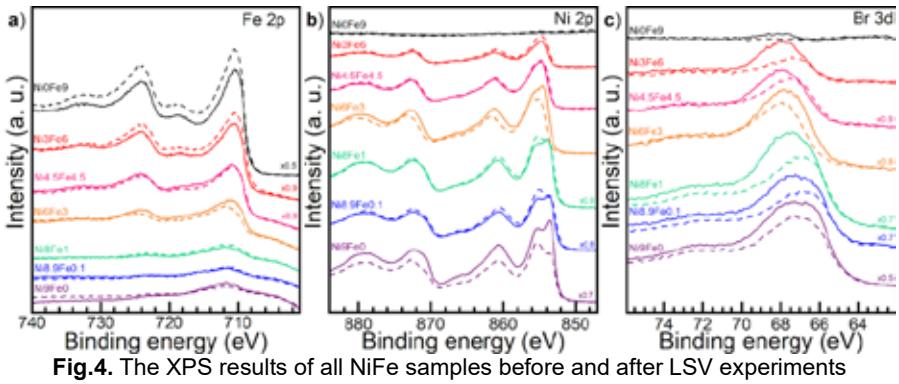

Fig.4. The XPS results of all NiFe samples before and after LSV experiments

4. CONCLUSIONS

We applied the lyotropic liquid crystalline strategy to fabricate mesoporous iron nickel oxide thin films for OER. We tuned the phase, composition, crystallinity of mesoporous iron nickel oxide. The trace content of iron yields mesoporous Fe-doped NiO and higher content of Fe promotes the formation $NiFe_2O_4$. We examined the OER activities of various phase and composition of mesoporous iron nickel oxide, including neat NiO and Fe_2O_3. The OER activity trend follows NiFeOx > $NiFe_2O_4$ > NiO > Fe_2O_3

ABSTRACT
The importance of development of fuel cell technologies is well understood in the recent years. One of the most critical components in fuel cells is the polymer electrolyte membrane (PEM). For a long time perfluorinated Nafion^{TR} membranes and their derivatives have been used as an industry standard. But since they are not suited for all types of fuel cells, costly and environmentally not friendly, alternative PEMs especially from non*fluorinated hydrocarbon-based polymers have been studied in the recent years widely. Also, the approach of developing novel composite membranes developed by the incorporation of a functional inorganic material filler having properties such as being hygroscopic, proton conductive, decreasing fuel permeability etc is a promising and preferred method. Among the polymer side, polybenzimidazole (PBI) and its derivatives are also promising materials for further development. Therefore, in this study pyridine PBI was synthesized first and characterized as the host matrix of a novel composite membrane. Then from the inorganic filler alternatives hexagonal boron nitride (hBN) was selected because of its very good intrinsic properties (having no electronic conductivity but some intrinsic protonic conductivity) suitable for a fuel cell operation. Further this hBN was also functionalized by adding functional group for increasing the synergistic effect of the composite membrane and its compatibility. In this study both the synthesis of the polymer and its characterizations, and also the synthesis of functionalized hBN and its characterization were explained. py-PBI and amine functionalized hBN were successfully prepared according to FTIR and XRD results. Then filler was used at a fixed amount to produce the composite PEM by solvent casting method and a homogeneous well-formed film was obtained. Its most important property for a potential PEM to be used in a fuel cell, which is the proton conductivity, was measured by electrochemical impedance spectroscopy.

Keywords: polymer electrolyte membrane, composite membrane, py-PBI, hexagonal boron nitride, amine functionalization

1. INTRODUCTION

The areas of use of PEM (Proton Exchange Membrane) cells are especially in hydrogen fuel cells for energy production.[1][2] PEM fuel cells stand out as devices that directly convert chemical energy into electrical energy.[3] They are used in energy storage and conversion applications due to their advantages such as high-power density, environmentally friendly features, silent operation and fast start up speeds. The purpose of using functionalized boron nitride (BN) in proton exchange membranes is to increase the performance of PEM fuel cells and reduce material costs.[4], [5] The superior thermal and mechanical stability and high proton conductivity of boron nitride play an important role in improving the poor thermal and mechanical properties of Polybenzimidazole (PBI) membranes. In this context, the addition of BN provides a lower cost and environmentally friendly alternative compared to existing perfluorinated membranes, providing a wider potential for use in energy applications.

The unique properties of hexagonal boron nitride (h-BN) have made it a focal point in fields like electronics, energy storage, and biotechnology. Its combination of high thermal conductivity and electrical insensitivity renders it suitable for thermal management and dielectric applications. Functionalization further enhances h-BN's utility by modifying its surface properties[5] Techniques such as hydroxylation, silanization, and amination are employed to boost attributes like hydrophilicity, thermal stability, and dispersibility. These enhancements improve h-BN's integration into various matrices and broaden its potential applications, particularly in proton exchange membranes (PEMs) used in fuel cells. In PEMs, h-BN serves as a reinforcing agent, improving proton conductivity and thermal stability while addressing water retention and mechanical robustness under hydrated conditions. This makes h-BN an invaluable material for advancing the performance and longevity of PEM-based fuel cells, as well as composites and catalytic systems.[6]

In this study, h-BN was functionalized with amine groups (NH_2-) through sonication method and used to obtain a composite membrane with pyridine polybenzimidazole (Py-PBI) polymer to be utilized in a proton exchange membrane.

2. MATERIALS AND METHODS

2.1. Materials

Monomers, Polyphosphoric acid (PPA,115%), 2.5-Pyridinecarboxylic acid (PCA,98%), Sodium carbonate,99.7%,3,3'-Diaminobenzidine (DAB,98%), N, N-Dimethylacetamide (DMAc), were purchased from Sigma-Aldrich and used for polymerization. H-BN was purchased from Nanografi (99.7%) and urea (99.1%) purchased from Sigma Aldrich.

2.2. Synthesis of pyridine Polybenzimidazole

Pyridine polybenzimidazole (Py-PBI) was successfully synthesized via condensation polymerization in polyphosphoric

acid (PPA) at a temperature range of 150–230°C. The process involved dissolving 3,3'-Diaminobenzidine (DAB,98%) in PPA, followed by the addition of 2,5-pyridinedicarboxylic acid in a 2000-mL Pyrex® resin reaction vessel. The polymerization proceeded under a nitrogen atmosphere with continuous mechanical stirring. The resulting polymer was precipitated in cold water and purified through sequential washing with distilled water and a sodium bicarbonate solution [6-9]. Then, the polymer is dried between 150 °C for 4 h on a hot plate. PBI poweder was obtained after grinding the dried polymer and then PBI solution was formed with DMAc. Lastly, solution casting was conducted in vacuum overn at 80°C for 14 h. The whole procedure is given on Fig.1.

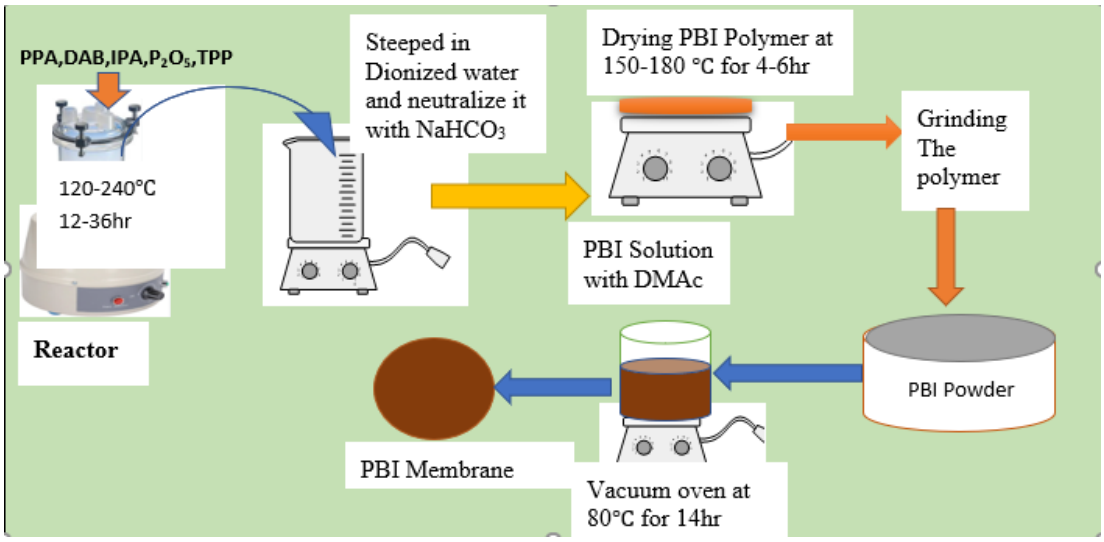

Fig. 1. A simple PBI synthesis flow diagram on a laboratory scale

2.3. NH_2-Functionalization of h-BN

The functionalization of hexagonal boron nitride (h-BN) with amine groups (NH_2) was carried out to enhance its chemical properties and compatibility with various applications. The process involved dispersing 1 g of h-BN in 100 mL of deionized water along with 60 g of urea. This mixture was subjected to ultrasonication for 1 hour to promote exfoliation and interaction between urea and h-BN. Following sonication, the BN(NH_2) suspension was centrifuged five times at 3000 rpm for 10 minutes to remove un-exfoliated h-BN. The supernatant, containing highly concentrated exfoliated BN(NH_2) nanosheets, was carefully decanted. The concentrated suspension was then filtered and thoroughly washed with ethanol and reverse osmosis (RO) water to eliminate any unreacted urea. Finally, the obtained material was dried in an oven at 60°C to obtain NH_2-functionalized h-BN.

2.4. Composite membrane of Py-PBI/h-BN

The boron nitride (BN) was functionalized, and the Py-PBI composite membrane was successfully prepared. The composite membrane was fabricated using the solvent casting method. First, 1 wt% Py-PBI polymer and functionalized h-BN were separately dissolved in 20 mL of DMAc at 150°C and 200°C for 24 hours, respectively. After dissolution, the two solutions were combined and stirred on a magnetic stirrer at 80°C for 24 hours. To ensure uniform dispersion, the mixture was then subjected to ultrasonic mixing at 60°C for 1 hour. After homogenization, 10 mL of the solution was cast onto a Petri dish. The solvent (DMAc) was gradually evaporated in a ventilated oven at 80°C for 24 hours. Finally, the dried composite membrane was carefully peeled off from the Petri dish.[6]

3. RESULTS AND DISCUSSION

The characterization of py-PBI polymer involved viscosity, thermal stability, proton conductivity, and structural analysis. The polymer exhibited an intrinsic viscosity of 1.51 dL/g and an average molecular weight of 70,999 Da.[7] Thermal analysis indicated moderate stability, with py-PBI powder retaining 76.17% residual weight at 600°C, while the undoped membrane showed lower stability at 63.72%.[8] Electrochemical impedance spectroscopy (EIS) was performed using a Gamry Instrument 3000 over a frequency range of 1 MHz to 1 Hz. Proton conductivity reached 0.26 S/cm at 120°C, making py-PBI suitable for moderate-temperature applications, though its performance declined at higher temperatures due to dehydration and structural changes.[8] FTIR analysis confirmed key structural modifications. The N-H stretching peak shifted from 3309.46 cm^{-1} to 3228.83 cm^{-1} after immersion, indicating reduced hydrogen bonding. The C=O stretching vibration at 1735.79 cm^{-1} shifted slightly, suggesting structural rearrangement, while the C-N stretching peak

(1347.9 cm^{-1}) remained stable, preserving the polymer backbone.[8][7]. In another case, the FTIR and XRD results confirm the successful functionalization of h-BN.

4. CONCLUSIONS

The successful functionalization of h-BN with amine groups (NH_2) and its integration into the py-PBI composite membrane demonstrated significant improvements in material properties. the solvent casting method enabled the uniform dispersion of functionalized h-BN within the py-PBI matrix, contributing to enhanced structural and thermal stability. Characterization results confirmed the polymer's high thermal resistance, electrochemical impedance spectroscopy (EIS) indicated a proton conductivity of 0.26 s/cm at 120°C for py-BI, making it suitable for high-temperature applications. FTIR analysis further validated the structural modifications and successful functionalization of h-BN and py-PBI. These findings highlight the potential of py-PBI/BN-11 composite membranes for advanced fuel cell and high-performance applications.

ABSTRACT
This study aims to elucidate the kinetics and reaction mechanisms of WO_3 photoanodes in water splitting reactions through structural and photo-electrochemical (PEC) characterization techniques.
In this study, we focused on the charge carrier dynamics behaviors that occur at the millisecond time regime such as charge accumulation, trapping, recombination and charge transfer. The effect of these kinetic events on the oxygen evolution reaction (OER) mechanism occurring on the WO_3 surface was investigated in different environmental and surface conditions. In this context, the different performance of nitrogen-doped WO_3 compared to plain WO_3 was investigated. Subsequently, nickel oxide (NiO), which is known to directly affect PEC performance, was deposited on the surface as a cocatalyst and its structural and photoelectrochemical tests were completed and compared with bare WO_3. Charge trapping occurring on the W sites is a critical bottleneck and can be circumvented by the cocatalyst layer.

Keywords: photoanode, WO_3, OER, charge carrier,

1. INTRODUCTION
Green hydrogen is essential for renewable energy and lowering CO_2 emissions. Using semiconductor materials, photoelectrochemical (PEC) water splitting effectively transforms solar energy into hydrogen. The goal of research is to create stable, affordable, and scalable photoelectrodes for various settings. A photoanode, a photocathode, and an electrolyte make up the PEC system. The photoanode undergoes the oxygen evolution reaction (OER), whereas the photocathode undergoes the hydrogen evolution reaction (HER)[1].
The choice of an appropriate semiconductor photoanode is essential for the advancement of PEC technology. It needs to be stable over a range of pH values, have an acceptable band gap, and absorb light efficiently. Though it has issues including sluggish charge transport and fast recombination that lower OER efficiency, tungsten trioxide (WO_3), an n-type semiconductor, is a promising candidate. Because of its complexity and energy-demanding nature, OER is the step that determines the rate in PEC applications[2].
Numerous techniques, including the introduction of co-catalysts, doping, surface passivation, and nanostructuring, are employed to increase OER efficiency. Although nanostructuring can create trap sites that result in recombination, it also improves surface area and charge separation. Although nitrogen doping increases photocurrent and light absorption, it can also result in structural disorder that alters surface states and OER efficiency. Charge utilization is still a major obstacle despite advancements in OER development[3].
It is essential to understand charge dynamics and utilizations in order to improve OER performance. It is important to examine charge behaviors such as charge accumulation, trapping, recombination, and transfer over time and at different potentials. Particularly in the millisecond-to-second time range, PEC characterization techniques are crucial for studying charge transport, recombination, and surface reactions.

2. MATERIALS AND METHODS
Experimental materials, including ammonium metatungstate hydrate, hydrochloric acid, methanol, and sodium sulfate, were obtained from Merck. FTO-coated glasses were used as substrates. For the preparation of WO_3 photoanodes, a solution of deionized water, HCl and ammonium metatungstate hydrate was mixed, transferred to an autoclave and subjected to hydrothermal synthesis at 180°C for 6 hours. The FTO substrates were cleaned and the coated films were annealed at 600°C to evaluate their properties.
For nitrogen doping, ammonia and nitrogen gases were introduced into a three-zone furnace at 425°C for 1 hour after the annealing part. NiO deposition as cocatalyst using $NiCl_2$ solution was done by using the drop-casting method under 250°C. PEC measurements were performed using a VSP-300 potentiostat with a three-electrode setup, including an Ag/AgCl reference electrode and a platinum wire counter electrode. A solar simulator with a 100 W Xe lamp was used to simulate sunlight at an intensity of 100 mW-cm^{-2}. Electrolyte solutions of Na_2SO_4 and H_2SO_4 were used for the PEC tests. The Nernst equation was used to convert the potential data to values relative to the reversible hydrogen electrode (RHE).

3. RESULTS AND DISCUSSION

Structural characterizations of the synthesized samples were conducted to investigate the material's crystal structure, absorption characteristics, defect analyses, and binding energy. A subsequent review of the results revealed that the nitrogen atom in the structure and the NiO catalyst had an impact on the material. Subsequent analysis was undertaken using PEC tests to gain deeper insights into the observed phenomena.

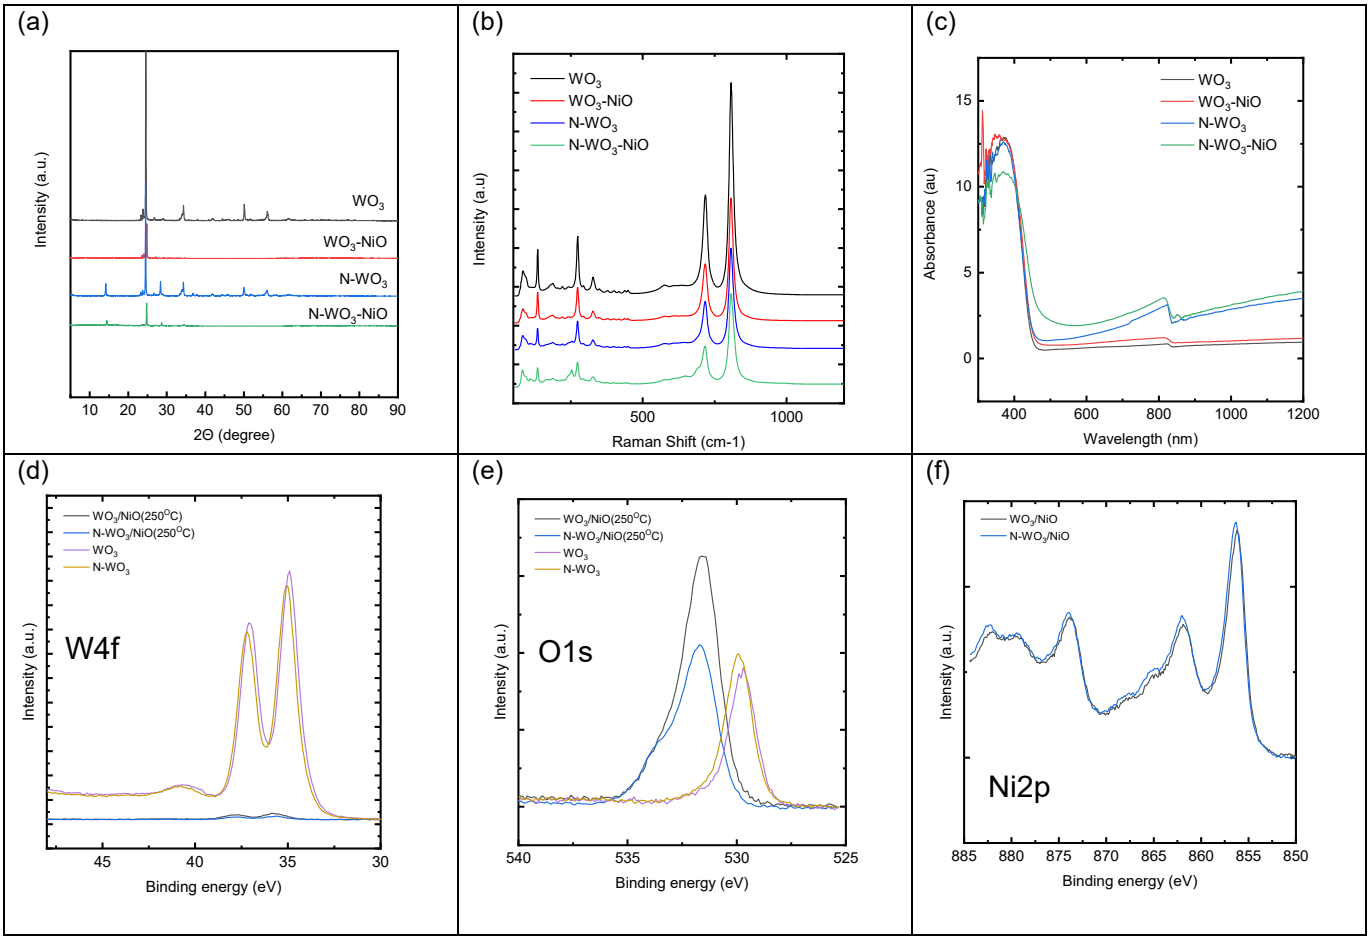

Fig.1. Structural characterizations of WO_3, WO_3-NiO, N-WO_3 and N-WO_3-NiO, (a) XRD, (b) Raman spectroscopy, (c) UV-Vis spectroscopy, (d) W 4f, (e) O 1s, (f) Ni 2p XPS

XRD and Raman spectroscopy investigations reveal that N-doping does not influence the crystal structure of WO_3. However, a small shift to higher wavelengths is observed in in UV-vis measurements, indicating that N-doping can induce a smaller bandgap. Impact of the N-doping is apparent in W 4f and O 1s XPS spectra. The absence of new XRD peaks after the cocatalyst deposition indicates that NiO overlayer is disordered. Both Raman and XPS spectral features confirm the NiO cocatalyst layer has a similar chemical composition and thickness on both WO_3 and N-WO_3.

Subsequently, all samples were subjected to a series of PEC tests. The alterations induced by the deposited cocatalyst on both bare WO_3 and N-WO_3 surfaces were investigated, leading to several conclusions. In general, the FTO-WO_3-NiO hierarchy caused an increase in thickness, resulting in weak performance in terms of charge diffusion and lower performance compared to bare WO_3. The current–voltage behavior of the photoanodes for water oxidation is shown in Fig. 2a. Linear sweep voltammograms (LSVs) show that the photocurrent density of NiO-WO_3 is significantly larger at potentials lower than 0.9 V. In addition, photocurrent onsets below 0.3 V in NiO-WO_3. A lower onset potential indicates that a smaller external driving force is required for the water oxidation reaction on NiO-WO_3 and higher photocurrent density at low potentials can be generated from the increased charge transfer rate at the interface of the photoanode/electrolyte, or reduced recombination of the charge carriers at the photoanode surface in NiO-WO_3. Howevet, the incident photon conversion efficiency (IPCE) of the NiO-WO_3 is not the highest. We investigated the charge transfer resistance at the interface of the WO_3/electrolyte using electrochemical impedance spectroscopy (EIS). Fig. 2c shows the Nyquist plots of the photoanodes under illumination. The lowest charge transfer resistance (R_{ct}) can be attributed to

an improvement in charge transfer kinetics and reduced charge recombination. NiO on both WO_3 and N- WO_3 leads to reduced R_{ct}. Electrochemical surface areas (ECSA) of the photoanodes appear to be lower after deposition of NiO cocatalyst layers.

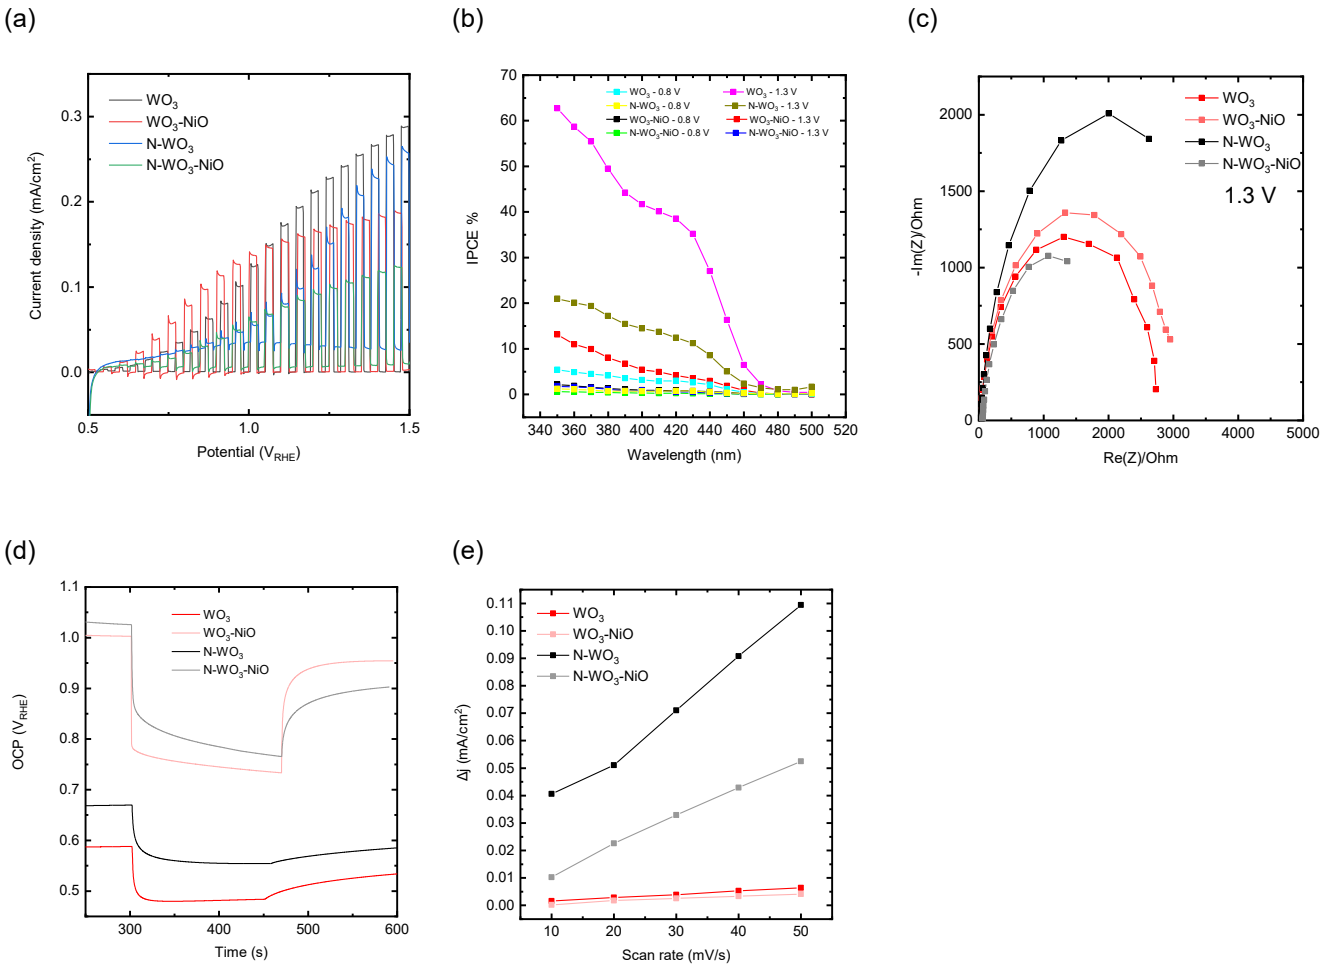

Fig.2. PEC tests, (a) LSV, (b) IPCE, (c) PEIS, (d) OCP, (e) ECSA

To better understand the effect of N-doping and NiO on the activity of WO_3, we performed transient photocurrent (TPC) measurements using a short-pulsed LED light and illuminated the photoanodes for 200 ms under different applied potentials. TPC results obtained demonstrated an increase in photocurrent with increasing potential, observed in both cases. When the light is turned on, charge accumulation was clearly evident in the bare WO_3 sample, however, this phenomenon was not observed in the N-WO_3, owing to the sluggish kinetics at the surface. This can be attributed to low mobility of charges introduced by defects and high recombination rate of N-WO_3. When the light was turned off, a negative peak was observed at low potentials, which was attributed to electron-hole recombination. Since the rate of recombination is lower at high potentials, negative peaks vanish. Furthermore, time-dependent TPC experiments were conducted in both scavenger and non-scavenger environments, thereby demonstrating the positive effect of hole scavengers on PEC performance. The hole scavenger, which has been shown to inhibit recombination events, was found to improve the charge transfer of the photoanode and increase the photocurrent.

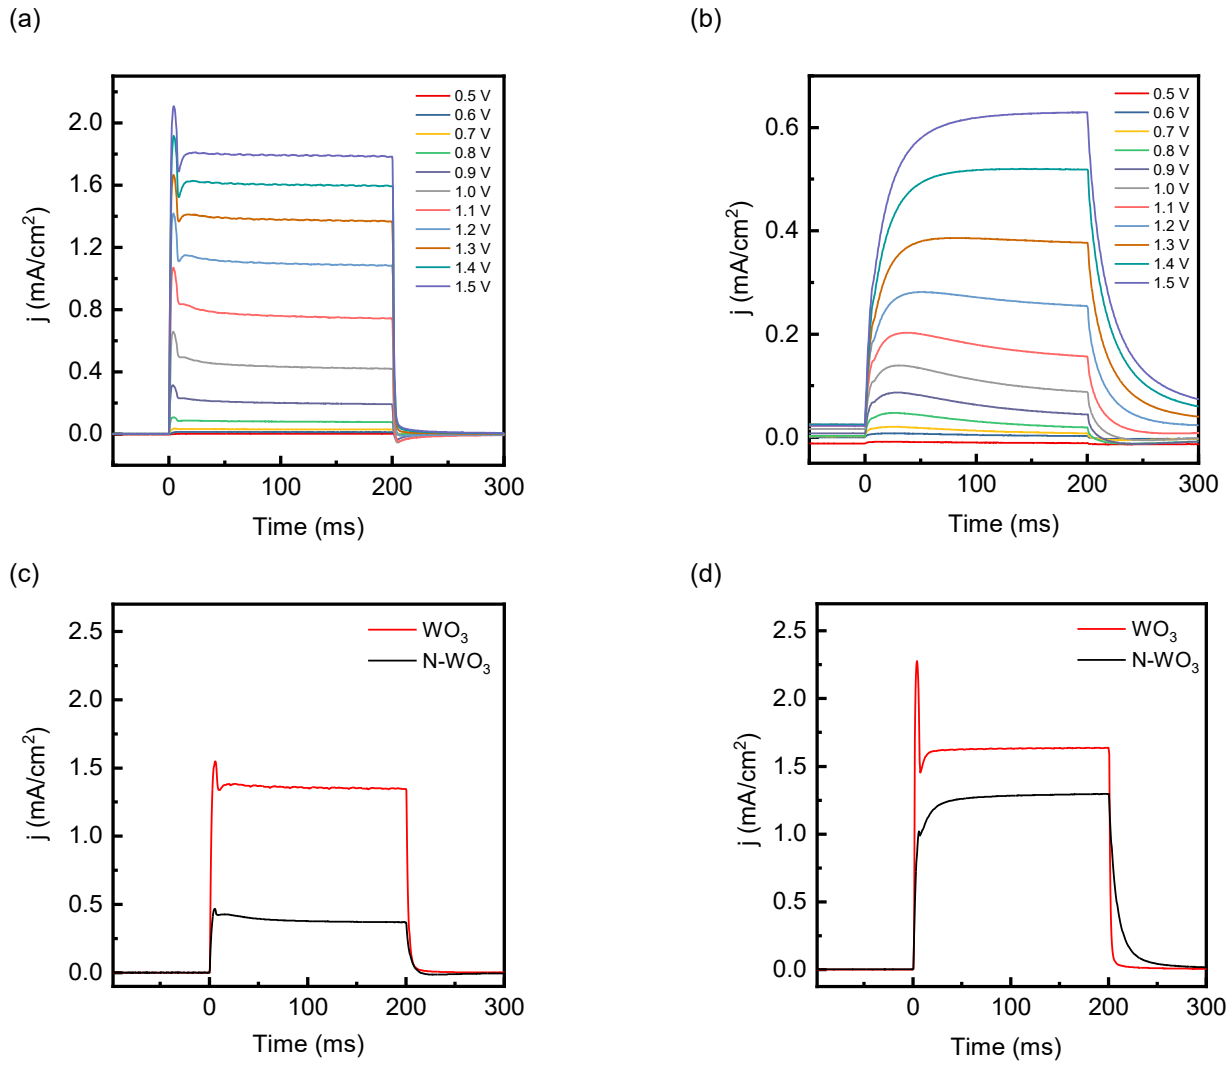

Fig.3. TPC experiments of WO_3 and N-WO_3, (a) potential-dependent TPC of WO_3 in Na_2SO_4 electrolyte, (b) potential-dependent TPC of N-WO_3 in Na_2SO_4 electrolyte, (c) TPC of WO_3 and N-WO_3 in Na_2SO_4 electrolyte, (d) TPC of WO_3 and N-WO_3 in Na_2SO_4 electrolyte with hole scavenger.

4. CONCLUSIONS

To sum up, the structural characterizations of the produced WO_3, WO_3-NiO, N-WO_3, and N-WO_3-NiO samples provide important information about their binding energies, crystal structure, absorption characteristics, and defect features. The effects of these alterations were further clarified by PEC testing, which showed that the nitrogen doping and NiO catalyst had a considerable impact on the material's characteristics. Under certain circumstances, nitrogen doping improved the photocurrent response, and NiO caused the onset potential to shift negatively, indicating better electrochemical performance for OER at lower potentials. All things considered, the results show how crucial cocatalyst alterations are for increasing photocatalytic efficiency, opening the door for more developments in material design for energy applications.

ABSTRACT
Cobalt-based molecular catalysts with polypyridyl and bis-bipyridyl ligands have been extensively studied for photocatalytic hydrogen evolution reactions (HER). While distorted ligand geometries enhance H_2 production, catalysts with ideal octahedral coordination exhibit lower efficiency. To elucidate the role of ligand structure in HER, we employed *ab initio* molecular dynamics (AIMD), density functional theory (DFT), and free energy perturbation theory to examine the reaction mechanisms of Co-based catalysts. For the pentapyridyl $CoPy_5$ complex, we simulated each intermediate of the ECEC mechanism, determining spin states and solvent responses. Although $CoPy_5$ maintains similar spin states as its distorted counterparts, its compact structure hinders H_2 diffusion, limiting catalytic turnover. Similarly, in the case of the cobalt bis-bipyridyl planar catalyst, the reaction follows two successive reductions before protonation due to an energy barrier preventing direct cobalt-proton interactions. These findings highlight the critical influence of ligand geometry on HER efficiency and provide insights for designing next-generation cobalt-based catalysts.

1. INTRODUCTION

Hydrogen (H_2) production via photocatalytic water splitting represents a promising approach to sustainable energy, utilizing solar radiation to drive the bond break in water molecules and form into hydrogen and oxygen. Unlike traditional electrolysis, which relies on electricity primarily sourced from fossil fuels, photocatalytic water reduction offers a renewable and cost-effective alternative. The core mechanism involves the excitation of a photosensitizer by photon absorption, electron transfer to a catalyst, which facilitates the reduction of water molecules into hydrogen. The electron donor present in reaction solution refreshes the photosensitizer, ensuring continuous catalytic cycles.

A key focus of recent research has been on molecular catalysts having transition metals for the hydrogen evolution reaction (HER) in solution. While noble metals such as platinum (Pt) and ruthenium (Ru) exhibit excellent catalytic efficiency, their high costs hinder large-scale application. Consequently, cobalt (Co)-based catalysts have emerged as a viable alternative due to their abundance and relatively lower cost. Polypyridyl cobalt complexes have gained significant attention for long-term stability and activity. The coordination environment of the cobalt center, determined by ligand symmetry and steric effects, plays an important role in determining effective HER activity.

HER mechanisms of a cobalt-based pentapyridyl molecular catalyst ($CoPy_5$) were studied using advanced computational methodologies, including Ab-initio Molecular Dynamics (AIMD) and Density Functional Theory (DFT) [1,2]. Previous experimental studies have demonstrated the stability and hydrogen generation efficiency of $CoPy_5$, achieving turnover numbers (TON) exceeding 1200 H_2/Co under specific reaction conditions [3]. Our theoretical approach provides critical insights into the stepwise electron transfer and protonation events (ECEC), elucidating the influence of ligand geometry on catalytic efficiency [1]. Furthermore, our study explores the EECC (electron-electron-proton-proton) mechanism of HER for the $CoPy_5$, assessing how variations in spin multiplicity and ligand coordination impact the reaction pathway [2]. Our findings reveal that the proton transfer dynamics are significantly influenced by the steric arrangement of pyridyl ligands, with an ideal octahedral coordination leading to a comparatively lower hydrogen production rate than its distorted counterparts. We also analyze the role of solvent interactions, particularly the diffusion behavior of hydroxide (OH^-) ions, in advancing the proton transfer in the close vicinity of the Co.

Furthermore, in our previous work, we explored the EECC (electron-electron-proton-proton) mechanism of HER for a catalyst having Co as reaction center and bis-bipyridyl ligands, $Co(bPy)_2CO$, assessing how variations in spin multiplicity and ligand coordination in this catalyst impact the reaction pathway [4]. Notably, the $Co(bPy)_2CO$ complex exhibits a distinct preference for the EECC mechanism which was verified using Metadynamics simulations. We also analyze the role of solvent interactions, particularly the diffusion behavior of hydroxide (OH^-) ions, in advancing proton transfer in the close vicinity of the Co.

Overall, our research contributes to the broader understanding of photocatalytic water splitting by shedding light on the mechanistic aspects of cobalt-based catalysts. By bridging theoretical and experimental insights, we aim to advance efficient and cheaper design of photocatalysts for sustainable hydrogen production.

2. MATERIALS AND METHODS

AIMD simulations were conducted to model the intermediate states of both ECEC and EECC mechanisms for the H_2 production through water splitting for the $CoPy_5$ catalyst. All simulations were performed using the open-source CP2K simulation package [5]. The PBE density functional in the generalized gradient approximation (GGA) formalism was applied for the AIMD simulations [6]. GTH pseudo-potentials [7] were used and only valence electrons were explicitly modeled. The DZVP-MOLOPT basis set [8] was employed and a cutoff of 400 Ry was utilized in all simulations. Dispersion interactions were accounted for using the rVV10 density functional [9]. Simulation cells were always extended in x-y-z directions and spin polarization were always taken into account.

We analyzed HER mechanisms for the $Co(bPy)_2CO$ catalyst, namely ECEC and EECC. The initial protonation step of the ECEC was modeled using metadynamics (MTD) simulations, a well-established technique for simulating rare events over shorter timescales. The catalysts were immersed in a cubic simulation box containing 215 water molecules. The simulation box volumes were optimized applying AIMD-NPT simulations. Following, each reaction step was simulated using AIMD-NVT simulations. AIMD time step was set to 0.5 fs. The simulation temperature was kept fluctuate around 300 K using the CSVR thermostat [10]. For more details on our computational approach, see Refs. [1-2, 4].

3. RESULTS AND DISCUSSION

We first start with the results obtained for the $CoPy_5$ catalyst. The first step of the ECEC reaction mechanism involves the first electron injection. This step was simulated by injecting one electron into the system while modeling both singlet and triplet spin states of the Co center. In the triplet spin, a stable coordination between a water molecule and the Co center is maintained throughout the simulation, with minimal conformational changes. In contrast, for the singlet spin, the closest water molecule undergoes a conformational change, forming a Co-H+ bond, and a second water molecule interacts with the reaction center which is a necessary step for the first protonation. The second of the ECEC mechanism is the first protonation, where a proton from the closest water molecule binds to the Co center, forming a stable Co-H hydride. This process is accompanied by the formation of an H_3O+ ion, and the proton remains stable at the Co center throughout the simulation. The third step, the second electron injection, was modeled for both doublet and quartet spin. In the doublet state, only one proton coordinates with the Co-H hydride, while in the quartet state, both protons from surrounding water molecules interact with the Co center. This suggests that the H_2 production reaction proceeds more favorably in the quartet spin due to the increased availability of protons. The final step is the second protonation, leading to H_2 molecule formation. The H_2 molecule remains stable at around 0.8 Å in bond distance, but struggles to diffuse away from the Co center due to the tight coordination and surrounding water molecules in the $CoPy_5$ catalyst. This reduced diffusion of the H_2 molecule explains the lower activity observed for $CoPy_5$ compared to more distorted catalysts, which are summarized in [1]. Our analysis for the EECC mechanism of the $CoPy_5$ catalyst also reveals the similar restricted diffusion of the produced H_2 molecule, for more details, see [2].

The Co center of the $Co(bPy)_2CO$ complex exhibited a doublet spin multiplicity and a +2 charge, maintaining a planar structure with Co–N distances around 1.90 Å. After geometry optimization, the catalyst was placed in water, where two water molecules coordinated with the Co center, maintaining stable Co–O_{wat} distances of ~2.25 Å during AIMD simulations. Electron injection was simulated for both singlet and triplet spin, with no conformational changes observed in the water molecules near Co [4]. However, an energy barrier prevented water molecules from changing conformation, hindering the protonation step in the ECEC mechanism. The second intermediate step of the ECEC meshanism, protonation, did not lead to Co-proton coordination, which hinders protonation reaction. Thus, an energy barrier has to be overcome in order for the water molecule to change its conformation and to exemplify the system in which the Co-H^+ bond is established. Thus, we modeled direct coordination of Co and the protons of the water molecules applying independent metadynamics (MTD) simulations having different collective variables (CVs). For the first MTD simulations the coordination numbers between Co and the nearest two proton were chosen as collective variables, see Fig. 1-(a). When the H is close to Co, the coordination number (CV1) is 1, and when they are farther away, the coordination number is 0. Snapshots taken from the MTD simulations carried out for the singlet spin are depicted in Fig. 1-(a) and Fig. 1-(b). At the starting of the MTD, oxygens have direct coordination with the Co center. As MTD simulations prolong, water molecules changes their coordinations allowing proton-Co coordination. However, H_{wat1} and H_{wat2} periodically approach and move away from the Co center, see Fig. 1-(c). At 0.3 ps, Co-H_{wat1} and Co-H_{wat2} decrease to 1.5 Å, while at 0.6 ps corresponding distances increase to 3.5 Å. The hydrogens spend more time away from the Co atom and they change their conformation again as soon as their distance with Co decreases to 1.5 Å. The snapshots taken from the MTD trajectory of the triplet spin are provided in Fig.2-(a) and Fig. 2-(b). As in the case of singlet spin, the distances between Co-H_{wat3} and Co-H_{wat4} oscillates between 1.5 Å and around 3 Å, as depicted in Fig.2-(c). Throughout the simulation, H_{wat3} and H_{wat4} simultaneously approach and move away from the Co center periodically and show the same fluctuating behavior as in the singlet spin case. At around 0.3 ps, the Co-H_{wat3} and Co-H_{wat4} distances decrease to 1.5 Å, while at 0.6 ps the distances again increase to 3 Å. Similarly, it is seen that the distances decrease to 1.5 Å at 0.9 ps. The reason for the increase in the Co-H_{wat3} and Co-H_{wat4} distances is the establishment of direct coordination between the O_{wat3} (O_{wat4}) and the Co center. The other protons in the solvent do not reach to the Co center.

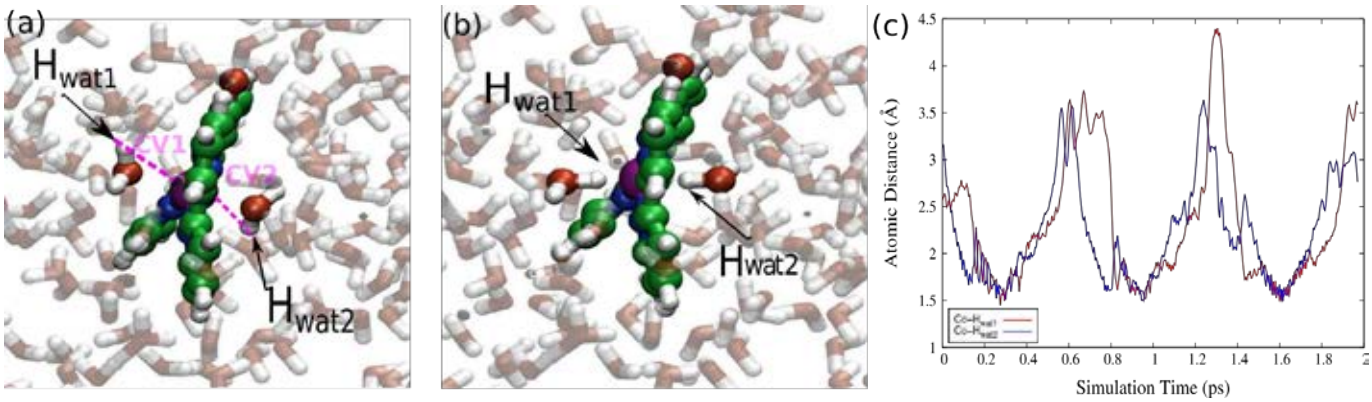

Fig. 1. Snapshots taken from the MTD trajectory of the singlet spin state of $Co(bPy)_2CO$ (a) obtained at the 0.1 ps simulation time and (b) 0.27 ps simulation time. The coordination number between Co and H_{wat1} is labeled as CV1, and coordination number between Co and H_{wat2} is labeled as CV2 in (a). (c) Interatomic distances between Co-H_{wat1} and Co-H_{wat2} are shown with red and blue lines, respectively.

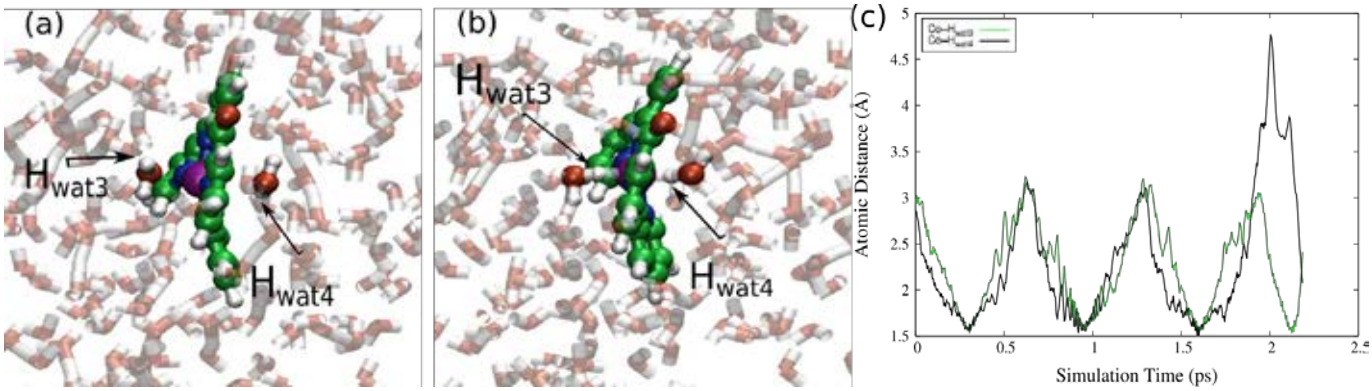

Fig. 2. Snapshots taken from the MTD trajectory of the triplet spin state of the $Co(bPy)_2CO$ (a) obtained at the 0.1 ps simulation time and (b) 0.3 ps simulation time. (c) Interatomic distances between Co-H_{wat3} and Co-H_{wat4} are shown with green and black lines, respectively.

Further MTD simulations for the singlet spin were conducted with modified collective variables (CVs). The goal was to maintain a stable Co-H coordination, so we defined the first CV (CV1) as the coordination number between Co and the proton of the closest water molecule (H_{wat1}). For the second CV (CV2), we chose the coordination number between the oxygen atom of H_{wat1} and the proton of a neighboring water molecule in the solvent. This new set of CVs was designed to better capture the stability of the Co-H coordination during the simulation. Energy barrier for establishing Co-H^+ direct coordination was calculated as 0.3 eV. The energy barrier hindered protonation in the ECEC mechanism, but protonation occurred more readily in the EECC mechanism, especially for the doublet spin. For the EECC mechanism of the Co(bPy)2CO, after a second electron injection into the Co center, we obtained steady Co-H^+ direct coordination followed by protonation of the Co center. The last step involved the protonation and the successful formation of an H_2 molecule, with Co–H_2 distances fluctuating around 4.5 Å. This contrasts with the results obtained for $CoPy_5$, which showed restricted H_2 diffusion due to compact ligand structure. For more details on the results, see Ref. [4].

4. CONCLUSIONS

We investigated the H_2 production mechanism of the $CoPy_5$ catalyst with a penta-pyridyl ligand in an octahedral arrangement, using AIMD and DFT simulations in water. The singlet spin favored proton bonding with Co due to a positional change in the closest water molecule, unlike the triplet state. During protonation, Co received a proton from the solvation shell water molecule, forming an OH^- anion that hydrogen bonds with the solvent. For the reduction step, the reaction proceeded with the quartet spin due to proton coordination. The final step showed H_2 formation, but steric hindrance from the compact structure of $CoPy_5$ limited H_2 diffusion, potentially acting as the rate-limiting step [1]. The EECC mechanism also revealed the similar restricted diffusion for the produced H_2 [2]. Investigation of the H_2 evolution mechanism of the $Co(bPy)_2CO$ catalyst, featuring a planar structure, in explicit water revealed that after the first reduction, energy barriers in the singlet and triplet spin prevent water molecules from changing conformation and coordinating with Co. MTD simulations showed a 0.3 eV barrier for direct Co-proton coordination, essential for the first protonation (ECEC). In the EECC pathway, Co-H^+ coordination was established following the second reduction, allowing proton coupling for the first protonation in the doublet spin. Following the last protonation, H_2 formed and diffused into the solvent, as

summarized in [4]. The planar catalyst follows the EECC mechanism, forming H_2 and enabling its diffusion. The study highlights how ligand type and coordination influence reaction mechanisms, aiding the design of efficient H_2 production catalysts for sustainable energy.

ABSTRACT
Lithium-ion battery capacity forecasting is critical to optimizing energy storage devices, and equivalent forecasts for fuel cells are needed to attain power generation efficiency and extended system lives. The current research used discharge data with lithium-ion battery capacity values to create four single time-series data sets, of which 10 features per series were created, resulting in 40 feature matrices. Both linear regression and Long Short-Term Memory (LSTM) models were used to predict battery capacity. The linear regression model worked with an RMSE of 0.0058, and the LSTM-based model was compared based on RMSE and loss function metrics. The results indicate the possibility of applying these methods to predict capacity accurately. The proposed approach sets a foundation for subsequent optimization and adjustment toward fuel cell data for more stable prediction and better control over the energy system in future work.

Keywords: Capacity prediction, Linear regression, LSTM model, Fuel cell data

1. INTRODUCTION
Lithium-ion batteries (Li-ion) are widely used in various applications, from electric vehicles to renewable energy storage systems, due to their high energy density and long cycle life [1]. One key element of maximizing such batteries' performance and longevity is accurately forecasting their capacity over time [2]. A battery's ability, i.e., its energy storage and delivery capacity, decreases over usage. Hence, capacity prediction becomes critical for effective energy management and battery life extension [3]. Capacity forecasting can assist in planning maintenance, reducing battery lifespan, and improving system reliability by preventing sudden failures [4].

The same capacity prediction methods can be used for fuel cells, which are increasingly considered a sustainable energy alternative to traditional sources [5]. Fuel cell technologies like lithium-ion batteries utilize future performance prediction to optimize power output and manage energy storage systems. The data and feature extraction techniques used in battery capacity prediction [6] can also be applied to fuel cell data, giving more accurate energy storage and fuel efficiency models.

Linear regression and long short-term memory (LSTM) models have been used in the current research for capacity estimation. Linear regression is used where the dataset size is small, not intricate, and needs quick outputs with minimal computation [7]. However, with more extensive and complex datasets, LSTM models are helpful [8] since they can learn and discover latent temporal patterns of time-series data. Applying these models, this study examines how capacity forecasting can be improved, not only for lithium-ion batteries but also potentially for fuel cell usage in the future.

2. MATERIALS AND METHODS
The study aims at predicting the lithium-ion battery capacity using time-series discharge data. The approaches employed are extracting features from the data and applying Linear Regression for small data sets [9] and LSTM models for big, complex data sets to improve the accuracy of capacity prediction.

2.1. Data and Feature Extraction
The capacity values of the discharge data were extracted from the.mat file. Four time-series datasets were prepared differently, and 10 features were extracted from each of the four datasets, resulting in 40 feature matrices. The matrix form to extract the voltage feature is presented below:

[mean(Discharge_voltage),std(Discharge_voltage),min(Discharge_voltage),max(Discharge_voltage), rms(Discharge_voltage),var(Discharge_voltage),skewness(Discharge_voltage),kurtosis(Discharge_voltage), abs(var(Discharge_voltage)), geomean(abs(Discharge_voltage))]

Other features were similarly extracted for current, voltage load, and current load. Ultimately, the final feature matrix was constructed as follows:

features = [voltage_features, current_features, voltage_load_features, current_load_features] labels_for_regression = capacity

2.2. Linear Regression

Linear regression is a statistical modeling technique that aims to make predictions by relating a dependent variable (Y) to one or more independent variables (X). The model learns the linear relationship between the data and makes predictions using these relationships.

Basic Concepts:

• Independent Variable (X): Variables used for the model to make predictions. These variables are considered input data in the model.

• Dependent Variable (Y): The predicted or modeled output. In other words, the variable that the linear regression model tries to predict.

The general model of the method is given as follows. Here, $\beta 0$ represents the constant term (intercept), $\beta 1, \beta 2, \ldots, \beta n$, the regression coefficients (the parameters that the model is trying to learn), and ϵ represents the error term (the model's estimation error).

$$Y = \beta 0 + \beta 1 X1 + \beta 2 X2 + \cdots + \beta n Xn + \epsilon \quad (1)$$

Linear regression uses the least squares method to minimize the squares of the error terms in the data. The goal is to find the linear model that best represents the relationship between independent and dependent variables. It is frequently used in economic forecasting, biomedical research, and machine learning applications. The benefits of linear regression are that it is simple and easy to comprehend, rendering it a suitable model for many uses. It is also computationally efficient, thus enabling fast predictions when working with small datasets. Another plus is that it offers interpretable outcomes since the relation between the input variables and the output is understandable and easy to grasp. These characteristics make linear regression an attractive option for applications where model interpretability and computational efficiency are important.

2.3. Long Short-Term Memory (LSTM)

LSTM is a member of the deep learning and recurrent neural networks (RNN) family and is used especially in predictions made with time series data and sequence data. LSTM can learn long-term dependencies based on past information, which makes it extremely effective on sequential (ordered) data. LSTM is a powerful tool for time series analysis. If changes in data over time and past events are critical for future predictions, the LSTM model can be used. LSTM allows for more accurate forecasts by capturing long-term dependencies in time series data. LSTM will be effective in cases where predictions will be made based on the past performance of some systems. LSTM is an RNN architecture optimized to handle time-series data and efficiently learn long-range dependencies. The fundamental structure of LSTM includes memory cells, which retain information over time and affect future predictions by remembering past information for long periods. LSTM cells possess three main gates: the Forget Gate, which determines what information from the past must be forgotten; the Input Gate, which determines if new information is to be included in the memory; and the Output Gate, which determines how much of the previous information will be included in the model's output. The main advantage of LSTM over other RNNs is the ability to learn long-term dependencies using these gates, resulting in more stable and long-term learning. This is extremely helpful for time-series data, where historical data points are essential to make accurate future predictions. LSTM is applied in various contexts, from time-series prediction like financial market predictions and weather forecasting, natural language processing like text generation and language translation, healthcare for patient monitoring and biomedical data analysis, and gaming or simulation for sequence-based data analysis. Although it has some advantages—e.g., it can capture long-term dependencies, provide strong performance with sequential data, and learn effectively—LSTM also has disadvantages, e.g., longer training time, increased computational requirements, and potential interpretability problems due to its complexity. The study divided the dataset into 80% training and 20% testing. The hyperparameters used for the created model are given in Table 1.

Table 1. Hyperparameters for the model

Hyperparameters	Space	The best hyperparameters
numHiddenUnits	[50 100 200 500]	100
optimizer	["sgdm" | "rmsprop" | "adam" | "lbfgs"]	"adam"
'MaxEpochs'	[100 200 500 1000]	Justification: justified 1000
'MiniBatchSize'	[8 16 32 64 128]	128

3. RESULTS AND DISCUSSION

According to the results obtained from linear regression, the actual and estimated capacity results are obtained as in Fig. 1. RMSE for linear regression was obtained as 0.0058.

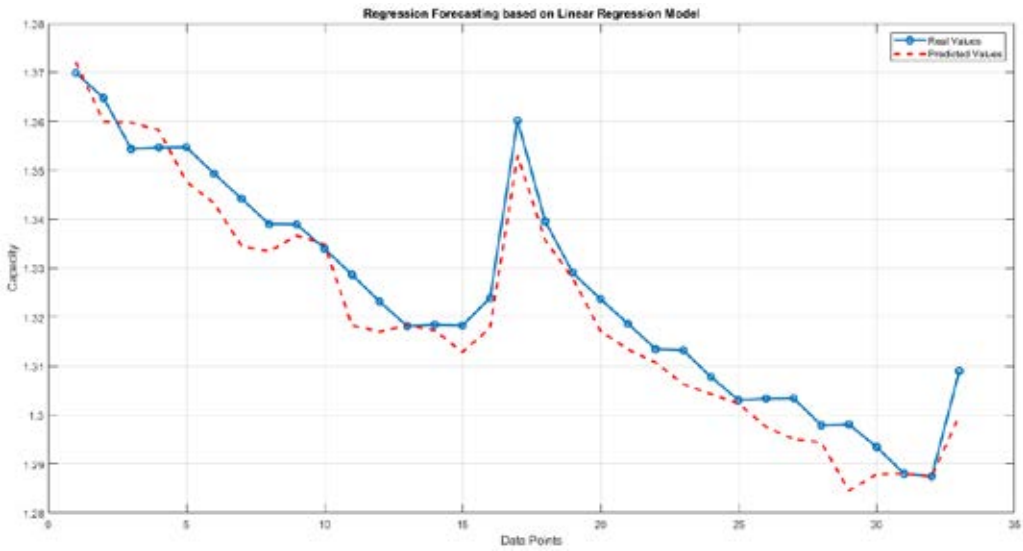

Fig. 1. Estimation of linear regression model

The model created based on LSTM was evaluated using RMSE and Loss function metrics. The graph showing the training process of this model is given in Fig. 2.

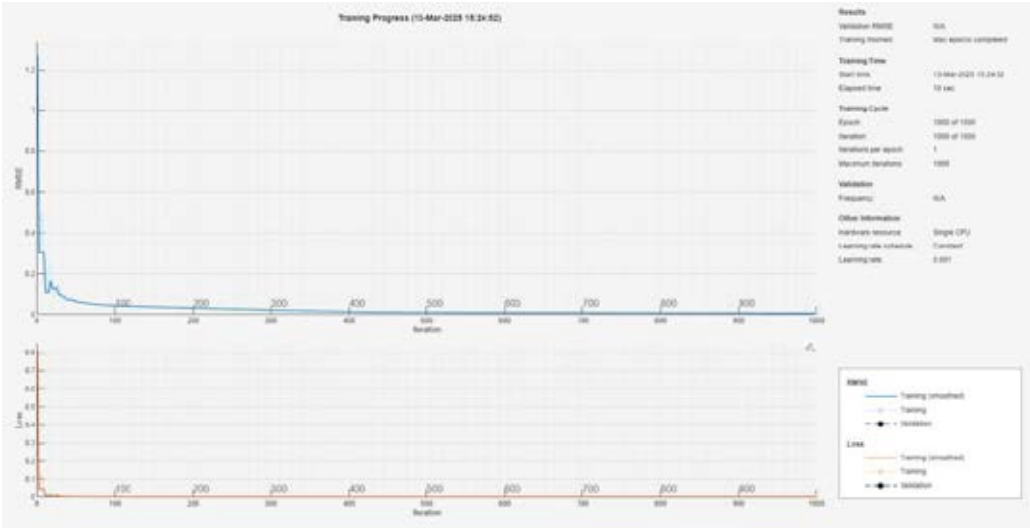

Fig. 2. Training process of LSTM method

According to the results obtained from LSTM regression, the actual and estimated capacity results are given in Fig.3. RMSE for LSTM Regression was obtained as 0.01.

Fig. 3 shows that, albeit slightly, LSTM is obtained with a higher RMSE between the two methods. The effective factors here are as follows: optimization based on these will improve the result. There are many reasons why LSTM has a larger RMSE (Root Mean Squared Error) than linear regression. Data inadequacy is one of the main reasons, as LSTM models need large volumes of data to learn and generalize well. When there is limited data, the learning ability of the model is hindered, thus tending to overfit, i.e., concentrating too much on the noise in the training data, which causes it to perform poorly on test data. Also, the complexity of LSTM models, with numerous parameters, can be troublesome when working with small datasets because the model may not use its capacity and may learn spurious patterns or noise.

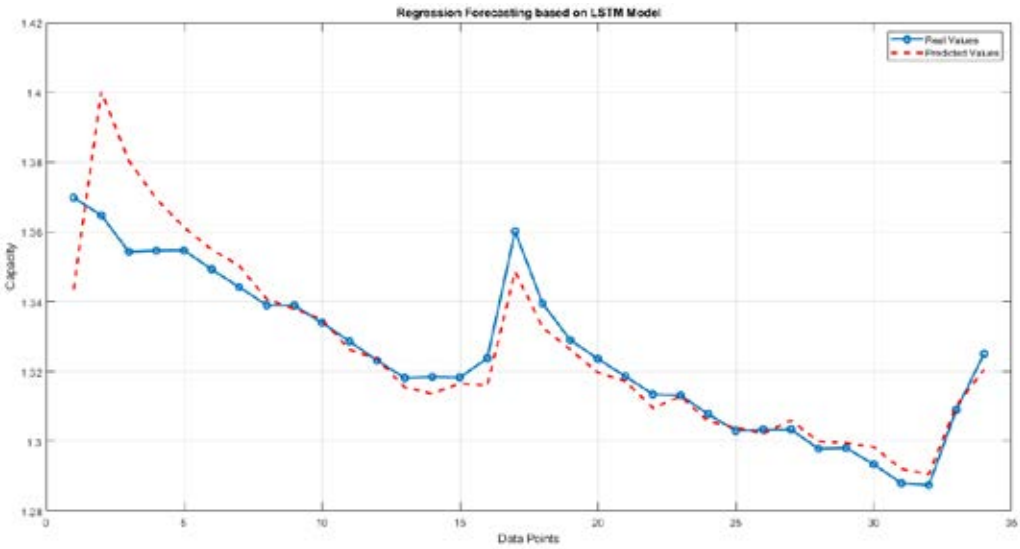

Fig. 3. The actual and estimated capacity results of the LSTM method

The training process and hyperparameters, such as learning rate and training time, can also influence performance. If the learning rate is too high, the model will overshoot the optimal values, and too little training can prevent the model from adequately learning, increasing the error. Conversely, linear regression, a simpler model with fewer parameters, will do better on smaller datasets as it will not overfit and is very well suited to learning linear relationships. Also, when the data does not have strong temporal relations, LSTM's advantage does not get very far, while linear regression might still do better in such cases. Finally, erroneous hyperparameter tuning like batch size, epochs, and dropout can disrupt LSTM's learning. In the case of small datasets, it would be more rewarding to use simple models like decision trees or linear regression instead of complex models like LSTM.

4. CONCLUSIONS

This study created features for lithium-ion batteries and capacity prediction using linear regression and the LSTM model. The findings were that while linear regression performed slightly better with low datasets, LSTM's intricate framework could potentially use more extensive and complicated datasets. The difference in performance between the two models can be attributed to LSTM's ability to capture long-term dependencies in time-series data but inefficiency with small datasets because it is susceptible to overfitting and needs more data. The presented method will be extended in the future to use a fuel cell dataset and optimization methods toward better prediction accuracy. This could potentially render the model more usable, solid, and realistic in form for application in energy storage systems. Through the development of these methods, the research hopes to make a positive impact toward even more efficient and accurate predictive models of energy systems, paving the way for further innovations in energy management and technology.

ABSTRACT
Anion exchange membrane electrolyzers (AEMEs) are gaining attention for their potential to enable cost-effective and sustainable hydrogen production by combining the benefits of alkaline water electrolyzers (AWEs) and proton exchange membrane electrolyzers (PEMEs). However, optimizing their efficiency requires an in-depth understanding of two-phase flow characteristics and thermal effects. This study presents a numerical analysis of how different flow channel geometries influence mass transport and electrochemical performance in a non-isothermal AEM electrolyzer. A computational model was developed using COMSOL, incorporating electrochemical kinetics, gas-liquid phase interactions, and heat transfer. Various serpentine flow fields were examined to assess their impact on gas removal, ion conductivity, and temperature distribution. The findings demonstrate that multi-serpentine counter-flow configurations promote uniform temperature distribution and improved ionic conductivity, whereas single serpentine designs enhance gas bubble detachment. The polarization curve obtained from the simulations closely corresponds with experimental results from the literature, validating the model's accuracy in predicting electrolyzer behavior. These insights contribute to optimizing AEM electrolyzer designs, advancing their practical implementation in hydrogen production technologies.

Keywords: Anion exchange membrane electrolyzer, two-phase flow, flow channel configurations

1. INTRODUCTION

Anion exchange membrane electrolyzer (AEME), a modern technology that combines the advantages of alkaline water (AWE) and proton exchange membrane (PEME) electrolyzers, is the vital solution for the mentioned issue regarding the mentioned electrolyzers. Although AEME offers low-cost and sustainable H_2 production, studies of these types are still limited and impossible in commercial production. From open literature, most studies aimed to improve the performance and efficiency of AEME. This objective is achieved by minimizing component-based overpotential losses, which focuses on catalyst and membrane development and relies laboriously on experimental methods. Regarding catalyst influencing, the studies specifically focused on the oxygen evolution reaction (OER) catalyst layer, revealing the impact of critical properties such as catalyst conductivity, morphology, and catalyst layer resistance on performance [1]. These studies emphasize the importance of anode design using commercial ($NiFe_2O_4$) and custom-synthesized (Ni_8Fe aerogel) catalysts. For advanced membranes, the studies highlight the importance of membrane properties, such as ionic conductivity, physicochemical stability, mechanical durability, and compatibility with non-precious metal catalysts in improving the performance and sustainability of AEME [2]. Furthermore, the studies employed commercial catalysts in AEME to reduce the structure cost [3]. The other key parameters that play a vital role in current density and efficiency, especially in optimizing mass transport processes, are the design and properties of gas diffusion layers (GDL). The material composition, porosity, thickness, and manufacturing method are the parameters used to explore the GDL performance [4].

In addition to experimental studies, modeling is a powerful tool for analyzing complex interactions of phenomena in electrolyzers, especially when investigating the effects of electrochemical reactions, dual-phase interactions, and changing operating conditions on performance. This method provides a better understanding of physicochemical phenomena occurring within the system and provides a basis for system analysis, control, and optimization. Furthermore, simulation of the electrolyzer decreases the time-consuming, costly nature of experimental processes and recreates a critical role in determining the optimum design and operating conditions. Although these simulation studies provide valuable information in understanding the electrochemical nature of electrolyzers, experimental studies are also required to ensure the accuracy and reliability of the simulation results. Recently, researchers have shown increasing interest in parallel conducting experimental studies and modeling analyses [5]. The significance of these kinds of studies is associated with exploring the AEME optimum flow channel design. The design of flow channels directly affects water and gas flows to the reaction zones and efficiently removes formed products, including O_2 and H_2 gases, from the system. Extensive research has been conducted on the design of electrolyzer flow field structures, particularly for AWE and PEME [6]. The parameters are explored to understand their influence on the electrolyzer performance and durability, including the distribution of flow, velocity, temperature, pressure, and separation phenomena bubbles [5, 6]. On the other hand, the study of the flow structure of AEME is yet in the premature stage and is not ready for commercial utilization. Therefore, further studies on the design flow structure of AEME are an urgent necessity to address a reliable unified conclusion on the effect of flow field structure on the performance of AEME and to support selecting the best one from different criteria. This study contributes to the AEME field by investigating the effects of different flow channel geometries on two-phase flow dynamics in a non-isothermal AEM electrolyzer cell. Through modeling, it seeks to understand how variations in

channel design influence gas bubble behavior, mass transport, and overall cell performance under realistic operating conditions. Furthermore, this research will provide valuable insights into optimizing flow channel configurations to enhance the efficiency and effectiveness of AEM electrolyzers. By integrating these findings, efficient and cost-effective AEM electrolyzers can be developed, thereby advancing the practical implementation of hydrogen as a clean energy carrier.

2. MATERIALS AND METHODS

This study presents a comprehensive numerical model developed in COMSOL to analyze two-phase flow effects in a non-isothermal AEM electrolyzer. The model incorporates electrochemical reactions, gas-liquid interactions, heat transfer, and varying flow channel geometries to assess hydrogen production performance. As shown in Fig 1, the 3D electrolyzer cell consists of porous gas diffusion electrodes (GDEs) facilitating electrochemical reactions and gas transport, an anion exchange membrane (AEM) ensuring ion conduction, and different flow channel configurations directing electrolyte flow and gas removal.

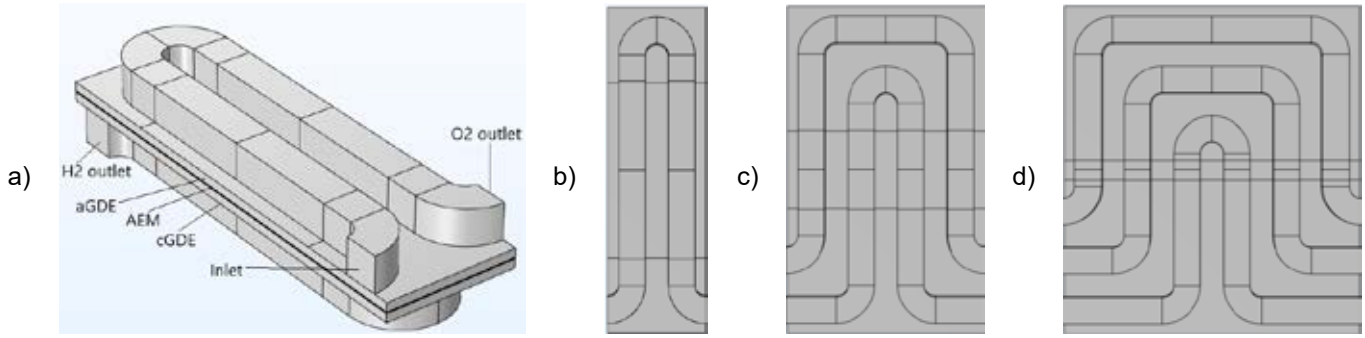

Fig. 1. a) 3D representive model b) 1-path serpentine channel c) 2-path serpentine channel d) 3-path serpentine channel

The mixture model in COMSOL was employed to simulate the two-phase gas-liquid interactions within the electrolyzer. This approach treats the gas phase as a dispersed component within the liquid electrolyte, allowing for the prediction of gas bubble distribution, volume fraction, and transport dynamics. The model effectively captures the influence of different flow channel geometries on gas removal efficiency and overall cell performance. To simplify the model, the following assumptions were made: (1) steady state condition, (2) ideal gas, (3) laminar flow in the channels, and (4) porous media flow in GDEs.

Table 1 shows the modelling parameters, and Table 2 presents the governing equations used in the current modelling simulations.

Table 1. Modelling parameters used in COMSOL simulations

Parameters	Value
GDEs thickness	0.2mm
GDEs width	10mm
AEM thickness	70µm
Channel width	0.7mm
Channel height	0.8mm
Anode and cathode exchange current densities	$i_{0,an}$=0.256 A/m^2, $i_{0,cat}$=8.885 A/m^2
Anode and cathode transfer coefficient	α_{an}= 0.5, α_{cat}=0.5
GDE porosity	0.7
GDE permeability	1e-10m^2
Inlet flow velocity	0.01m/s
Outlet pressure	25atm
Electrolyte concentration	1M
Electrical conductivity of GDE	1E5 S/m
Applied cell voltage	1.5-2.1V

3. RESULTS AND DISCUSSION

In the current study, the obtained polarization curve is in strong agreement with the experimental data published by Liu et al. [7]. In particular, the effects of critical factors such as gas bubble transport and ion conductivity on cell performance exhibit similar trends. These results support the reliability and accuracy of the current model and provide valuable information for the optimum structure of flow channel geometries and the improvement of electrolyzer design.
All the results obtained should be discussed in detail.

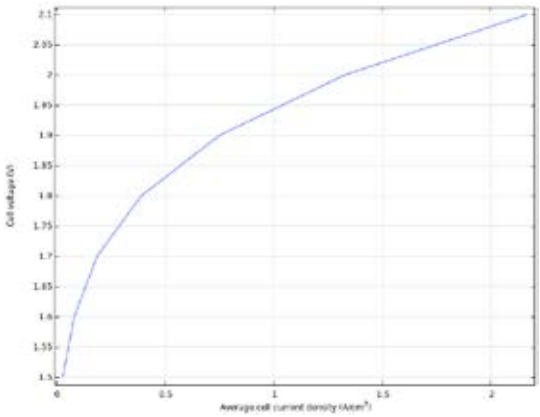

Fig. 2. Polarization curve of current modelling

a) b) c)

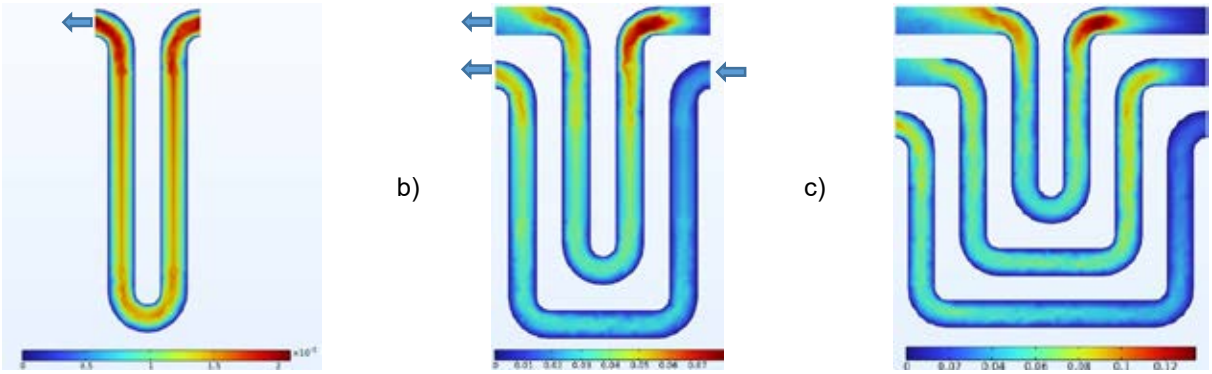

Fig. 3. Velocity magnitude (m/s) over cathode channels

a) b) c)

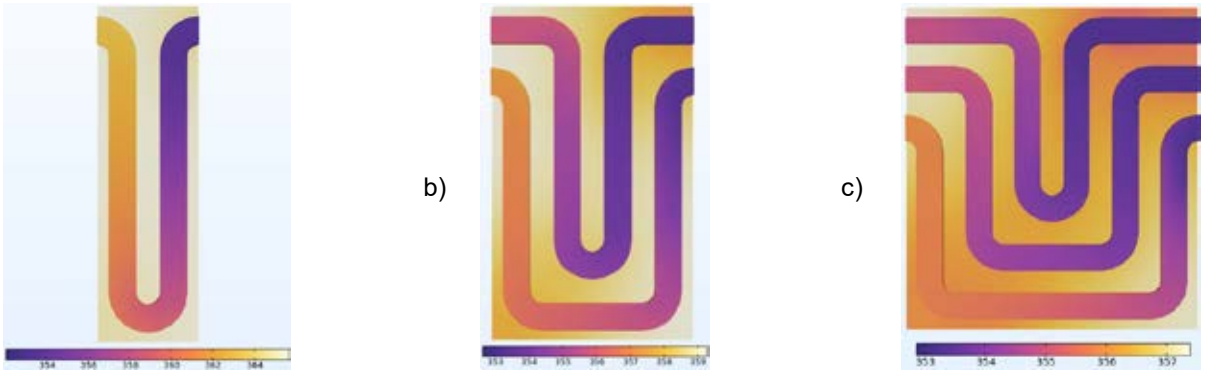

Fig. 4. Temperature distribution (K) over cathode side domains

Fig.3 indicates that increasing the number of serpentine channels (from single to double and triple) resulted in diminished performance. This decline is likely due to the division of electrolyte flow among multiple channels, reducing the flow rate in each and impairing the efficient removal of gas bubbles. Consequently, gas accumulation occurs, leading to increased ohmic resistance and reduced active electrode area. This phenomenon aligns with the findings of Ponce de León et al[11]., who observed that higher numbers of serpentine channels can lead to reduced mass flow rates, thereby affecting bubble removal efficiency and overall cell performance.
Concerning the temperature distribution, Fig.4 reveals that the multiple serpentine configurations (b and c) exhibit a more uniform temperature distribution compared to the single serpentine channel (a). This contrasts with typical co-flow

designs where local heating tends to occur near the outlet. In the single serpentine configuration (Figure 4a), a distinct temperature gradient develops along the flow path, with higher temperatures concentrated near the outlet region. This is due to the continuous flow path where heat accumulates as the electrolyte progresses through the channel. For the double and triple serpentine designs (Figures 4b, 4c), the counter-flow mechanism allows for more effective heat exchange between the anode and cathode sides, leading to a more uniform thermal distribution throughout the electrolyzer. The heat generated in one section is partially dissipated by the cooler flow from the opposite side, preventing excessive local heating. These findings are consistent with studies such as Kim et al.[12] who have shown that counter-flow configurations improve temperature regulation, reduce membrane degradation risks, and increase long-term operational stability

4. CONCLUSIONS

In the current study modeling of AEM electrolyzer was successfully aligned well with the experimental data reported in the literature. The result analysis shows the critical role of flow channel design in the performance of AEM electrolyzers. The single serpentine configuration emerges as the most effective design, offering uniform flow distribution and efficient gas bubble removal. the multi-serpentine counter-flow configurations result in more uniform temperature distribution, compared to single serpentine designs, which exhibit localized heating near the outlet. This counter-flow effect enhances heat dissipation, improves ion conductivity, and stabilizes electrochemical reactions, ultimately leading to higher efficiency and longer durability of AEM electrolyzers.

ABSTRACT
The increasing demand for energy, driven by population growth and technological advancements, is guiding the modern world toward addressing the issue of global warming. Especially in the past 20 years, this awareness has gained significant momentum compared to earlier periods. It is universally accepted that emissions of CO, CO2, SO2, and NOX are the primary causes of glacier loss. The iron and steel industry is responsible for 7-9% of these emissions. All countries associated with the European Union must comply with the European Green Deal, in line with the goal of achieving zero carbon emissions by 2050. One of the common production methods in the iron and steel sector is continuous casting. One of the sections where hydrocarbon fuels are most commonly used in continuous casting facilities is the tundish heating system. There are no studies in the literature regarding the use of a natural gas and hydrogen mixture in tundish heating systems. This thesis aims to conduct a theoretical study on the use of a natural gas and hydrogen mixture in tundish heating systems of slab casting. Mixture rates will be determined and compared to 0 %to 10 %.
Keywords: Green Deal, Tundish Heating, Continuous Casting, Natural Gas and Hydrogen Mixture, Green Steel

1. INTRODUCTION
The increasing demand for energy, driven by population growth and technological advancements, is pushing the modern world to address the issue of global warming. Especially in the past 20 years, this awareness has gained significant momentum compared to earlier periods. The International Energy Agency (IEA) World Energy Outlook 2024 report highlights that the time remaining to limit global warming to 1.5°C is rapidly decreasing. This report from the IEA once again strongly emphasizes the need to accelerate the global energy transition and for governments to take immediate action and support one another. In 2023, the world achieved record growth by adding more than 560 GW of new renewable energy capacity to the global energy system. However, the distribution of this growth worldwide is far from being equal across technologies and countries. This situation shows that the measures taken against global warming are not sufficient. [1]

Emissions of CO, CO2, SO2, and NOX are globally recognized as the primary contributors to glacier losses. The steel industry accounts for 7-9% of these emissions. In addition, the sector emitted 1.91 tons of CO2 per ton of crude steel produced in 2022. Furthermore, the energy intensity in the industry was 20.99 GJ per ton of crude steel in 2022. Steel plays a critical role in virtually all aspects of modern life, from the computers used for this research to the vehicles we drive. The steel industry has been fundamental in building the modern world, and as the sector evolves, it has become indispensable. Total 1 763 Mt crude steel were used by sectors on 2023 as showed Fig 2. However, this indispensability has also made it a major driver of global warming. In 2024, global crude steel production totaled 1,892 Mt, with approximately 2% of the world's steel produced in Turkey.[2]

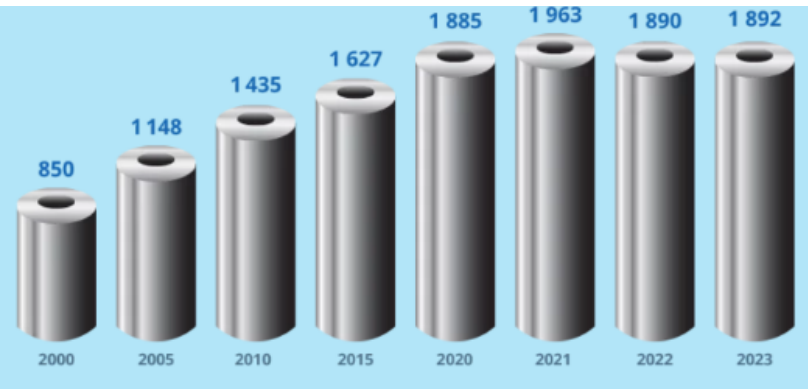

Fig. 1. Crude steel production 2000 – 2023.[2]

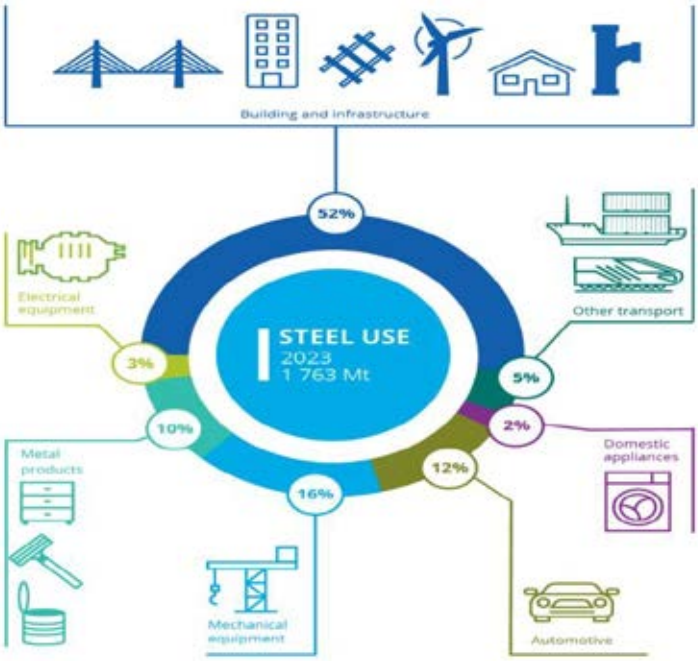

Fig. 2. Steel use by sectors on 2023.[2]

Since March 2020, the COVID-19 pandemic, which has affected the entire world and negatively impacted the economies of many countries, led numerous nations to prioritize pandemic response and economic recovery, causing the issue of global warming to fall lower on the agenda. However, in 2021, natural disasters, fires, and floods in various parts of the world brought the importance of climate change back into focus. Europe has found a solution in the form of establishing a new and lasting agreement. All countries associated with the European Union are required to adhere to the Green Deal in alignment with the zero-carbon target for 2050. This agreement aims to gradually reduce the emissions of the steel industry to zero by utilizing renewable energy sources. [3] (Ucak & Villi, 2021)

The process that began in October 2023 primarily covers heavy industries such as steel, fertilizer, energy production, and cement. Within the transition period, which will continue until January 2026, emissions from the production of products imported into the EU from these sectors, as well as the indirect emissions from the electricity used in their production processes, will be reported. As part of this compliance framework, the steel industry has increased its investments in emission reduction and energy efficiency measures by shifting towards alternative energy sources. The most critical factor in the industry's adaptation to the new regulations is undoubtedly the use of hydrogen as a fuel, produced using renewable energy sources. The global adoption of this approach is driven by the fact that hydrogen energy is considered an ideal fuel and energy carrier. It is easy to produce, a suitable fuel for all sectors, allows energy to be efficiently converted into other forms, provides high efficiency, and is environmentally harmless.[4]

2. MATERIALS AND METHODS

One of the most common production methods in the steel industry is continuous casting. The continuous casting process involves passing liquid metal through a copper mold, which has open ends and is cooled by water, to solidify it as showed in Fig.3. One of the sections of a continuous casting plant that consumes the most hydrocarbon fuel is the tundish heating system. The tundish is defined as an intermediate vessel used for the removal of inclusions from steel and for temperature control. Tundishes consist of refractory bricks and mortar applied over a steel structure. To prevent the refractory from melting and to ensure the quality of the liquid steel, the tundish must be preheated according to the steel quality before casting. Typically, it is heated to approximately 1100°C using natural gas. This process is usually performed with burners powered by coke gas or natural gas. One of the key advantages of using hydrogen either as a substitute for or in combination with natural gas is that it can be used with existing combustion turbines. However, when designing the systems, the differences between hydrogen fuel and natural gas will be significant. Firstly, the chemical formulas of the two substances differ. While the combustion of hydrogen does not result in carbon emissions, methane combustion does produce carbon emissions. [5] No studies have been found in the literature regarding the use of a natural gas and hydrogen mixture in tundish heating systems. This thesis intends to conduct a theoretical study on the application of a natural gas and hydrogen mixture in tundish heating systems.

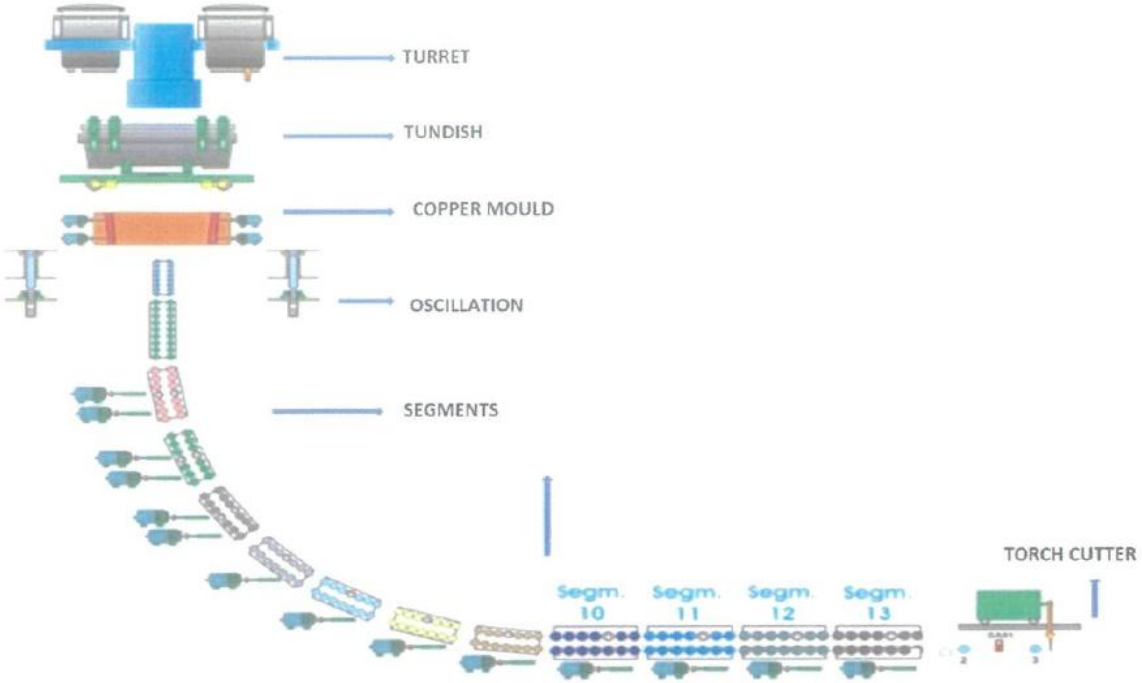

Fig. 3. Slab Casting Chart

In steel plants, due to the high consumption of natural gas, it is stored in tanks, allowing the facilities to continue operating for a period of time even if the central grid is disconnected. For this reason, hydrogen injection into the tundish heating system of the continuous casting plant cannot be performed through the main tank. The relevant injection can be made through the pipeline before the tundish heating system. Research studies are investigating the changes in emulsion values and temperature control resulting from the combustion of a natural gas-hydrogen mixture with different ratios in heaters equipped with combustion chambers and burner systems. Additionally, the hydrogen production methods required for this mixture are being explored. As is well known, according to the Green Deal, hydrogen production methods must be green. Depending on the location of the steel plant, energy required for electrolysis will be provided by utilizing wind, solar, and geothermal resources.

The prediction results obtained from the numerical simulation will be compared with the results from the literature. The differences in the flame region will be monitored in composite fuels containing varying amounts of hydrogen. Additionally, temperature control in hydrogen-rich composite fuels will be simulated and tested.

3. RESULTS AND DISCUSSION

Research studies generally indicate that in hydrogen-rich fuel mixtures, the emulsion values decrease and the temperature curve rises. The potential damage to tundish refractories due to this temperature increase or the ability to control the temperature is being investigated. The renewable energy sources to be utilized for hydrogen production will be determined based on the geopolitical situation of the regions where the research is conducted. The cost of green hydrogen will also be calculated throughout these processes. Furthermore, the percentage of total green steel production resulting from the steel produced after the tundish heating activity using green hydrogen will be calculated.

CO and CO2 values decreased in emulsions as a result of the reduction of the methane ratio in the theoretical examinations and increasing the amount of hydrogen. Mixture rates are 0 %H2- 100 %CH4, 3 %H2- 97 %CH4, 5 H2- 95 %CH4, 10 %H2- 90 %CH4, respectively, respectively. The amount of CO and C02 after the reaskiyon, which was performed by using these rates, decreased by 7-12 %.[6] (Tur & Buyukkaya, 2024)

4. CONCLUSIONS

The comparison and Ansys analyses to be conducted after this study may contribute to green steel production and the literature. Additionally, once sufficient equipment is acquired, its application will be tested in the field. The results will help for next researches.

ABSTRACT

The performance of fuel cells is significantly influenced by operating parameters and the mechanical design of components. This study investigates the effects of operating conditions, including cell temperature, anode and cathode flow rates, and torque, on fuel cell performance using Response Surface Methodology (RSM). A stainless-steel end plate and a centered bolt arrangement configuration were employed to ensure homogeneous pressure distribution. The analysis included 27 experiments to evaluate current density, power density, and internal resistance under varying operating conditions. The findings highlight that cell temperature and cathode flow rate are critical factors influencing performance. Optimal cell temperature enhances reaction kinetics and proton conductivity, leading to increased current and power density while minimizing resistance. Cathode flow rate also plays a vital role on the fuel cell performance. The torque applied to the end plate was found to have minimal impact within the tested range, confirming the effectiveness of the closure design. Maintaining the cell temperature at an optimal level in a fuel cell has enhanced the impact of gas flow rates on performance. These results emphasize that in fuel cell design and operation, optimizing individual parameters alone is insufficient; the interactions and synergistic effects between parameters must also be considered.

Keywords: Fuel cell, Operating Conditions, Performance, Response Surface Methodology.

1. INTRODUCTION

Fuel cells stand out among environmentally friendly energy production systems due to their high efficiency and low emission characteristics. Technologies such as Proton Exchange Membrane Fuel Cells (PEMFC) meet a wide range of energy demands, from portable devices to transportation applications. However, the performance of fuel cells is directly linked not only to the efficiency of electrochemical reactions but also to the design of mechanical components and operating parameters. In this context, the force applied to the end plate and the bolt distribution have a critical impact on the operating parameters of fuel cells.

The literature includes numerous studies examining the effects of clamping force and bolt distribution on fuel cell performance. For instance, experimental studies demonstrate that excessive clamping force reduces the permeability of gas diffusion layers, leading to performance losses in the cell. Simulation-based studies model the effects of various bolt arrangements on pressure distribution, providing valuable contributions to the design process.

Dey et al. [1] examined the impact of end plate design on fuel cell performance. The study used the finite element method to analyze parameters such as cell geometry, bolt configuration, gasket thickness, and material properties on contact pressure. Experimental validation showed that the number and distribution of bolts significantly affected contact pressure, with a configuration of 10 bolts achieving a uniform distribution.

In the study by Liu et al. [2], a novel compression mechanism was proposed to optimize the contact pressure distribution and deformation of the MEA and improve the electrochemical performance of fuel cells. Using the finite element method, models of PEMFCs with traditional bolt mechanisms and a new pneumatic compression mechanism were developed. The new mechanism increased maximum power density by 10%.

Zhao et al. [3] examined the effects of bolt distribution, end plate thickness, end plate material, geometry, and clamping force on the performance of a single-cell fuel cell with a 50 cm² active area. The study found an optimal GDL compression ratio of approximately 75% as a function of clamping force and end plate thickness.

Barzegari et al. [4] analyzed the parameters of pneumatic compression systems in fuel cells using response surface methodology and finite element methods. The study concluded that pneumatic compression systems with end plates were more efficient than traditional systems.

This study aims to examine the effects and interactions of operating parameters under the conditions identified in our previous research [5], where homogeneous pressure was achieved using a stainless-steel end plate and a centered bolt arrangement (8b configuration). The objective is to analyze how these specified conditions influence the performance of the fuel cell under various operating conditions. Additionally, this study highlights the interactions between design and operating parameters that impact fuel cell performance, offering valuable recommendations to guide design engineers. A comprehensive investigation into this topic is essential to ensure that fuel cell systems operate more efficiently and sustainably.

2. EXPERIMENTAL

Selecting the appropriate end plate, configuration, and clamping force for a fuel cell is crucial to minimize ohmic resistance and identify the optimal configuration. However, the impact of operating conditions on fuel cell performance must also be examined under this configuration. In the study by Yılgın et al. [5], a configuration using stainless steel and an centered bolt arrangement (8b configuration) (Fig. 1a) with a clamping force of 9 Nm was determined. In this study, the effect of operating conditions identified through the response surface methodology on fuel cell performance was investigated using the stainless steel and centered bolt arrangement.
In the conducted research, a 50 cm² (7.071 cm x 7.071 cm) active area was selected for the fuel cell, and the MEA was prepared accordingly. The MEA was placed within the designed end plate, and the fuel cell assembly was completed. This cell is shown in Fig. 1b.

(a) (b)

Fig. 1. Centered Bolt Arrangement (8b) (a) and Test Cell (b)

The effects of operating temperature, flow rate, and torque on fuel cell performance were investigated using the fuel cell test system (Figs. 2 and 3). The test system primarily consists of gas supply/flow control modules, anode and cathode humidifiers, temperature controllers, an electronic load, and other components.

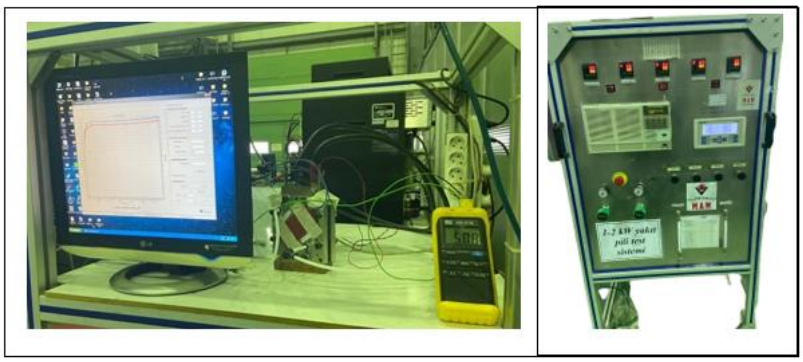

Fig. 2. Fuel Cell Test System

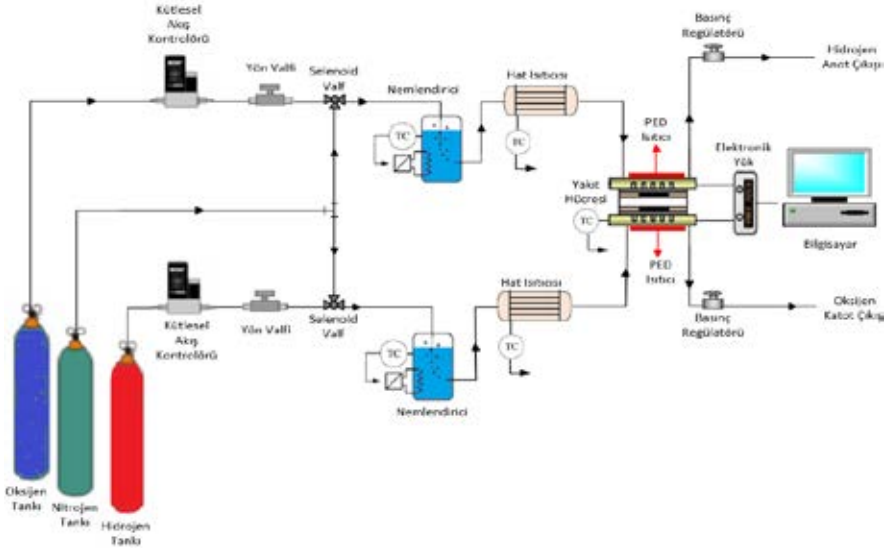

Fig. 3. Schematic Representation of the Test System

3. ANALYSIS

In this study, a total of 27 experiments were conducted, with the experimental design and analysis performed using the Design-Expert software. The experimental plan and levels of independent variables are temperatures of 35, 50, and 65 °C; anode flow rates of 0.3, 0.6, and 0.9 L/min; cathode flow rates of 0.01, 0.05, and 0.1 L/min; and torque values of 1, 5, and 9 Nm. The current density, power density, and resistance values were derived from polarization data obtained from the test system at an operating voltage of 0.6V.

4. RESULT AND DISCUSSIONS

The effect of parameters such as temperature, anode flow rate, cathode flow rate, and torque on the current density, power density and resistance of the test cell was analyzed using the response surface methodology. Fig. 4 presents 3D views of the effects of parameters such as cell temperature, anode flow rate, cathode flow rate, and torque on current density, modeled using the response surface methodology (RSM). According to RSM, the interaction between cell temperature and cathode flow rate has a more significant influence on current density than the other parameters. Cell temperature is a fundamental parameter that affects the electrochemical reaction rate of the fuel cell. Higher temperatures accelerate reaction kinetics, increase proton conductivity, and reduce membrane resistance. However, excessively high temperatures can cause membrane dehydration and performance loss. The graph indicates that within the studied range, cell temperature increases current density to an optimal point, after which it begins to decrease. As observed in the graphs, increasing the cathode flow rate enhances cell performance, even at the lowest torque levels. In other words, a higher cathode flow rate improves performance, indicating that higher oxygen flow rates are preferable for this model. In this study, at a cell temperature of 65°C, an anode flow rate of 0.3 L/min, a cathode flow rate of 0.1 L/min, and 1 Nm torque applied to the stainless-steel closure plate, the cell achieved its optimal current density. According to the RSM results, the maximum current density was found to be 513.93 A/cm².

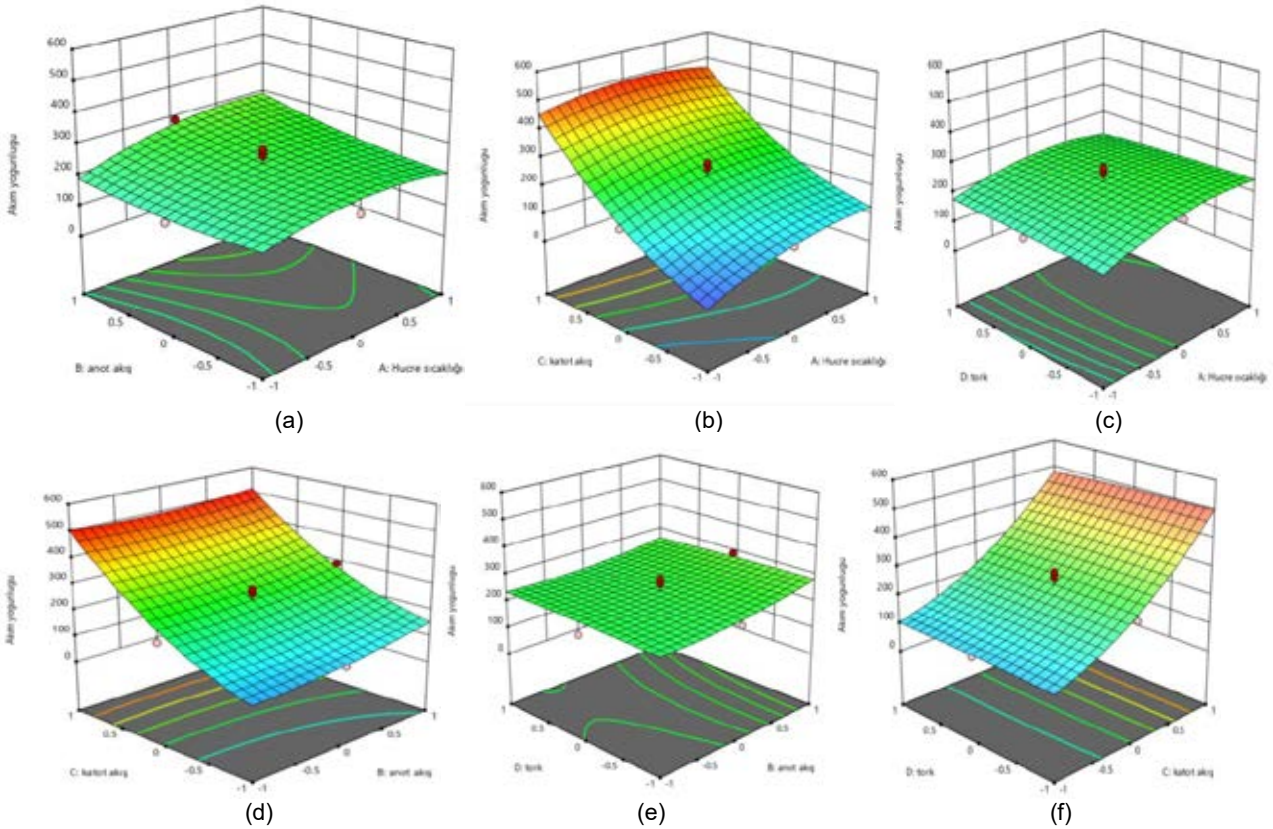

Fig. 4. 3D View of Current Density According to RSM

As shown in Fig. 5, increasing the cathode flow rate enhances cell performance, even at the lowest torque. In this study, when the cell temperature was 65°C, the anode flow rate was 0.3 L/min, and the cathode flow rate was 0.1 L/min, applying 1 Nm torque to the stainless-steel end plate resulted in the optimal power density for the cell. The RSM analysis determined the maximum power density to be 307.20 W/cm².

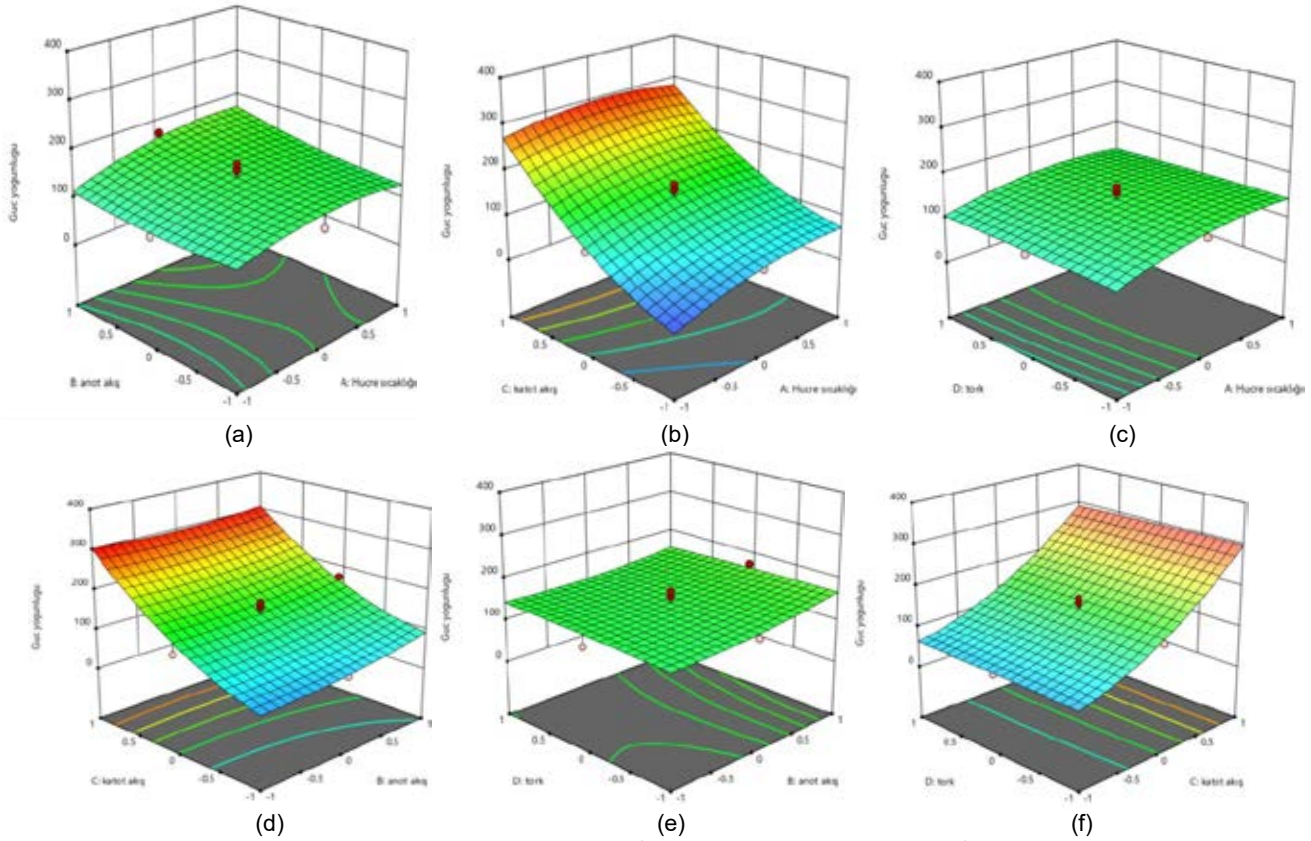

Fig. 5. 3D Visualization of Power Density According to RSM

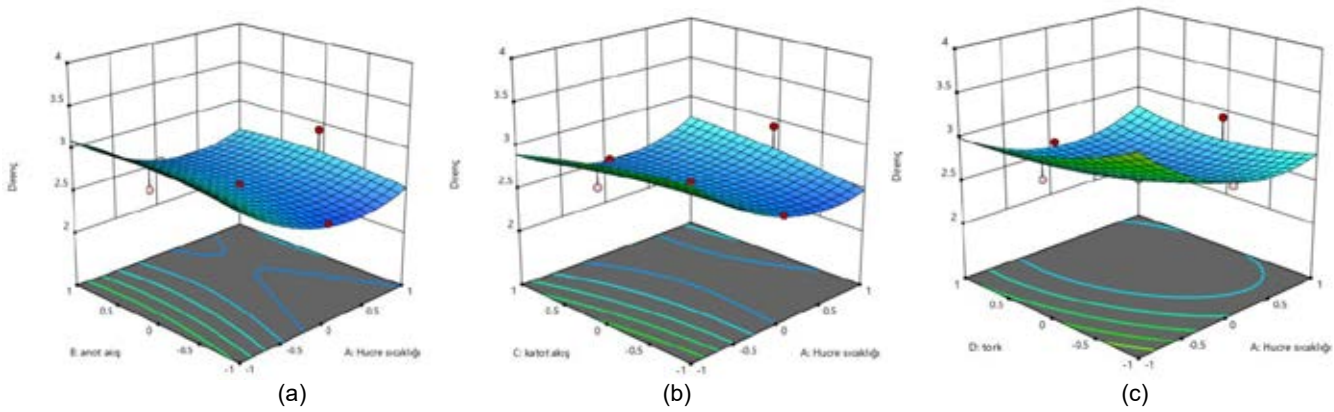
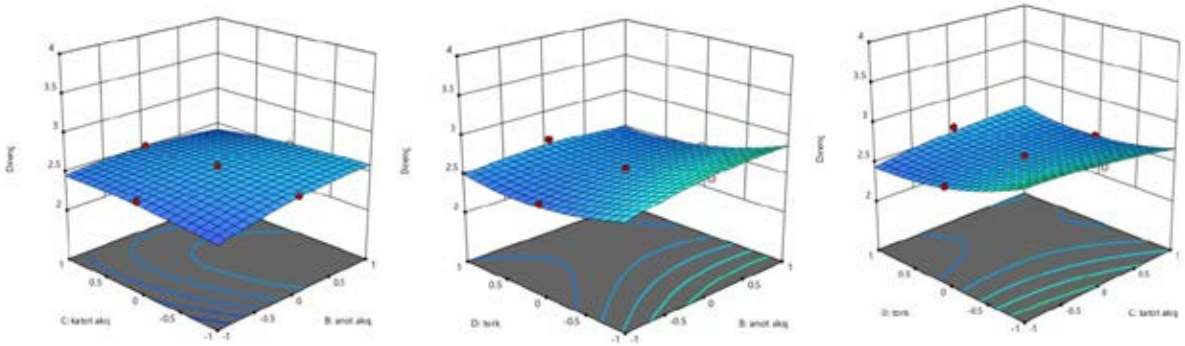
Fig. 6 presents 3D views modeled by the RSM method, showing the effects of parameters such as temperature, anode flow rate, cathode flow rate, and torque on resistance. As observed in the resistance graph, increasing the torque value reduces cell resistance. At the lowest torque value, resistance is at its highest. However, even when torque increases from 1 Nm to 9 Nm, the difference in resistance is minimal. This outcome confirms the suitability of the cell design parameters established by Yılgın et al. (2024) and demonstrates that internal resistance varies with operating conditions. Increasing the clamping force homogeneously leads to proper compression of the membrane and gas diffusion layers, reducing internal resistance. However, excessive clamping force may cause membrane deformation, block gas flow channels, and complicate water management, resulting in increased resistance. At low temperatures, the decrease in proton conductivity within the membrane and its reduced water retention capacity, along with reduced gas diffusion on the electrode and slower electrochemical reactions, contribute to an increase in internal cell resistance. A slight reduction in resistance is observed with higher anode and cathode flow rates. This reduction is due to improved reaction efficiency and water formation, which decreases resistance when sufficient fuel and oxidant are supplied. However, excessively high flow rates may lead to membrane drying and disrupt energy balance within the cell.





(d) (e) (f)

Fig. 6. 3D View of Resistance According to RSM

4. CONCLUSIONS

In this study, the effects of operating temperature, anode and cathode flow rates, and torque on cell performance in a fuel cell were investigated using the RSM experimental design method, employing stainless steel end plates and a previously determined closure configuration. According to the ANOVA analysis, 27 experiments were conducted to evaluate fuel cell performance, and the results of these experiments were analyzed in terms of current density, power density, and internal cell resistance. The findings obtained from the graphs highlight the critical importance of optimizing these parameters in fuel cell systems. It has been demonstrated that the increase in current and power density and the reduction of internal cell resistance are directly dependent on operating conditions. This study is significant in demonstrating the interactive relationship between parameters such as cell temperature, anode and cathode flow rates, and torque. For example, maintaining the cell temperature at an optimum level in the fuel cell increases the effect of gas flow rates on performance. These results indicate that fuel cell design and operation require not only the optimization of individual parameters but also consideration of the interactions and synergistic effects between parameters. The results obtained are summarized below:

Cell Temperature: Cell temperature is one of the most critical variables affecting the fundamental performance parameters of the fuel cell. The graphs obtained during the study indicate that temperature has a direct impact on both current and power density as well as resistance. An increase in cell temperature improves reaction kinetics while also enhancing proton conductivity within the membrane, resulting in greater current density and lower resistance. However, excessive temperatures can cause membrane drying, which limits performance.

Anode Flow Rate: An increase in anode flow rate was observed to slightly enhance current and power density. This is primarily due to the sufficient supply of reactants supporting electrochemical reactions. However, excessively high anode flow rates can disrupt water management within the cell and result in energy losses, necessitating optimization within an optimal range.

Cathode Flow Rate: The findings reveal that low cathode flow rates limit current and power density and increase resistance. This is due to insufficient oxygen transfer, which negatively affects reaction kinetics. While higher cathode flow rates improve performance up to a certain point, excessively high flow rates can cause energy losses and disrupt the membrane's moisture balance. The cathode flow rate should be optimized in harmony with other operating parameters.

*End Plate Clamping Force:*The torque applied to the end plate is a parameter used to ensure the mechanical stability of the fuel cell stack, prevent gas leakage, and optimize reactant flow. While the material, force, and configuration of the end plate were examined in our previous study, this study focused on observing the interaction of operating conditions with end plate force. As expected, no significant impact on performance was observed within the investigated range. However, a minimal effect on internal cell resistance was observed depending on the operating parameters.

ABSTRACT
Proton Exchange Membrane Fuel Cell (PEMFC) systems' complex and non-linear characteristics necessitate precise modeling for design and optimization purposes. The mathematical representation of fuel cells is typically constructed using empirical equations, as the output voltage is influenced by various losses, including activation, ohmic, and concentration losses. These losses depend on specific parametric coefficients; thus, optimizing these parameters is crucial for minimizing losses and enhancing fuel cell performance.
In this study, a novel heuristic optimization approach—the Manta Ray Foraging Optimization (MRFO) algorithm—is employed to determine the optimal parameters of PEMFC models. The MRFO algorithm is also applied to optimize the parameters of various fuel cell types for which experimental data are available. Based on the resulting parameter selections, error calculations are conducted. Furthermore, the proposed validation technique validates the voltage-current (V-I) curve against experimental data.

Keywords: Manta ray foraging optimization, Fuel cell, Optimization

1. INTRODUCTION

The growing environmental concerns have accelerated the transition to renewable energy sources. As a result, the demand for hydrogen, a clean and sustainable energy carrier, has been steadily increasing. Moreover, hydrogen can be utilized for electricity generation through electrochemical processes. Among various hydrogen-based energy conversion technologies, Proton Exchange Membrane (PEM) fuel cells stand out as one of the most widely adopted systems for efficiently converting chemical energy into electrical energy.

Owing to their high efficiency, high power density, short start-up times, and environmentally friendly characteristics, Proton Exchange Membrane (PEM) fuel cells have been increasingly utilized in various applications. Consequently, improving the performance of fuel cells has become a critical area of research. In general, the performance of a PEM fuel cell is influenced by key operational parameters, including pressure, relative humidity, and reactant gas flow rate [1]Although experimental studies play a crucial role in achieving an improved design process, they are often constrained by their complexity, time-consuming nature, and high costs. As a result, such studies are typically conducted within specific operational parameter ranges. Therefore, developing mathematical models to efficiently and accurately predict the performance of Proton Exchange Membrane Fuel Cells (PEMFCs) under varying operating conditions has become essential. In recent years, numerous models have been proposed, and various metaheuristic and bio-inspired algorithms have been explored to estimate PEMFC model parameters. This study, the Manta Ray Foraging Optimization Algorithm is proposed for this purpose.

This method, which is a metaheuristic algorithm, was employed to evaluate the parameters, and the validity of the model was verified by testing the simulated values against experimental data through a polarization curve The predictive accuracy of the optimized models was quantitatively assessed using statistical metrics—R-squared (R^2), Mean Absolute Error (MAE), and Root Mean Square Error (RMSE)—by comparing simulated voltage values with experimentally measured data.

2. MODELLING OF PEMFC

While mathematical modeling can predict fuel cell performance, a parametric model allows for a rapid analysis of operational parameters such as temperature and pressure [1]. Some challenges arise in this context, including the complexity of equations and the uncertainty of model parameters. Semi-empirical methods can be employed to address these issues [2]. To mitigate certain limitations, voltage losses such as ohmic, concentration, and activation losses must be carefully evaluated, and the physical background should be thoroughly analyzed. The voltage for a single cell of a PEMFC steady-state conditions is given by Eq. 1 [3].

$$V_{cell} = E_{Nernst} - \eta_{act} - \eta_{ohm} - \eta_{con} \quad (1)$$

E_{Nernst} is the thermodynamic potential of the cell, η_{Act} is the activation overvoltage, η_{Ohm} is the ohmic overvoltage, and η_{con} is the activation overvoltage.

The activation overpotential can be expressed in a parametric form as follows. [4]

$$\eta_{act} = \xi_1 + \xi_2 T + \xi_3 T \ln(C_{O2}) + \xi_4 T \ln(I)$$

where T is the cell operating temperature (K), I is the cell current (A), and ξ are semi-empirical coefficients. These coefficients have clear physical significance and are determined through mechanistic equations based on PEMFC thermodynamics, electrochemistry, and kinetics.

3. RESULTS AND DISCUSSION

As previously described, these seven parameters ξ_1, ξ_2, ξ_3, ξ_4, λ, B, and R_c must be determined. The selection of appropriate initial search bounds for each parameter is crucial when employing numerical optimization algorithms for parameter estimation, as it significantly influences the accuracy and efficiency of the optimization process.

Table 1. The lower and upper bounds of PEMFC model parameters.[5]

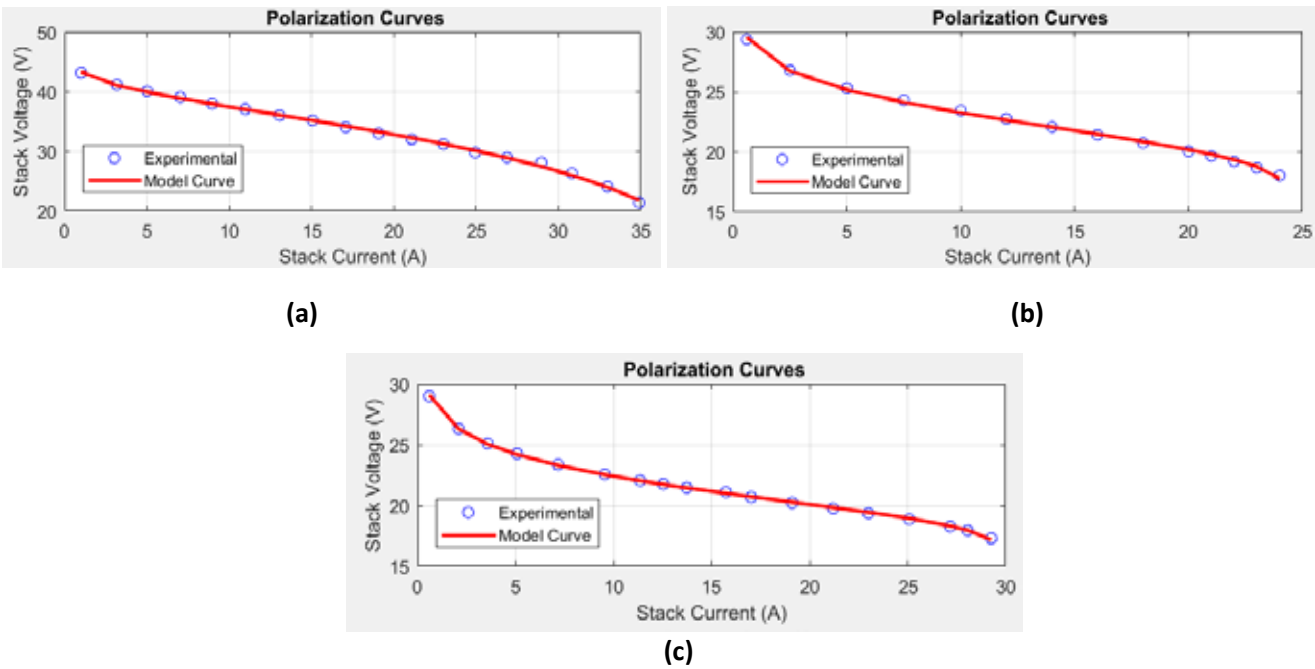

Fig. 1. Comparison of PEM fuel cell model predictions with experimental data (a) SR-12 PEMFC stack, (b) HORIZON 500 PEMFC stack, and (c) BCW 500 PEMFC stack.

4. CONCLUSIONS

The error rates for three models with experimental studies in the literature were calculated using the manta ray foraging algorithm, and the suitability of the proposed model was tested. As observed in the polarization curves, it is evident that the model exhibits an acceptable curve fit.

It is also evident that, alongside other powerful algorithms such as PSO, it is an advanced algorithmic method.

ABSTRACT
This study proposes a data-driven dual attention long short-term memory (DA-LSTM) approach for predicting the degradation trends of proton exchange membrane fuel cells (PEMFCs) under dynamic load conditions. Addressing key challenges in fuel cell durability and reliability, the proposed model is compared against traditional long short-term memory (LSTM) architectures to assess its effectiveness in capturing complex degradation patterns. The predictive performance of each model is evaluated using root mean squared error (RMSE), mean absolute error (MAE), and the coefficient of determination (R^2). The results demonstrate that DA-LSTM outperforms the conventional LSTM model, offering enhanced feature selection and improved long-term prediction accuracy through its dual-stage attention mechanism. These findings highlight the potential of DA-LSTM for fuel cell prognostics, providing a robust framework for prognostics and health management (PHM) systems and advancing the development of sustainable energy technologies.

Keywords: PEMFC, Dual attention LSTM, Remaining useful life, Voltage degradation prediction

1. INTRODUCTION

Global reliance on fossil fuels has been a driving force behind industrial and economic progress for centuries; however, this dependency has come at a significant environmental cost, necessitating an urgent transition to cleaner and more sustainable energy sources to mitigate the effects of climate change [1]. Among the promising alternatives, proton exchange membrane fuel cells (PEMFCs) stand out due to their high efficiency, zero emissions, and versatility in applications such as power generation, energy storage, and various transportation sectors, including automotive and marine industries, where they are increasingly adopted for sustainable mobility solutions [2, 3].

Despite their potential, PEMFC systems face significant challenges, including performance degradation due to operational factors such as temperature, humidity, and load variations [4]. Accurate prediction of PEMFC degradation behavior is essential for enhancing system durability, reducing maintenance costs, and ensuring reliable operation. Prognostics and Health Management (PHM) frameworks are widely employed to monitor the state of health (SOH) and estimate the remaining useful life (RUL) of PEMFCs, enabling a proactive transition from a “fail to fix” strategy to a “predict to prevent” approach [3].

Existing methods for PEMFC performance prediction can be categorized into model-based and data-driven approaches. Model-based methods rely on physical principles, such as electrochemical reactions and state equations, to predict degradation, but they often struggle with the inherent complexity of PEMFC systems. On the other hand, data-driven methods leverage large experimental datasets to establish nonlinear mapping relationships between operating conditions and degradation patterns. Specifically, recurrent neural networks (RNNs), long short-term memory networks (LSTMs), and their attention-enhanced variants have demonstrated success in capturing long-term dependencies in PEMFC degradation data [4]. This success is primarily due to the ability of RNN-based approaches to model sequential dependencies in time-series data and their high capacity for learning long-term patterns. While traditional artificial neural networks (ANNs) primarily focus on static data, RNN and LSTM models retain past information, making the decision-making process more dynamic and particularly well-suited for predicting the degradation of time-evolving systems such as PEMFCs. The LSTM model, with its forget gate and cell state mechanisms, selectively retains only relevant information, filtering out unnecessary noise and effectively learning long-range dependencies [3, 4].

The proposed approach aims to improve prediction accuracy and provide interpretable insights into the degradation process. By leveraging the success of RNN- and LSTM-based methods, this study aims to establish a foundation that can be integrated with more advanced predictive models in future research. Integrating LSTM with attention mechanisms enhances the model’s ability to focus on critical time steps and essential features, improving accuracy and interpretability. Thus, rather than merely repeating existing methods, this study builds upon an adaptable framework that can be further refined with more complex hybrid approaches in future advancements.

2. MATERIALS AND METHODS

2.1. Dataset

The dataset utilized in this study originates from a long-term dynamic durability test conducted on a single PEMFC. The durability assessment was carried out using a Greenlight G20 test station, which provides precise control over load variations, gas supply conditions, and thermal management. This study follows the European Harmonized Test Protocol, which is based on ECE R15, a widely recognized test procedure for evaluating vehicle emissions and fuel efficiency

under standardized conditions [5].
Like real-world driving profiles, the ECE R15 driving cycle incorporates acceleration, deceleration, and steady-speed phases, making it a realistic benchmark for simulating fuel cell operating conditions. This protocol includes a combination of urban and extra-urban driving scenarios, ensuring that load fluctuations and transient behaviors experienced by fuel cells in automotive applications are accurately reflected. As illustrated in Figure 1(a), the urban driving cycle consists of four repetitions totaling 780 seconds, followed by a 400-second highway driving cycle, resulting in a total cycle duration of 1180 seconds, and the complete output voltage data of the PEMFC was processed and presented in Fig. 1(b) [6].

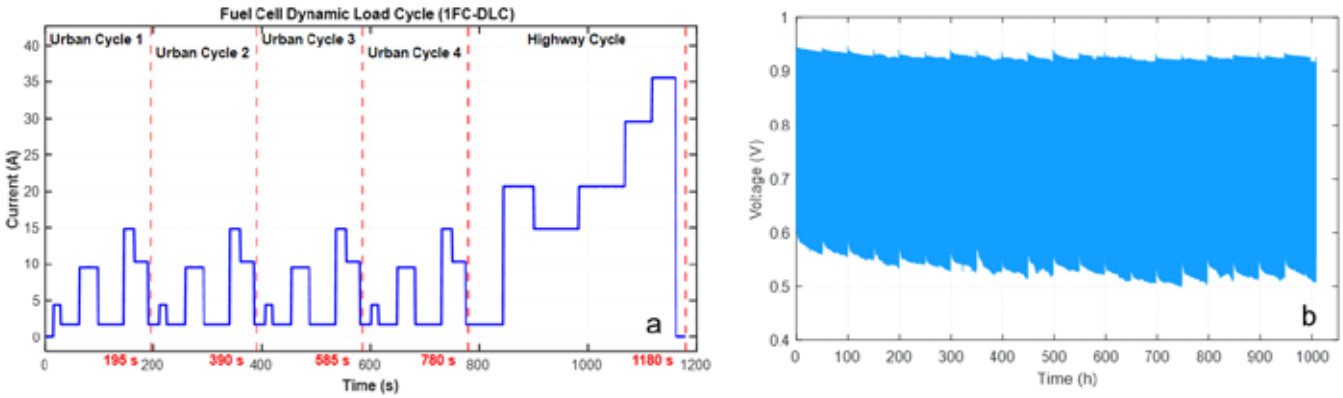

Fig. 1. (a) Current variation for one period of FC-DLC, (b) voltage change for 1008 hours of operation

In this study, the fuel cell dynamic load cycle (FC-DLC) was designed to replicate the fluctuating electrical demands observed in automotive fuel cells. This approach objectively evaluates fuel cell degradation patterns under long-term operating conditions. The FC-DLC protocol closely mimics the varying electrical requirements of automotive fuel cells, providing highly valuable degradation data for prognostics and health management (PHM) strategies [3]. The durability test consists of 3,076 FC-DLC cycles, covering approximately 1008 hours of operation. The test procedure involves applying cyclic current loads to the PEMFC while continuously monitoring electrical, thermal, and fluidic parameters, as presented in Table 1, at a sampling frequency of 1 Hz. These parameters are crucial for analyzing degradation phenomena, where the voltage drop trend is the primary indicator. At the same time, variations in temperature, pressure, and humidity offer insights into catalyst degradation and water management issues. Each test session comprises 152 FC-DLC cycles (~50 hours) and a characterization assessment. Additionally, after every 100 hours of operation, the system undergoes a 12-hour shutdown rest period. This process simulates real-world vehicle stop-start cycles, allowing for the evaluation of transient recovery effects on fuel cell degradation [5].

Table 1. Aging parameters gathered during the long-term durability test

Index	**Physical meaning**
Time	Aging time (s)
Current, voltage, power	The operating load (A), output voltage (V), and power (W) of PEMFC
Pressure anode inlet; Pressure anode outlet	Inlet and outlet pressure of H_2 (KPa)
Pressure cathode inlet; Pressure cathode outlet	Inlet and outlet pressure of air (KPa)
Temp anode inlet; Temp anode outlet	Inlet and outlet temperature of H_2 (°C)
Temp cathode inlet; Temp cathode outlet	Inlet and outlet temperature of air (°C)
Temp anode dewpoint water	Dewpoint water temperature of H_2 (°C)
Temp cathode dewpoint water	Dewpoint water temperature of air (°C)
Total anode stack flow	Total stack flow of H_2 (NLPM)
Total cathode stack flow	Total stack flow of air (NLPM)
Temp anode endplate	Operating temperature of PEMFC (°C)

These parameters are essential for understanding the multi-faceted degradation phenomena in PEMFCs. The voltage drop trend over time serves as the primary degradation indicator, while temperature, pressure, and humidity variations provide valuable insights into catalyst degradation, membrane thinning, and water management issues.

2.2. Data Preprocessing

Several preprocessing steps were implemented to enhance data quality and maintain consistency before model training. The raw dataset, collected from a fuel cell endurance test, underwent an abnormal value check to detect irregularities in the recorded parameters. Additionally, a cycle integrity verification was performed to ensure that each dynamic load cycle

contained the expected number of steps without missing or extra values. Only complete and validated cycles were retained for further processing. Furthermore, unnecessary columns were removed to streamline the dataset [3, 4]. Any rows containing NaN values were filtered out to handle missing values, ensuring that only complete data points were used [3]. The dataset was also downsampled from its original recording frequency of 1 Hz to 1/60 Hz, reducing the computational load while retaining essential degradation patterns [4].
A key step in preprocessing was applying a moving average smoothing technique, which helped reduce high-frequency noise and transient fluctuations in the voltage readings. This method ensured that the extracted features better represented the overall degradation trend rather than short-term variations [3, 4]. In alignment with prior studies, voltage was selected as the target variable for degradation prediction. The dataset was divided into training and testing subsets, with 60% allocated for training and 40% for testing. This time-based split maintained the chronological order of degradation, ensuring that the model was trained on earlier data and evaluated on later, unseen degradation trends. These preprocessing steps helped create a structured and noise-reduced dataset, optimizing the predictive model's performance in capturing long-term fuel cell degradation behavior.

2.3. Model Architecture and Training Strategy

This study utilizes RNN-based architectures to predict degradation patterns in PEMFC systems. While RNNs capture temporal dependencies effectively, they suffer from vanishing and exploding gradients, limiting their performance in long-term modeling [3]. To overcome these challenges, LSTM networks were integrated. LSTM uses memory cells with gating mechanisms to control information retention. Key components include forgetting, input, and output gates, facilitating long-range dependency learning while mitigating gradient issues [3, 4].
The computations in an LSTM cell are as given in Eqs. (1)-(6).

$$i_t = \sigma(W_{xi}x_t + W_{hi}h_{t-1} + b_i) \quad (1)$$
$$f_t = \sigma(W_{xf}x_t + W_{hf}h_{t-1} + b_f) \quad (2)$$
$$o_t = \sigma(W_{xo}x_t + W_{ho}h_{t-1} + b_o) \quad (3)$$
$$c_t^{\sim} = tanh(W_{xc}x_t + W_{hc}h_{t-1} + b_c) \quad (4)$$
$$c_t = f_t \odot c_{t-1} + i_t \odot c_t^{\sim} \quad (5)$$
$$h_t = o_t \odot tanh(c_t) \quad (6)$$

Where i_t,f_t,o_t are the input, forget, and output gates, respectively, c_t is the cell state, and h_t is the hidden state. The weight matrices W and b biases are trainable parameters, and σ denotes the sigmoid activation function. The model predicts voltage as the output variable based on input features related to fuel cell performance. An attention mechanism was added to enhance learning efficiency by focusing on key time steps. Assigning varying importance to different time steps improves feature extraction and prediction accuracy, making it valuable in fuel cell degradation modeling [3,4]. For further accuracy, a data-augmented LSTM (DA-LSTM) framework was implemented. This model uses a dual-stage attention mechanism within an encoder-decoder structure. While LSTM captures temporal dependencies, the attention mechanism enhances feature selection and temporal weighting for better long-term predictions [4]. The encoder extracts key features, and the decoder integrates them over time to refine predictions. This approach dynamically adjusts attention weights to improve understanding of degradation trends [4].
The model was trained using the Adam optimizer with mean squared error (MSE) as the loss function. Hyperparameter optimization was performed via grid search, adjusting hidden layers, dropout rate, and batch size for optimal accuracy. To prevent overfitting, a 30% dropout was applied to the LSTM layer [4]. The model was trained with dynamically loaded PEMFC degradation data and evaluated using RMSE, R^2, and MAE metrics to ensure robustness [3, 4].

3. RESULTS AND DISCUSSION

This section presents the predictive performance of the proposed DA-LSTM model in estimating PEMFC degradation trends. The results regarding prediction accuracy, model robustness, and comparative evaluation against conventional time-series prediction architectures such as standard LSTM are analyzed. The model’s effectiveness is demonstrated through time-series prediction plots, parity plots, and quantitative error metrics, including RMSE, MAE, and R^2.

3.1. Time-Series Prediction Analysis

The DA-LSTM model was evaluated using the test dataset, where predicted voltage values were compared against actual recorded values from the long-term durability test. As illustrated in Figure 2, the time-series prediction plot highlights the model's ability to track the observed degradation patterns closely. The red line represents DA-LSTM predictions, while the blue line represents the voltage values. The proposed model effectively captures the nonlinear degradation behavior of the PEMFC system, aligning well with the measured data over time. Notably, the model maintains high accuracy even in later operational stages, where voltage degradation accelerates due to cumulative aging effects.

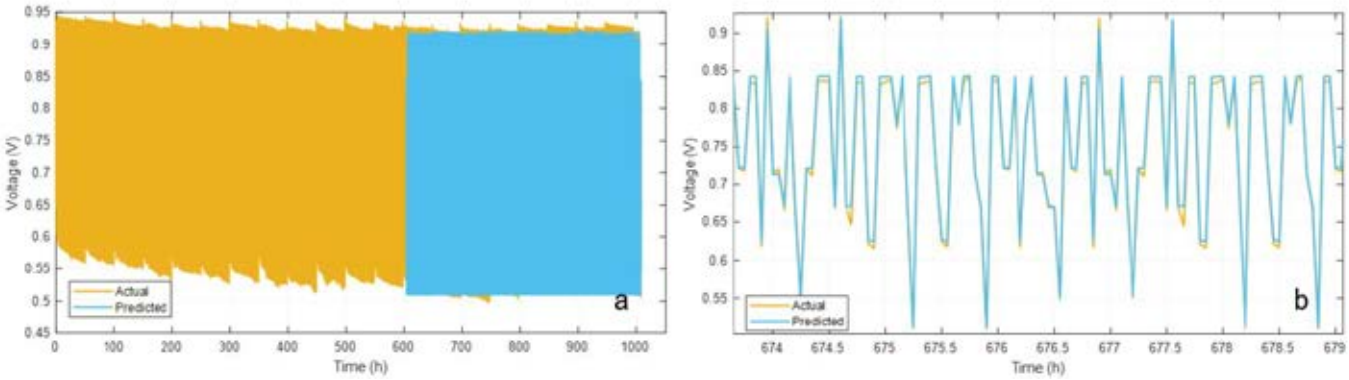

Fig. 2. (a) Time series prediction of PEMFC degradation using DA-LSTM, (b) corresponding zoomed-in view.

3.2. Comparative Performance Evaluation

The DA-LSTM model was compared with the conventional LSTM model using standard performance metrics to assess the predictive performance further. Table 2 presents the results.

Table 2. Performance comparison of DA-LSTM, LSTM, and RNN models

Model	RMSE	MAE	R^2
LSTM	0.0186	0.0143	0.9640
DA-LSTM (Proposed)	0.0135	0.0100	0.9805

The results indicate that DA-LSTM outperforms LSTM in predicting PEMFC voltage degradation, achieving the lowest RMSE and MAE values while maintaining the highest R^2 score. The DA-LSTM model's dual-stage attention mechanism enhances feature selection and temporal weighting, leading to better long-term prediction performance.

4. CONCLUSIONS

This research contributes to the growing work on PEMFC durability by developing a data-driven framework for performance degradation prediction. Leveraging deep learning techniques, including LSTM and DA-LSTM, this study provides accurate and interpretable predictions, facilitating better maintenance strategies and operational planning for PEMFC systems. Preliminary results indicate that attention-based models outperform conventional architectures, with DA-LSTM achieving the lowest RMSE of 0.0135, MAE of 0.0100, and highest R^2 of 0.9805, demonstrating its effectiveness in capturing degradation trends. The comparative analysis confirms that deep learning models can effectively model PEMFC degradation behavior under dynamic load conditions, making them suitable for real-world prognostics applications. Future work will focus on integrating experimental results, refining models based on real-world conditions, exploring new architectures to enhance predictive accuracy, and optimizing computational efficiency to ensure robust and practical implementation in PEMFC health monitoring and predictive maintenance systems.

ABSTRACT
This study uses alkaline water electrolysis. Several factors influence electrolysis efficiency, including electrode arrangement, cell spacing, applied voltage and current, temperature, processing time, and electrolyte type. This research focuses on optimizing the electrolyte solution, which enhances the conductivity of pure water and facilitates the electrolysis process. For this purpose, NaOH-containing solutions were used to promote the ionization of pure water. Nanomaterials, which provide high conductivity at low voltages, can improve water dissociation efficiency. In this context, multi-walled carbon nanotubes (MWCNTs) were incorporated into the electrolyte solution of the HHO dry cell to enhance hydrogen production efficiency. The effects of this approach on electrolysis efficiency were evaluated.

Keywords: Hydrogen, HHO, nanomaterial, electrolyte

1. INTRODUCTION
Among renewable energy sources, hydrogen energy stands out as a sustainable and alternative energy [1]. Hydrogen can be produced from various energy sources, stored and used as an energy carrier, making it a more efficient option compared to fossil fuels. In addition, it has the potential to reduce carbon emissions and poses a lower risk of explosion [2]. However, the transition to large-scale hydrogen use requires significant infrastructure investments [3].

In this study, alkaline water electrolysis was used to produce hydrogen in a HHO dry cell targeting renewable and green hydrogen production. Various factors, including electrode arrangement, cell gap, applied voltage and current, temperature, process time and electrolyte type, affect the electrolysis efficiency [4]. This research focuses specifically on the optimization of the electrolyte solution, which plays an important role in increasing the conductivity of pure water and facilitating the electrolysis process. For this purpose, NaOH-containing solutions were used to promote the ionization of pure water. Studies show that nanomaterials that provide high conductivity at low voltages increase water splitting efficiency [5]. However, the use of nanomaterials in the electrolyte solution of HHO dry cell has not yet been extensively investigated.

2. MATERIALS AND METHODS
The HHO dry cell is a system that operates based on the principle of electrolysis. Electrolysis is the process in which water is separated into its components through a chemical reaction using electrical energy. In this study, 316L stainless steel plates with dimensions of 14 cm × 14 cm were used as electrodes, and a total of 12 plates were used for the experiments. Rubber seals were used to ensure insulation between the plates.

For the electrolyte solution, mixtures containing pure water, NaOH, and multi-walled carbon nanotubes (MWCNTs) were selected. The properties of the multi-walled carbon nanotube are provided in Table 1. Additionally, experimental test equipment was set up as shown in Figure 1.

Table1. Multi-walled Carbon Nanotubs (MWCNTs) Properties

Purity	*> 90%*
(-COOH) Functionality	*0.55%*
Color	*Black*
Outer Diameter	*50 – 80 nm*
Inner Diameter	*5 – 15 nm*
Length	*10 – 30 µm*
Bulk Density	*0.15 g/cm³*
True Density	*2.2 g/cm³*
Specific Surface Area	*50 m²/g*
Ash Content	*9%*
Electrical Conductivity	*98 S/cm*
Production Method	*CVD (Chemical Vapor Deposition)*

The experiments were conducted under constant NaOH ratios and constant current conditions, and the effect of the

nanomaterials in the electrolyte solution was investigated. The electrolyte was tested in four different mixtures.900 gram purewater and 100 gram NaOH were mixed (10:1 w/w) separately with 0.5 g, 1 g, 2 g, and 5 g concentrations of MWCNTs, and each mixture was stirred with a magnetic stirrer at 500 rpm for 30 minutes.

All tests were conducted under the same conditions using CCPWM (Constant Current Pulse Width Modulation) with a constant voltage (22V) at 3A, 6A and 9A. The HHO production rate of the solutions was measured over time and considered in the experimental study. Finally, the effects on production results were presented graphically.

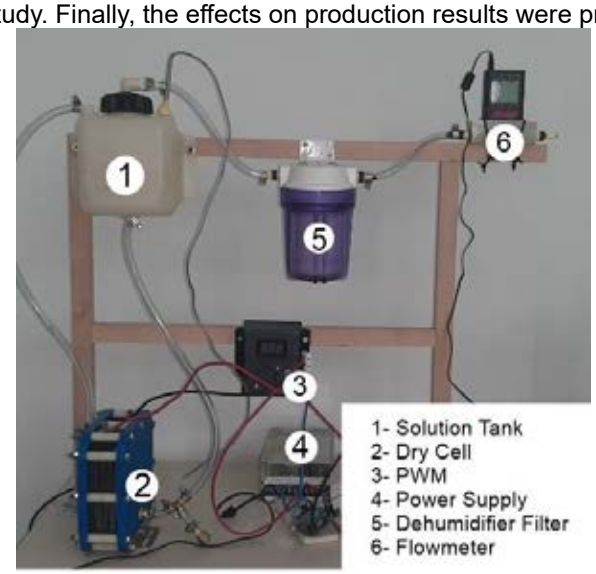

Fig.1. HHO dry cell setup

3. RESULTS AND DISCUSSION

Based on the graph below, it is observed that the HHO production rate increases as the current increases in HHO (Hydrogen-Hydrogen-Oxygen) dry cells. This trend indicates that higher current values lead to more electrical energy being supplied to the electrolysis process, thus contributing to more efficient hydrogen gas production. The increase in current accelerates the electrolysis reaction by facilitating the disintegration of water molecules into hydrogen and oxygen gases. However, it is important to note that the HHO production rate starts to decrease after certain current thresholds are reached. This phenomenon may indicate several fundamental issues, such as the onset of efficiency losses, possible overheating of the system, or a shift in the electrolysis reaction dynamics leading to diminishing returns.

Further analysis shows that the use of 3A and 0.5 grams of MWCNTs results in approximately 115% more HHO production compared to the use of 0 g of MWCNTs. This significant increase in production highlights the positive impact of MWCNTs on the electrolysis process, which is probably due to their ability to increase the surface area of the electrodes and thus increase the hydrogen production rate.

Additionally, the study observed efficiency losses at higher amperages, particularly at 6A and 9A. This suggests that, beyond a certain point, increasing current does not linearly translate into higher production rates. Rather, the system may experience energy losses due to factors such as increased resistance, heat generation, or less efficient electrolysis conditions at higher currents.

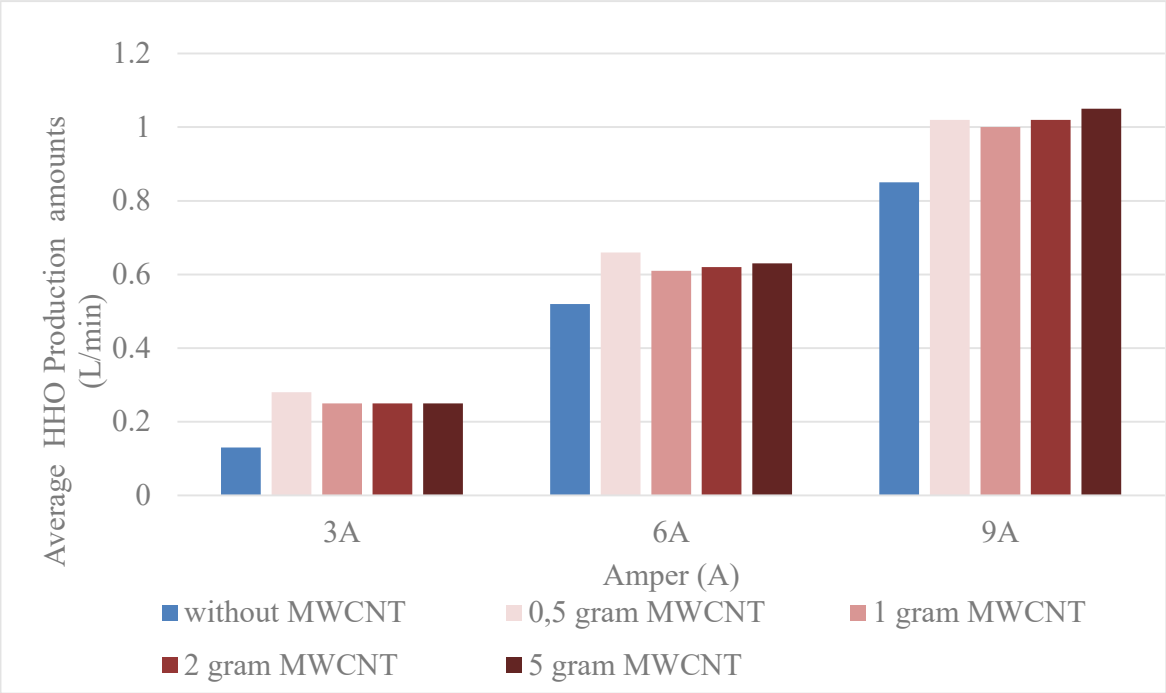

Fig.2. Impact of Current on HHO Production with MWCNT

4. CONCLUSIONS

Further research on the effects of MWCNTs in this system and optimization with experimental data will be crucial to increase efficiency. The potential of MWCNTs to enhance electrolysis performance is promising, but further studies are needed to fully understand the underlying mechanisms and determine the most effective concentrations and operational parameters. Detailed studies focusing on the interaction between MWCNTs and the electrolysis process will help fine-tune the system to achieve optimum hydrogen production rates.

Considering the cost of MWCNTs, the use of 3A with 0.5 g MWCNTs is considered a more efficient and cost-effective option compared to higher concentrations. Although 3A with 5 g MWCNTs shows significant improvements in production rates, the associated cost may not justify the marginal increase in hydrogen output. Therefore, using 0.5 MWCNT at 3A offers a balance between performance improvement and material cost, making it a more practical approach for large-scale applications. Moreover, this approach may provide a more sustainable solution, especially when cost reduction is an important factor.

In the next study, experiments will be conducted with currents ranging from 3 to 6 A and MWCNT quantities ranging from 0.1 g to 0.5 g. This range will allow for a more detailed examination of the optimum current and MWCNT concentration for maximum hydrogen production. Preliminary results indicate that increasing the current and MWCNT content can lead to higher production rates, although the rate of increase tends to be more pronounced at lower currents (3 A–6 A). Therefore, further optimization studies will focus on determining the current and MWCNT combination that leads to the most efficient production process. To maximize efficiency, adding 0.1 g to 0.5 g of MWCNT appears to be the most reasonable option, as it provides a good balance between improved production and material cost.

ABSTRACT
Hydrogen, with its environmentally friendly, renewable, and highly efficient properties, emerges as an alternative solution in the face of fossil fuel depletion and rising prices. When produced through electrolysis using renewable energy sources, hydrogen offers a sustainable option. HHO gas, produced via water electrolysis, has the potential to improve fuel efficiency and combustion performance, particularly when added to traditional diesel and Otto engines. It reduces fuel consumption and emissions. HHO gas production is influenced by parameters such as electrode configuration, voltage, current, and temperature. In recent years, the use of nanomaterials has improved the efficiency of water electrolysis. The aim of this study is to investigate the effects of graphene additives in the electrolyte solution on hydrogen production. The study will examine how graphene improves electrolysis efficiency by enhancing electrical conductivity and is expected to contribute to the development of new approaches for using nanomaterials in hydrogen production processes.

Keywords: Hydrogen, HHO, nanomaterial, electrolyte, graphene

1. INTRODUCTION
Hydrogen stands out as an alternative solution in the face of fossil fuel depletion and rising prices due to its lightness, high efficiency, environmentally friendly nature, and renewability. When blended with fuels such as gasoline, natural gas, and biogas, hydrogen enhances engine performance. Additionally, when produced through electrolysis using renewable energy sources, it offers a sustainable option [1,2]. By 2050, hydrogen is expected to reach a level where it can compete with fossil fuels and become more widespread [3].

HHO gas, also known as hydroxy gas or Brown's gas, is produced through water electrolysis and is preferred particularly for its potential to improve fuel efficiency and combustion performance. When introduced into conventional diesel and Otto engines, HHO gas enhances engine performance, reduces fuel consumption, and lowers emissions [4].

Several parameters influence HHO gas production, including electrode configuration, the number of plates, applied voltage, current, time, temperature, and the type of electrolyte used [5]. In recent years, the use of nanomaterials in water electrolysis has become a significant trend [6]. Research has shown that nanomaterials, which provide high conductivity at low voltage, improve water-splitting efficiency [7]. However, there is a limited number of studies in the literature regarding the effects of nanomaterial additives on HHO gas production processes.

This study aims to investigate the effects of graphene additives in the electrolyte solution of an HHO dry cell on hydrogen production. Specifically, the study will evaluate how graphene enhances electrolysis efficiency by improving electrical conductivity. The findings obtained from this research are expected to contribute to the development of new approaches for using nanomaterials in hydrogen production processes.

2. MATERIALS AND METHODS
The HHO dry cell is a system based on the electrolysis process, where water is decomposed into hydrogen and oxygen gases using electrical energy. In this study, 14 cm × 14 cm plates made of 316L stainless steel were used as electrodes, and a setup consisting of 12 plates was assembled. Rubber gaskets were used to ensure electrical insulation between the electrodes.

For the electrolyte solution, a mixture of pure water, NaOH, and graphene was used. The properties of graphene are provided in Table 1. To measure the system's performance and conduct the experiments, a dehumidifier, Alicat flow meter, and PWM were incorporated into the experimental setup (Figure 1).

The experiments were conducted under constant NaOH concentration and fixed current conditions to investigate the effect of graphene addition on the electrolysis process. The electrolyte solution was prepared with four different graphene concentrations. 900 g of pure water and 100 g of NaOH were separately mixed with 0.5 g, 1 g, 2 g, and 5 g of graphene (10:1 w/w ratio).

Table1. Graphene Properties

Purity	99,9%
Width	3 nm
Diameter	1.5 µm
Specific Surface Area	800 m²/g
Electrical Conductivity	1500 – 1980 S/m
Color	Black

All experiments were performed using fixed current (22 V) at 3A, 6A, and 9A, applying CCPWM (Constant Current Pulse Width Modulation) method. During electrolysis, HHO production rates were measured at specific time intervals, and the experimental data were thoroughly analyzed. Finally, the effect of graphene addition on hydrogen production was evaluated through graphical and comparative analyses.

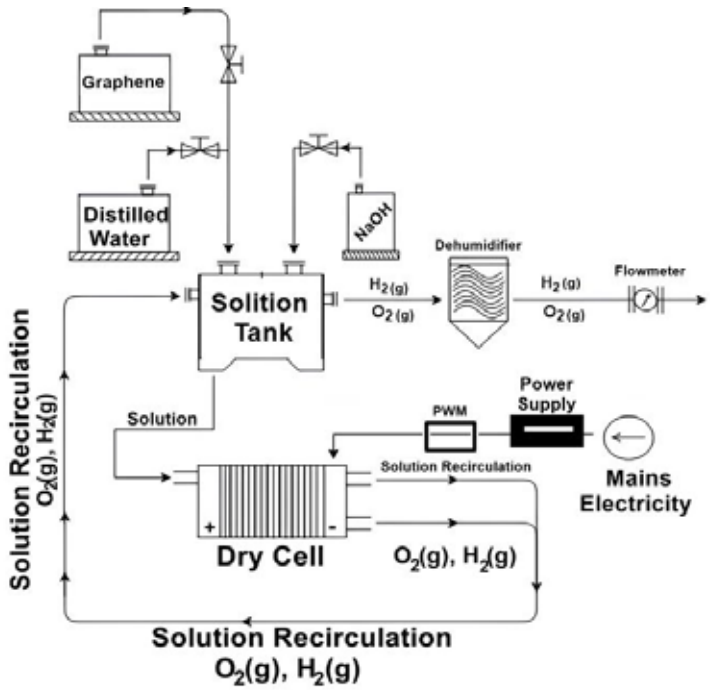

Fig.1. HHO dry cell setup

3. RESULTS AND DISCUSSION

The graph (Figure 2) shows a significant increase in the HHO production rate as current increases in HHO (oxyhydrogen) dry cells. This indicates that higher current provides more energy to the electrolysis process, thus increasing hydrogen gas production efficiency. Increasing current increases the rate at which water decomposes into hydrogen and oxygen gases, leading to a faster electrolysis reaction. However, once current reaches a certain level, the increase in HHO production rate begins to slow. This suggests that efficiency losses may have begun, possibly due to overheating or changes in the electrolysis reaction dynamics.

Detailed analysis showed that the tests conducted using 3A and 0.5 g of graphene resulted in twice as much HHO production compared to experiments without graphene. This significant increase highlights the positive effect of graphene on the electrolysis process.

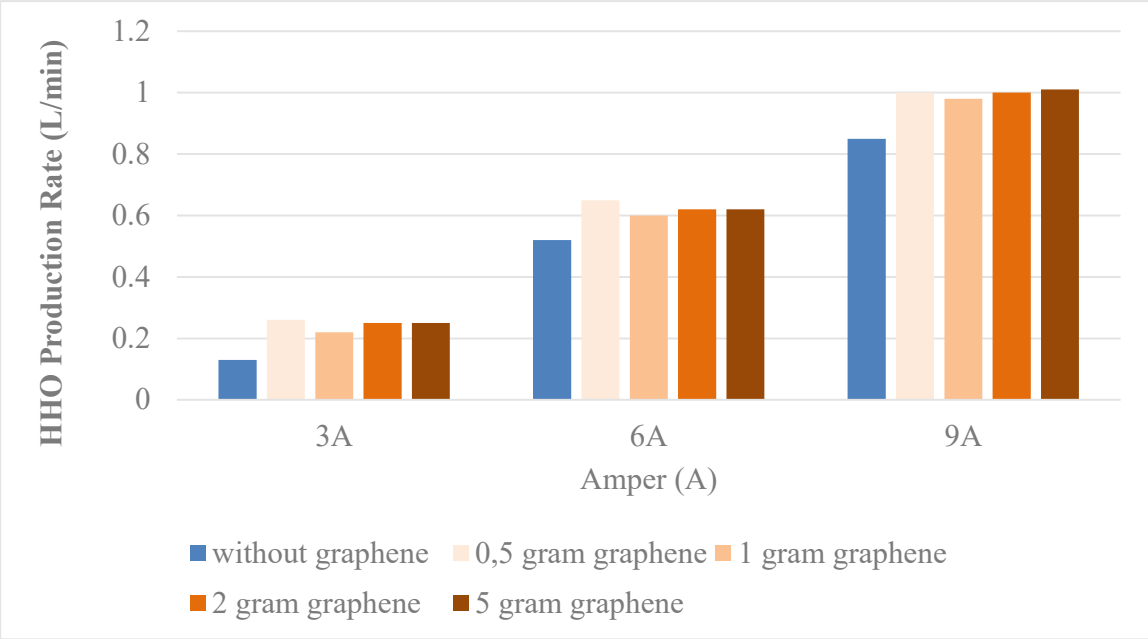

Fig. 2. Impact of Current on HHO Production with Graphene

4. CONCLUSIONS

Extensive research on the effects of graphene on the electrolysis process and optimization based on experimental data plays an important role in increasing efficiency. The potential of graphene to improve electrolysis performance is promising; however, further research is needed to fully understand this effect and to determine the most effective concentrations and operational parameters. In-depth studies on the interactions between graphene and electrolysis will contribute significantly to optimizing the system to maximize hydrogen production rates. These studies will help us better understand the impact of graphene's electrochemical properties on the hydrogen production process.

In the next stage, experiments will be conducted with currents ranging from 3A to 5A and graphene amounts ranging from 0.1 g to 0.5. This range will allow for a more detailed study of the optimum current and graphene concentration for hydrogen production.

In conclusion, ongoing studies on the effects of graphene offer significant opportunities to increase hydrogen production efficiency. However, it should be noted that further research is needed to determine the correct concentrations and parameters for the most effective results.

Abstract
This study explores the optimization of PID controller parameters for an HHO dry cell system utilizing metaheuristic algorithms. A reactor with 13 stainless steel plates (14×14 cm) was employed, and an electrolyte solution was prepared according to established methodologies. The primary objective was to regulate temperature effectively, leveraging Genetic Algorithm (GA) and Artificial Bee Colony (ABC) techniques to enhance system performance. The optimized control parameters were benchmarked against conventional On-Off and Fuzzy-PID controllers. Performance evaluation was conducted using key metrics, including Integral Square Error (ISE), Integral Absolute Error (IAE), Integral Time Absolute Error (ITAE), and Mean Square Error (MSE). Experimental and theoretical analyses revealed that metaheuristic-based PID controllers exhibited superior stability, minimized overshoot, and improved response time, highlighting their potential as effective solutions for temperature management in HHO systems.

Keywords: Artificial Bee Colony, Electrochemistry, Genetic Algorithm, HHO Dry Cell, Optimization

1. INTRODUCTION

Commercial application of electrolyzers commenced in the 1920s with alkaline variants but experienced economic downturn circa the 1970s with the advent of hydrogen production from natural gas and steam methane. In this investigation, the primary aim revolves around maintaining the temperature within the HHO reactor below 60°C through the modulation of Pulse Width Modulation (PWM) settings during hydrogen generation operations. Absent the utilization of PWM techniques, conventional HHO gas generator systems typically operate at full load, resulting in an elevation of the generator temperature to approximately 90°C [1]. Such elevated temperatures may precipitate critical damage to the tube material within the HHO generators. Furthermore, it is recognized that elevated temperatures within the reactor yield several adverse consequences. Firstly, heightened temperature levels contribute to increased water evaporation, consequently elevating the moisture content within the produced gas, thereby compromising the quality of the resultant hydrogen gas. Secondly, elevated temperature levels within the reactor curtail the operational lifespan of the system. Literature suggests that optimal temperature levels for HHO gas generators reside below 70°C [2-3]. The temperature control of HHO reactors emerges as a complex optimization problem. In this context, the necessity of utilizing modern artificial intelligence techniques alongside traditional control methods becomes apparent. Meta-heuristic optimization techniques inspired by natural intelligence, such as genetic algorithms and artificial bee colony, could play a significant role in managing the temperature of HHO reactors. These techniques offer potential in effectively navigating through multiple variables in complex systems, thereby potentially yielding optimized and energy-efficient solutions for temperature control in HHO reactors. Therefore, artificial intelligence-based methods such as genetic algorithms and artificial bee colony present themselves as significant tools in managing the temperature of HHO reactors.

2. EXPERIMENTAL AND NUMERICAL SET-UP

The regulation of temperature in a dry cell HHO reactor is a fundamental challenge within temperature control systems. This process can be mathematically represented through a first-order system transfer function, formulated as follows:

$$G(s) = \frac{K}{Ts+1} e^{-\tau s} = \frac{56.8}{1780s+1} e^{-50s} \tag{1}$$

where K denotes the static gain of the controlled process, represents the system's pure lag time, and T is the time constant defining the system dynamics. Consequently, the mathematical representation of the dry cell HHO reactor system's behavior is articulated through Equation 1.

The On-Off controller is widely recognized as the simplest form of feedback control. Its implementation requires minimal parameter tuning, typically involving only the determination of the on-value, off-value, and threshold level of the controller output. However, On-Off controllers often induce oscillatory behavior and generally exhibit a non-zero steady-state error. The governing equation for an On-Off controller is expressed as:

$$u(t)_{on-off} = \begin{cases} u_{on} \ for \ e(t) > 0 \\ u_{off} \ for \ e(t) < 0 \end{cases} \tag{2}$$

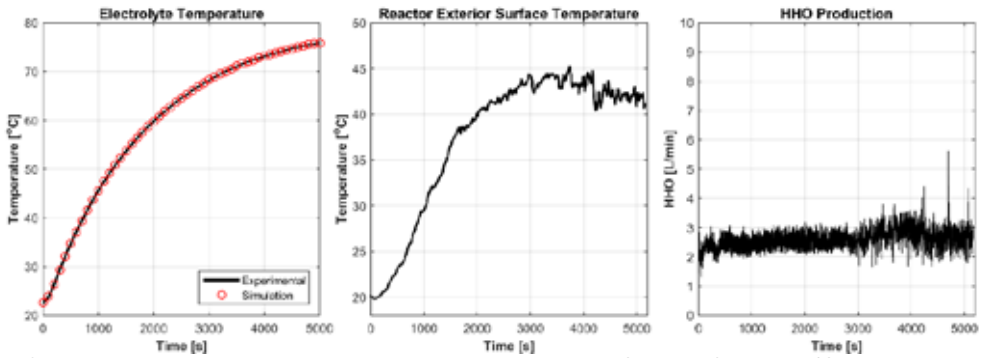

Fig. 1. Surface & electrolyte temperatures and hydroxy production rates of the HHO dry cell (Conker ve Baltacıoglu, 2020)

In this context, the output signal from the controller is denoted by *u(t)*, while the actuating error signal is presented by *e(t).*

A PID (Proportional-Integral-Derivative) controller is a ubiquitous feedback control mechanism extensively utilized in industrial control systems due to its favorable attributes, such as high reliability, stability, and computational simplicity. The PID controller aims to minimize the discrepancy between a measured process variable and a desired set point by computing and implementing corrective actions promptly to regulate the process effectively and minimize errors. The conventional transfer function of a PID controller can be expressed as follows:

$$u(t)_{PID} = K_p e(t) + K_i \int_0^t e(t)dt + K_d \frac{d(e(t))}{dt} \tag{3}$$

The suitability of a PID (Proportional-Integral-Derivative) controller is primarily limited to linear systems with well-defined mathematical models. However, the regulation of temperature in an HHO (Hydrogen-Hydrogen-Oxygen) reactor poses a distinct challenge due to its inherently non-linear, time-delayed, and time-varying characteristics.

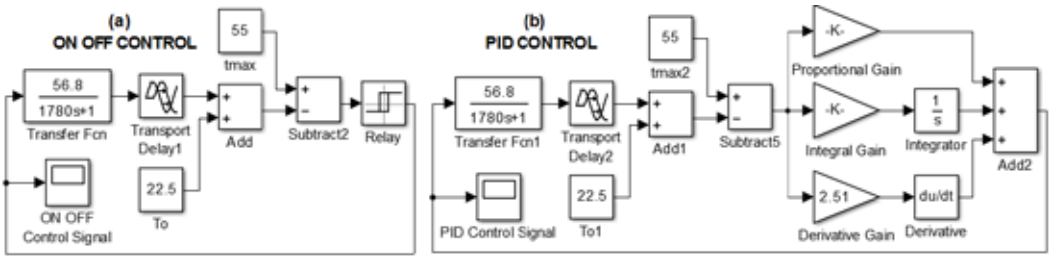

Fig. 2. Flow chart of on-off (a) and fuzzy PID (b) structures

3. ANALYSIS

Genetic Algorithm (GA)

The Genetic Algorithm (GA) begins by generating an initial population of chromosomes randomly. These chromosomes evolve iteratively through genetic operations, including selection, crossover, and mutation, with fitness evaluation guiding the optimization process. The algorithm continues until termination criteria are satisfied or a predefined number of iterations is reached. Key parameters such as population size, crossover rate, and mutation rate significantly influence the algorithm's convergence and efficiency. The evolutionary process of GA is illustrated in Fig. 3a.

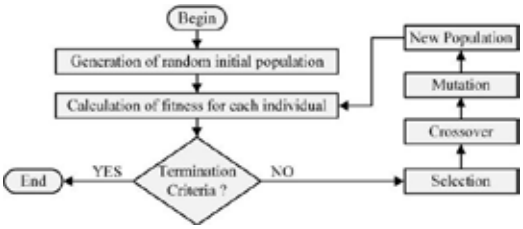

Fig. 3a. Genetic Algorithm Flowchart

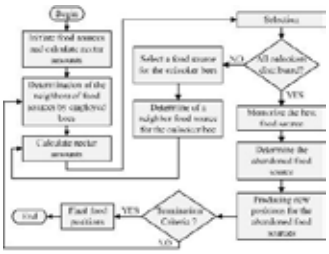

Fig. 3b. Artificial Bee Colony Algorithm Flowchart

Artificial Bee Colony (ABC) Algorithm

The ABC algorithm is inspired by the foraging behavior of honeybee colonies and comprises three distinct types of bees: employed bees, onlooker bees, and scout bees. Employed bees collect nectar from known sources and communicate information to onlooker bees, which select the most promising sources based on shared data. When nectar is depleted, bees transition into scout mode, exploring new sources randomly. The ABC algorithm seeks to locate the most optimal solution within the search space through iterative exploration and exploitation mechanisms. The operational structure of the ABC algorithm is depicted in Fig. 3b.

Fitting Functions

This section elaborates on the tuning methods utilized for various performance metrics, including Integral Square Error (ISE), Integral Absolute Error (IAE), Integral Time Absolute Error (ITAE), and Mean Square Error (MSE); Eq.4 to 7 respectively [4].

$$IAE = \int_0^t |e(t)|\,dt \tag{4}$$

$$ISE = \int_0^t e^2(t)dt \tag{5}$$

$$ITAE = \int_0^t t\,|e(t)|\,dt \tag{6}$$

$$MSE = \frac{1}{N}\sum_{k=1}^{N} e^2(k) \tag{7}$$

The primary control objective is to maintain various performance specifications, including rise time, settling time, maximum overshoot, and steady-state error, within desirable limits. To further validate the proposed technique and demonstrate its practical effectiveness compared to conventional methods, a series of experiments are conducted.

4. RESULTS AND DISCUSSIONS

The system, controller and optimization process are presented in Fig. 4. Besides, optimization results of GA and ABC due to ISE, IAE, ITAE, MSE are presented in Table 1 in numerical form. Graphical resresentation of them are shown in Figs. 5 and 6, respectively.

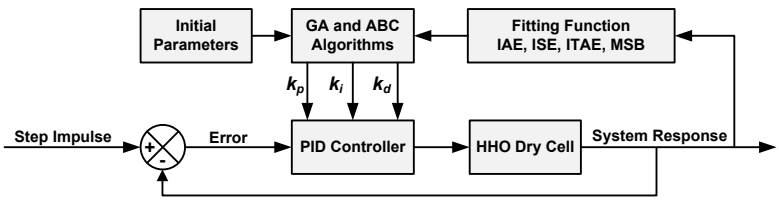

Fig. 4. Optimization and Controller Structure

Figs. 7a and 7b present system respons graphs of GA and ABC, respectively. The results indicate that, in comparison to the On-Off, PID, and Fuzzy controllers, the metaheuristic-based PID controller displays notable advantages. These include the absence of overshoot, a shorter adjustment time, improved dynamic response, and enhanced steady-state characteristics.

5. CONCLUSIONS

This study presents an optimized control strategy for HHO dry cell temperature regulation by leveraging Genetic Algorithm (GA) and Artificial Bee Colony (ABC) optimization techniques. The proposed approach effectively minimizes commonly used performance indices such as ISE, IAE, ITAE, and MSE, leading to optimal controller gain selection. The obtained results confirm the viability and efficiency of metaheuristic-based PID controllers in addressing temperature regulation challenges in HHO reactors. Future research should extend the analysis by incorporating alternative optimization methodologies to further enhance control system performance.

ABSTRACT
In light of growing concerns regarding climate change, there has been a significant increase in interest in hydrogen energy and related technologies, particularly those focused on clean hydrogen production through water electrolysis. This study explores the utilization of graphene oxide (GO) and dopamine-functionalized graphene oxide (DGO) as filler materials to enhance the performance of anion exchange membranes (AEMs) employed in water electrolysis. A comprehensive synthesis and characterization approach was undertaken to examine the structural, thermal, and conductive properties of these materials. The synthesis methodologies, including the Hummer method and the development of composite materials, are elaborated upon, alongside their influence on the properties of the membranes. The incorporation of DGO was found to improve KOH retention, conductivity, ion transport, and membrane stability. This investigation highlights the potential of these fillers in advancing AEM technology and offers valuable insights into their contribution to addressing climate change and promoting sustainable energy solutions.

Keywords: Graphene, graphene oxide, dopamine graphene oxide, anion exchange membrane

1. INTRODUCTION

Hydrogen is widely regarded as one of the most promising alternative energy carriers capable of addressing contemporary challenges related to energy security and environmental sustainability. It can be produced through various methods, including natural gas reforming, water electrolysis, and direct solar water splitting. Among these, water electrolysis stands out as a particularly advantageous technology for energy conversion, as it enables the utilization of intermittent renewable energy sources such as wind, tidal, and solar power to generate hydrogen from water. Water electrolyzers are highly efficient, capable of accommodating high current densities per unit surface area, operating in dynamic conditions, and responding rapidly to fluctuations. These characteristics make them well-suited for integrating with and storing energy from intermittent renewable sources, thereby supporting the transition to sustainable energy systems [1].

In addition to the widely utilized commercial alkaline electrolyzers (AEL) and proton exchange membrane electrolyzers (PEMEL), anion exchange membrane water electrolyzers (AEMWEL) offer a unique combination of the advantages associated with both technologies, enabling a compact and optimized system design similar to PEMELs while utilizing transition metals as catalysts instead of the noble metals required in PEMEL systems. Unlike AEL systems, which rely on concentrated potassium hydroxide (KOH) solutions, AEMWEL systems can operate using distilled water or low-concentration alkaline electrolytes. Furthermore, the membranes used in AEMWEL, which incorporate anion exchange groups, are more cost-effective compared to Nafion-based membranes utilized in PEMELs. Additionally, AEMWEL systems exhibit minimal interaction between CO2 and the membrane due to the absence of metal ions. This technology also offers several other benefits, including the elimination of corrosive liquid electrolytes, prevention of leakage, enhanced volumetric stability, ease of operation, and a reduction in the overall size and weight of the electrolyzer. These features collectively position AEMWEL as a promising and efficient alternative for hydrogen production [2,3].

The anion exchange membrane (AEM), a critical component in anion exchange membrane water electrolyzer (AEMWEL) systems, facilitates the transport of hydroxide ions (OH^-) from the cathode to the anode while preventing gas crossover and electron transfer during electrochemical processes. For effective application in electrolysis, AEMs must demonstrate high ion permeability, excellent ionic conductivity, robust thermal and mechanical stability, and superior chemical stability. Thus, both the cationic functional groups and the stability of the polymer backbone are crucial factors in ensuring the durability of AEMs. The incorporation of various filler materials has been explored to improve the mechanical properties of AEMs. Over the past decade, numerous strategies have been investigated to address the degradation of AEMs at elevated temperatures and to enhance their ionic conductivity, aiming to optimize their performance in demanding operational environments [4]. Graphene oxide (GO) has attracted significant attention as a nanomaterial filler owing to its exceptional thermal stability and high specific surface area. The synthesis of GO is commonly achieved through Hummer's method, which is preferred for its high efficiency and favorable safety characteristics. Additionally, composite GO materials integrated with phosphates and sulfates have been engineered to further enhance the properties of GO, thereby improving membrane performance [5,6]. To achieve this, extensive research and development have been conducted on advanced synthesis methodologies. Dopamine-functionalized graphene oxide (DGO) exhibits exceptional properties, including higher water uptake, enhanced tensile strength, greater elongation at break, and improved stability

in alkaline solutions. These characteristics make DGO an ideal filler for reinforcing anion exchange membranes (AEMs), ensuring superior mechanical durability, flexibility, and long-term performance in demanding applications such as water electrolysis [7].
This study is centered on the preparation of anion exchange membranes (AEMs) incorporating GO and DGO as fillers, along with a comprehensive characterization of the synthesized membranes. The findings demonstrate the successful synthesis of the targeted GO structures and reveal a significant enhancement in KOH retention, a critical factor influencing the performance of the AEMs.

2. EXPERIMENTAL SET-UP AND PROCEDURE

2.1. GO and Modified GO Preparation: The synthesis of GO was carried out using the Hummer method. Initially, 3.0 grams of graphite powder were mixed with 70 ml of sulfuric acid in a Teflon beaker, which was then placed in an ice bath and stirred continuously. Following this, 9.0 grams of potassium permanganate were gradually added to the mixture under constant stirring. The temperature of the mixture was increased to 40°C and maintained for 30 minutes with continuous stirring. Subsequently, 150 ml of distilled water was slowly added, and the temperature was raised to 95°C. After 15 minutes of stirring, an additional 500 ml of distilled water was introduced, followed by 15 ml of 30% hydrogen peroxide. At this stage, the mixture's color changed from dark brown to yellow. The solution was then allowed to settle for 24 hours. Finally, the mixture was centrifuged and washed three times with 250 ml of a 1:10 HCl solution and distilled water, after which it was dried in an oven at 60°C [6]. Additionally, DGO was synthesized for application in AEMWELs following established literature procedures [7], as illustrated in Figure 1.

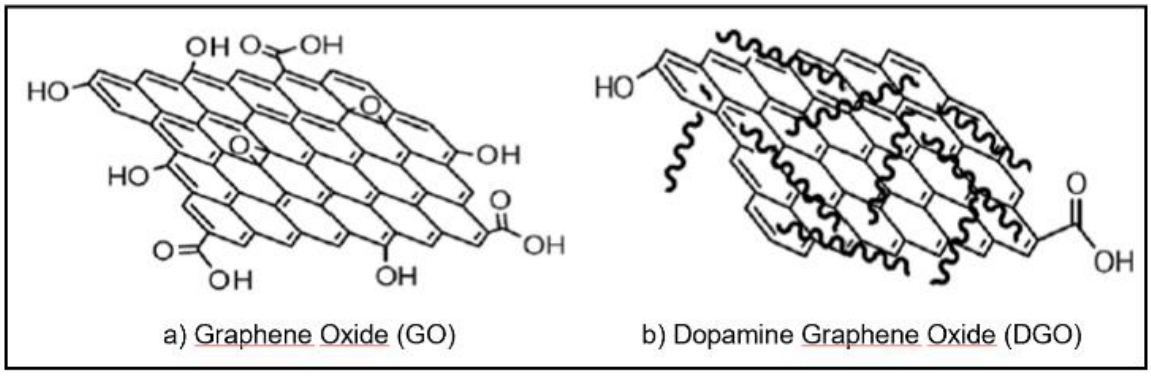

Fig.1. a) GO and b) Dopamine GO

2.2. Composite AEM Preparation: In this study, composite membranes were fabricated using a Fumion® solution as the base material. GO and DGO were incorporated into the Fumion® solution by the predetermined additive concentrations. The resulting mixture was stirred until a homogeneous solution was achieved, which was then cast onto a glass surface. Subsequently, the membranes were dried in a vacuum oven at 80°C for 12 hours to ensure complete solvent removal and proper formation of the membrane structure.

3. ANALYSIS

The crystalline structure of GO and its modified form was characterized using X-ray diffraction (XRD) (Rigaku Ultima-IV, Cu Kα radiation, λ = 1.54056 Å). The chemical composition and bonding states were analyzed via X-ray photoelectron spectroscopy (XPS) using a PHI 5000 VersaProbe instrument with Al Kα radiation under vacuum conditions (energy range: 0–900 eV, X-ray spot size: 100 µm). Fourier-transform infrared (FT-IR) spectra were acquired using a Bruker IFS 66/S spectrometer to investigate functional groups. Additionally, the membranes' suitability for AEM applications was assessed through measurements of KOH uptake and ionic conductivity.The electrochemical characterization was conducted by Electrochemical Impedance Spectroscopy (EIS).

4. RESULTS AND DISCUSSIONS

Figure 2a presents the XRD patterns of GO and its modified forms, with a sharp peak at 12.57° corresponding to the (002) planar reflection of GO layers, indicating a d-spacing of 0.703 nm. XPS analysis of dopamine-modified GO revealed new peaks at C=C (285.0 eV), C-C (282.0 eV), and C-P (288.0 eV), confirming functional group incorporation [8–10]. Figure 2b shows FTIR spectra of GO and dGO, with characteristic peaks for C-O-C (~1033 cm^{-1}), C-O (~1227 cm^{-1}), C=C (~1617 cm^{-1}), and C=O (1710–1720 cm^{-1}). The dGO spectrum exhibited N-H bending at 1512 cm^{-1}, while the absence of a CH_2 bending peak at 1345 cm^{-1} confirmed dopamine self-polymerization [5,10–12]. These results validate the successful synthesis and functionalization of GO for AEM applications.

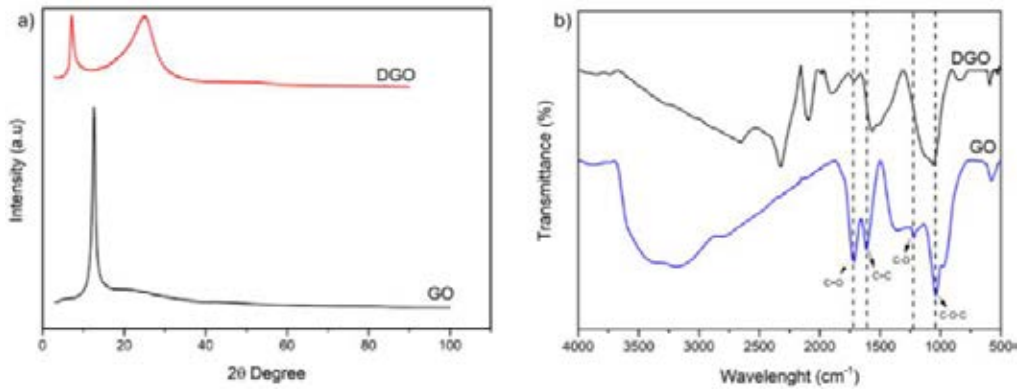

Fig. 2. a) XRD Patterns of GO, and DGO and b) FTIR Patterns of GO and DGO

Figure 3a shows the XPS survey and C1s spectra of graphene oxide (GO), highlighting high-intensity O1s peaks that confirm the presence of oxygen-containing functional groups. Quantitative analysis indicates a composition of 67.8% carbon and 31.4% oxygen, with C1s deconvolution revealing peaks for C-C (283.9 eV), C-O (285.8 eV), C-O-C (287.4 eV), and C=O (288.3 eV) [6,8]. In contrast, Figure 3b displays the C1s spectrum of dopamine-functionalized graphene oxide (DGO), deconvoluted into C=C (285.0 eV), C-C (282.0 eV), and C-P (288.0 eV), confirming successful dopamine modification [10]. These results demonstrate the structural and compositional differences between GO and DGO.

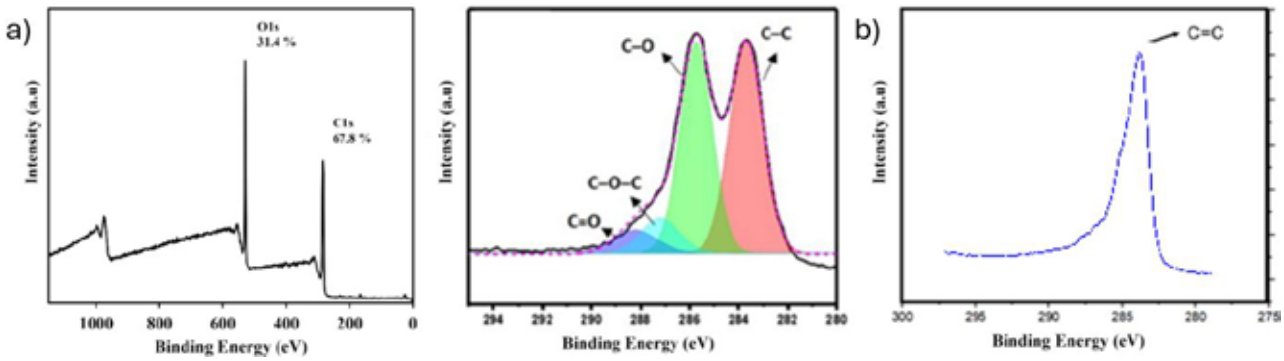

Fig. 3. XPS Patterns of a) GO and b) DGO

The ability of membranes to absorb KOH is a critical factor influencing their electrochemical performance for AEMWE applications. In this study, KOH uptake experiments were conducted on the synthesized composite membranes using a 0.1 M KOH solution. The KOH uptake rates for the commercial Fumasep, F/GO, and F/DGO membranes were measured at 30.6%, 47.6%, and 51%, respectively. The F/GO and F/DGO membranes demonstrated significantly higher KOH and water uptake capacities compared to the reference Fumasep membrane, indicating enhanced suitability for AEMWE applications. Table 1 shows the conductivity analyses, performed at temperatures between 30-80°C with 1M and 2M KOH doping, as well as after aging in 2M KOH, showed average increases of 31%, 46%, and 51% for GO and DGO-based membranes, respectively. These findings collectively highlight the superior performance of GO and DGO-based composite membranes in AEMWE applications, emphasizing their potential for advancing sustainable energy technologies.

Table 1. Ion Conductivity Analysis Results of Membranes

Temperature	Membrane					
	F/GO (1M KOH)	F/GO (2M KOH)	F/GO (2M KOH Ageing)	F/DGO (1M KOH)	F/DGO (2M KOH)	F/DGO (2M KOH Ageing)
30º C	40.5	46.5	32.5	79.0	83.5	90.0
40º C	49.0	53.5	46.0	82.5	110.5	90.0
50º C	74.0	70.5	51.5	85.0	114.5	89.5
60º C	85.0	83.5	78.5	94.5	117.0	90.5
70º C	88.5	90,5	86.0	102.0	118.5	93.5
80º C	103.0	113.5	108.5	116.0	121.0	97.5

5. CONCLUSIONS

In this study, composite anion exchange membranes (AEMs) incorporating graphene oxide (GO) and its modified forms were developed for application in anion exchange membrane water electrolyzers (AEMWEs), with their structural properties and performance systematically investigated. The results demonstrate that the GO-based composite membranes exhibit enhanced properties, making them highly suitable for AEMWE applications. This research provides valuable insights into the potential use of these synthesized fillers in advancing AEM technology, underscoring their role in enabling sustainable energy solutions and supporting global efforts to mitigate climate change. Continued research and development in this field hold significant promise for driving progress in the hydrogen economy and fostering environmental sustainability.

ABSTRACT
Hydrogen fuel cell vehicles stand out as technologies promising zero emissions and high efficiency. However, hydrogen's low density, high flammability, and pressurized storage requirements bring risks such as leakage, explosion, and system failures. This article evaluates the main risks observed in hydrogen fuel cell vehicles, including hydrogen leakage, high-pressure storage, fuel cell failures, accident scenarios, infrastructure, and operational risks within the framework of systematic risk analysis methodologies (MADS/MOSAR, FMEA, FTA). In the conclusion, strategies to minimize these risks are presented.
Keywords: Hydrogen Fuel Cell, Risk Analysis, Fuel Cell, Safety Management, High Pressure

1. INTRODUCTION
With the increasing focus on environmental sustainability in the automotive industry, hydrogen fuel cell vehicles are gaining significant attention. While hydrogen offers high energy content and zero-emission advantages, it also poses risks such as leakage, explosion, and material incompatibility due to its low density and rapid ascent properties [1,2]. This article examines the critical risk factors in the safety management of hydrogen fuel cell vehicles using systematic risk assessment methods and emphasizes applicable control strategies.

2. RISK CATEGORIES AND ASSESSMENT
2.1. Hydrogen Leakage and Explosion Risk
Definition: Hydrogen rises rapidly due to its low molecular weight. This property leads to severe explosion and fire hazards if even small amounts of hydrogen leakage combine with oxygen [1,2]. Hydrogen has a wide ignition range in air, between 4% and 75% [3].
Probability and Impact:
- Probability: High-pressure operation and mechanical connection errors can increase the risk of leakage.
- Impact: Sudden explosion, fire, and environmental damage.

Control Measures:
- Hydrogen leakage sensors monitor changes in thermal conductivity with concentration, enabling early detection.
- Development of leak-proof connection and sealing technologies.
- Emergency shut-off and evacuation mechanisms.

2.2. High-Pressure Storage and Material Compatibility Issues
Definition: Storing hydrogen under high pressure can cause mechanical stress in tanks and problems such as "hydrogen embrittlement" (material weakening) [4].
Probability and Impact:
- Probability: Mechanical fatigue and material incompatibilities can be observed in long-term use.
- Impact: Cracking, leakage, and sudden failures in storage tanks.

Control Measures:
- Special composite storage tank designs with a gravimetric capacity between 2.4% - 4.4%.
- Regular periodic maintenance and testing.

2.3. Fuel Cell Failures and Systemic Errors
Definition: Although fuel cell systems offer high efficiency, they can be subject to failures and performance degradation due to their technological complexity [5].
Probability and Impact:
- Probability: The probability of error increases with technological complexity and long-term operation.

- Impact: Decrease in fuel cell performance, need for emergency intervention.

Control Measures:

- Advanced diagnostic and remote monitoring systems.
- Regular maintenance, testing, and failure management plans.

2.4. Collision and Accident Situations

Definition: During vehicle accidents or collisions, damage to hydrogen storage tanks can trigger leakage and explosion risks [1].

Probability and Impact:

- Probability: Traffic conditions, operator errors, and external factors can increase this risk.
- Impact: Serious safety risks for passengers, structural damage, and emergency response.

Control Measures:

- Collision-resistant design, energy-absorbing materials, and configurations.
- Implementation of emergency stop systems and crash tests.

2.5. Infrastructure and Logistics Risks

Definition: Lack of compliance with international standards or technical errors at hydrogen refueling stations can lead to leakage and environmental risks [5].

Probability and Impact:

- Probability: Can increase due to regional infrastructure practices and operator inexperience.
- Impact: Leakage from refueling errors, explosion risk, and decreased user confidence.

Control Measures:

- Infrastructure compliant with international standards such as ISO and SAE.
- Employment of certified and trained operators.
- Regular inspections and systematic testing.

2.6. Operational and Usage Risks

Definition: Insufficient training of vehicle users and maintenance teams, procedural errors, and incorrect practices can increase operational risks [6].

Probability and Impact:

- Probability: Error rate increases due to lack of training.
- Impact: System failures, performance loss, and increased maintenance costs.

Control Measures:

- Comprehensive user and maintenance personnel training.
- Implementation of detailed user manuals and emergency procedures.
- Continuous updating of operational standards and maintenance plans.

3. METHODOLOGY

To systematically conduct risk analysis in hydrogen fuel cell vehicles, methodologies such as MADS/MOSAR, FMEA, and FTA were used. The study steps can be summarized as follows:

1. Risk Identification: Hydrogen leakage, high-pressure storage, fuel cell failures, collision, infrastructure, and operational risks were identified.
2. Risk Analysis: A risk matrix was created by evaluating the probability and impact of each risk.
3. Risk Assessment: Risk levels were calculated and prioritized.
4. Risk Reduction: Applicable control measures and strategies were developed.
5. Monitoring and Review: The sustainability of risk management was ensured through systematic monitoring.

Table 1. FMEA example

Failure Mode	Potential Causes	Effects	S (Severity)	O (Occurrence)	D (Detectability)	RPN	Preventive / Corrective Actions
Hydrogen Leakage	Faulty seal, connection failure, mechanical damage	Explosion risk, fire, environmental damage	9	7	5	315	Installation of leak sensors and alarm systems, periodic maintenance, connection improvements
Fuel Cell Failure	Insufficient cooling, control system malfunction	Reduced energy production, performance loss, need for emergency intervention	7	5	4	140	Advanced diagnostic systems, regular maintenance, optimization of cooling systems
High-Pressure Storage Issue	Material fatigue, use of weak alloy	Tank cracking, leakage, performance loss	8	6	6	288	Dual-layer tank design, material testing and regular inspection, selection of high-quality materials
Electronic Control Failure	Software error, faulty sensor	Incorrect data, situations requiring intervention, performance drop	6	4	7	168	Software updates, sensor calibrations, improvement of error monitoring systems
Material Damage Due to Collision	Accident, impact, or mechanical damage in a crash	Loss of structural integrity, leakage, need for emergency response	9	5	6	270	Impact-resistant design, structural tests, crash simulations, and accident scenario analyses

4. DISCUSSION

The potential advantages offered by hydrogen technologies must be balanced with the risks they bring. Academic studies [4,5] and international standards [2,6] offer suggestions for minimizing risks; however, in practical applications, the integration of regular maintenance, continuous training, and advanced technology monitoring systems comes to the forefront. Reducing operational and usage risks can be achieved, especially through user training and systematic failure management [7].

5. CONCLUSION

This article systematically examines the risks observed in hydrogen fuel cell vehicles, including hydrogen leakage, high-pressure storage, fuel cell failures, collision, infrastructure, and operational factors. Through appropriate control strategies and continuous monitoring practices, the aim is to safely utilize the advantages provided by hydrogen technology. Future technological developments and continuously updated academic research will further improve the safe use of hydrogen.

ABSTRACT
In this study, for the first time, carbon quantum dots supported nickel-based (Ni (0), Ni@Urea, Ni@DOT and Ni@CQD-MOF) catalysts were synthesized from urea by solvothermal method and inexpensive and highly catalytic catalysts for the dehydrogenation of dimethylamine borane (DMAB) and sodium boron hydride (SBH) were prepared. The catalysts synthesized herein were synthesized by different methods and their hydrolysis of both DMAB and SBH was investigated. The characterization of the synthesized catalysts was supported by some analytical methods. The catalysts were investigated at room temperature, catalyst effect, different substrates and different temperatures in DMAB and SBH. The kinetic parameters of the catalyst were found as activation energy 50.12 kj/mol for SBH and 50.86 kj/mol for DMAB. The other activation parameters were ΔH# = 48.20 kj/mol and ΔS# = -112.4 J/mol*K for SBH and ΔH# = 48.28 kj/mol and ΔS# = -48.48 J/mol*K for DMAB. However, the reproducibility of the catalyst was tested 6 times in the presence of both hydrogen sources. In addition, calculations were performed using DFT to investigate the activity of the catalyst. It was found that the calculations were in good agreement with the experimental data.

Keywords: DMAB, SBH, Hydrogen, Solvotermal, DFT

1. INTRODUCTION

Today, the trend towards renewable energy sources is increasing due to increasing environmental problems and the scarcity of fossil fuels. Since hydrogen, one of the renewable energy sources, has storage and transportation problems, borohydrides that will overcome these problems come to the fore [1-3]. Borhydrides, such as sodium borohydride (SBH) 10.9%, potassium borohydride (PBH) 7.9%, ammonia borane (AB) 19.6%, dimethyl aminborane (DMAB), are used due to some advantages such as high hydrogen content, ease of use and non-flammability. Among the available hydrogen sources, ammonia borane derivatives are attracting increasing interest due to their high hydrogen content, availability, stability, ease of use and non-flammability. The prominent ones are usually SBH and DMAB. DMAB is used because it remains in a stable form in air, is very cheap, and has a crystalline structure. However, they cannot be used as hydrogen sources without a suitable catalyst [4-7]. Both hydrogen sources are hydrolyzed at room conditions in the presence of suitable catalysts. Especially for the hydrolysis of DMAB, Pd, Ru and Ro based catalysts were used, or different heterogeneous catalysts were used. The hydrolysis reactions for both hydrogen sources (DMAB and SBH) are shown below.

$$NaBH_4 + 2\,H_2O \xrightarrow{Ni@CQDs\ Catalyst} NaBO_2 + 4H_2\uparrow \quad (1)$$

According to Equation (1), hydrolysis of 1 mole of $NaBH_4$ yields 4 moles of H_2. of this, 2 moles come from H_2O.

$$(CH_3)_2NHBH_3 + 2\,H_2O \xrightarrow{Ni@CQDs\ Catalyst} (CH_3)_2NH_2BO_2 + 3H_2\uparrow \quad (2)$$

According to Equation (2), theoretically, 3 mol H2 is obtained from the hydrolysis of 1 mol $(CH_3)_2NHBH_3$

Since the two hydrogen sources here are self-hydrolyzing, suitable catalysts with high catalytic activity are needed to control the reaction. As mentioned above, although studies with expensive catalysts are generally carried out, studies on cheap and active catalysts are limited. For this purpose, catalysts such as (Co, Cr, Fe, Cu, Mo and Ni), which are abundant in nature for hydrogen production in aqueous solutions of DMAB and SBH, are used and support materials are used to prevent their agglomeration and homogeneous dispersion. Support materials include carbon nanotubes (CNT), activated carbon (AC), metal organic framework (MOF), aluminum oxide (Al_2O_3) and carbon quantum dots (CQD). Among them, CQDs are notable for their potential catalytic applications due to factors such as their nanometer size (<5nm), surface properties, electron transfer and chemical functional groups of the materials, and green synthesis[8-9].

In this study, 4 different catalysts were synthesized by solvothermal method with 4 different synthesis models and their hydrogen activities in both DMAB and SB were compared. In addition, the 4 synthesized catalysts were characterized by analytical methods; XRD, BET, UV-PL, IR, TEM and XPS analysis. The H2 yield obtained as a result of hydrolysis of the synthesized catalyst in both DMAB and SBH, different Ni loading types on CQD support, different DMAB, SBH concentrations, different catalyst amounts and detailed kinetic studies of both hydrogen sources are presented. Here, hydrogen production rates for DMAB and SBH at 25o C for Ni@CQD in aqueous media were calculated as 862 and 1542 mL.min-1.g.cat-1, respectively. In addition, the activation parameters of the catalyst were calculated for each hydrogen source individually and the reusability of the catalyst was tested 6 times[10-11]. In addition, calculations were performed using DFT to investigate the activity of the catalyst. It was observed that the calculations were in agreement with the experimental data.

2. MATERIALS AND METHODS

2.1. Experimental procedure

Dimetil formamid (C_3H_7NO), Sodium borohydride ($NaBH_4$), Dimethylamine borane ($(CH_3)_2NHBH_3$) Nickel chloride hexahydrate ($NiCl_2.6H_20$) urea, and sodium hydroxide (NaOH) were purchased from Sigma-Aldrich and used in catalyst synthesis and hydrolysis. Ultra-distilled water was used for sample preparation.

2.2. Hydrogen generation measurement

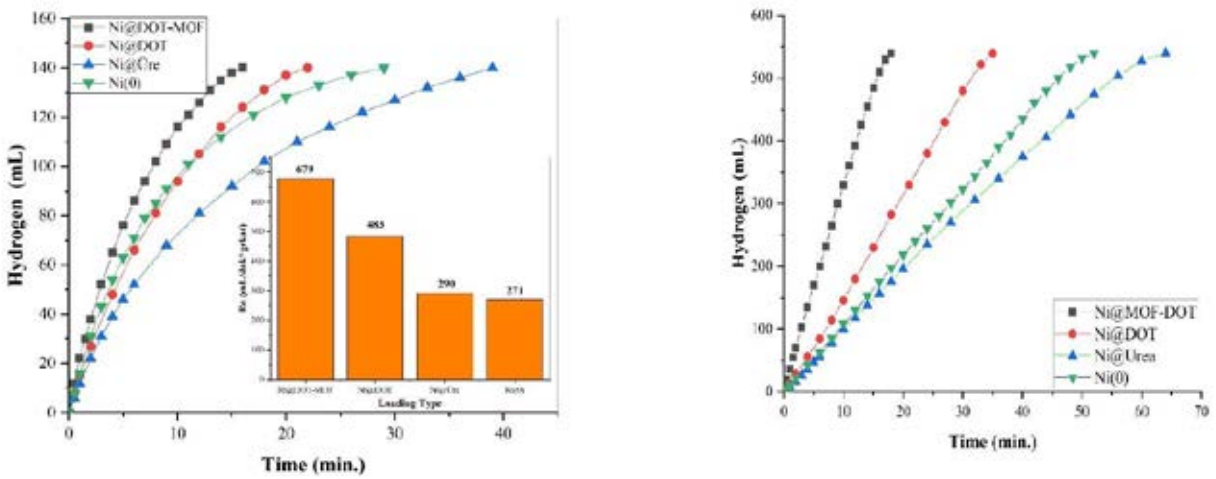
The measurement of the hydrogen gas produced during the methanolysis reaction was carried out using the water displacement technique. The experiment involved combining predetermined quantities of catalyst with quantities of SB and DMAB within a reaction flask. Subsequently, the reaction flask was placed in a water bath maintained at a temperature of 30 °C. Subsequently, the bottle was linked to the conical container housing water. Following the introduction of 10 mL of methanol into the reaction flask, the methanolysis of SB and DMAB occurs, resulting in the generation of H_2. Subsequently, the produced H_2 migrates to the conical flask that contains water. The reduction in water volume over a given period of time serves as an indicator of the quantity of hydrogen gas (H_2) generated during this chemical reaction. No mixing occurred during the course of this reaction. The hydrogen generation rate (HGR) was defined as mL min^{-1} g^{-1}.

2.3 Ni@CQD-MOF nano-catalyst characterization

A combination of techniques was employed to comprehensively analyze the structural, chemical, and physical properties of the Ni nanocatalyst. X-ray photoelectron spectroscopy (XPS, PHI 5000 VersaProbe) was used to examine the surface chemistry, oxidation states of elements, and their binding energies. Transmission electron microscopy (TEM, JEOL JEM 1220), ideal for high-resolution analysis, was applied to study the internal structure, particle sizes, and arrangement of the nanocatalyst. Energy-dispersive X-ray spectroscopy (EDX, HITACHI TM 3030 Plus) provided information on the elemental distribution, while X-ray diffraction (XRD, Rigaku Ultima-IV) patterns revealed the crystal dimensions and structural regularity of the material. Additionally, BET (Quantachrome Corporation, Autosorb-6) and FT-IR (Shimadzu IRTracer™-100) analyses were also carried out to determine the characteristics of the catalyst surface and the presence of functional groups on it.

3. RESULTS AND DISCUSSION

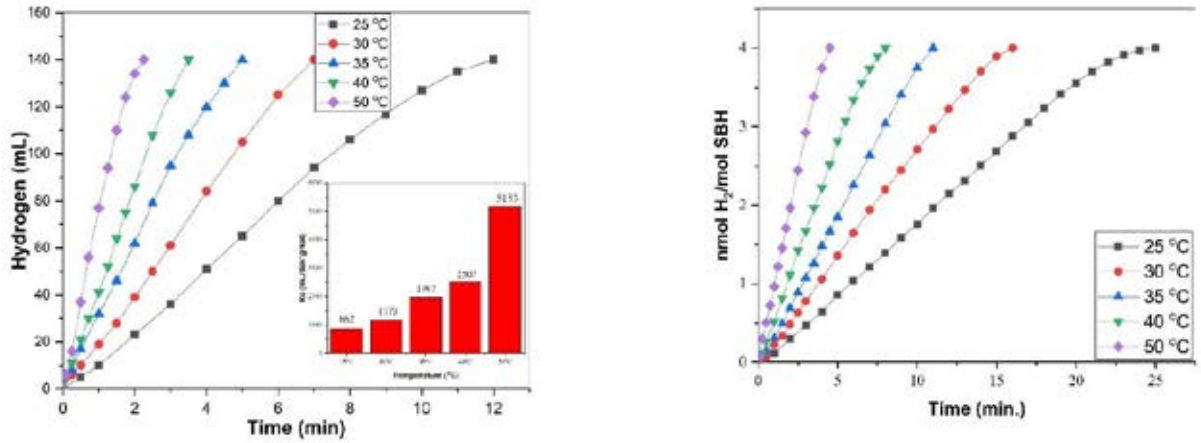
In this study, the catalysts were characterized and the hydrogen efficiency of both hydrogen sources in the presence of the catalyst was studied at different temperatures for different loading type, different NaOH effect, different subtract amount and activation parameters of the catalyst. The plots of hydrogen activity versus time for 4 different catalysts in both DMAB and SBH are given below in Fig. 1(a-b). Fig. 1a shows that Ni@DOT-MOF catalyst obtained by solvothermal method has higher catalytic performance than Ni(0) and Ni@Urea catalysts synthesized by impregnation method. Likewise, if we look at the 1-b graph, it is seen that the Ni@DOT-MOF catalyst completes the hydrolysis in a shorter time and the hydrogen production rate is about 3 times faster than Ni@Urea.



(a) (b)

Fig. 1. Different loading types of catalysts obtained by solvothermal method according to different hydrogen sources a) in the presence of DMAB (40 mg catalyst 25^{0}C, 2 mmol DMAB, 1% NaOH), b) in the presence of SBH (40 mg catalyst 25^{0}C, 0.2 g SBH, 5% NaOH).

Fig. 2 shows the hydrogen production on both DMAB and SB at different temperatures in the presence of Ni@DOT-MOF catalyst. As seen in both figures, as the temperature increases, the catalytic activity of the catalyst increases and the hydrolysis time shortens.



(a) (b)

Fig. 2. Temperature effect of catalysts obtained by solvothermal method according to different hydrogen sources a) in the presence of DMAB, b) in the presence of SBH

4. CONCLUSIONS

At the end of the experimental studies of the obtained Ni@DOT-MOF catalyst with respect to both SBH and DMAB concentrations, it was observed that SBH and DMAB hydrolysis reactions proceeded at the zeroth order. This shows us that the reaction rate is independent of the concentration of the reactant. However, the hydrogen production rates in both DMAB and SBH in the presence of Ni@DOT-MOF catalyst at 25 0C were calculated as 862 and 1542 mL.min-1.g.cat-1, respectively, and the activation energies were calculated as 50.86 and 50.12 kj/mol. However, the usable performance of the Ni@DOT-MOF catalyst for both hydrogen sources was performed exactly 6 times and it was observed that the catalyst retained its catalytic activity even after 6 times of usability.

ABSTRACT
This research proposes an advanced hydrogen (H_2) liquefaction process that optimizes energy consumption by integrating liquefied natural gas regasification for the pre-cooling stage. The structure is powered by 23.45 MW of renewable solar energy, supplied through photovoltaic (PV) panels, while an absorption refrigeration unit utilizes surplus heat within the facility. Process simulations were conducted using Aspen HYSYS V12.1, and the PV system was designed with PVsyst 7.3.1, considering Izmir's meteorological conditions. This innovative approach enhances energy efficiency and promotes sustainability through renewable energy integration. To supply the cycle's power demand, 18 Swiss Solar IBEX-60M-320 PV modules and 37 Hyundai HPC-500HL-EU inverters were utilized. The energy performance analysis of the system indicates that the maximum performance ratio (PR) was achieved in July at 91.2%, whereas the lowest PR was recorded in December at 80.5%. Additionally, the maximum available energy was recorded in July, reaching 3,726.8 MWh, while the lowest value was recorded in February at 3,304.6 MWh. Furthermore, mismatch losses peaked at 95.87 MWh in July and dropped to their lowest level in December at 42.95 MWh.

Keywords: Hydrogen liquefaction process, regasification of liquefied natural gas, energy saving, photovoltaic panels (PV), sustainability energy.

1. INTRODUCTION

Over the past decades, the rapid growth of Industrial sectors and the world market has significantly intensified energy demands and environmental challenges. Climate change and ozone layer depletion have raised serious concerns among environmentalists, as they pose significant threats to the long-term sustainability of the global ecosystem. Among various energy sectors, liquefied natural gas (LNG) transportation has emerged as a crucial method for natural gas distribution, accounting for 32% of global natural gas imports in 2012, offering an alternative to conventional pipeline transmission [1]. The market feasibility of LNG projects is primarily affected by the efficiency of the liquefaction process, as this stage requires considerable energy input.

Due to the substantial energy requirement involved in the liquefaction and deep cooling of natural gas (NG) to temperatures lower than -160 °C, improving energy efficiency in LNG plants remains a top priority. A significant portion of this energy demand arises from the operation of compression refrigeration cycles (CRCs) [2]. The mixed fluid cascade (MFC) cycle is widely adopted in large-scale LNG facilities, where the Linde and Statoil MFC configurations utilize three refrigeration processes with refrigerant mixtures of methane (CH_4), ethane (C_2H_6), propane (C_3H_8), and nitrogen (N_2). These cycles are responsible for the pre-cooling (-25 °C), liquefaction (-86 °C), and subcooling (-160 °C) stages in the NG manufacturing chain [3].

This study introduces an innovative LNG process configuration that integrates an MFC system powered by solar energy and PV and an absorption-refrigeration unit. The proposed cycle is modeled employing Aspen HYSYS V12.1 with the Peng-Robinson equation of state, whereas the PV system is analyzed through PVsyst 7.3.1 software. Many studies have focused on H_2 liquefaction using LNG regasification, such as reference [4–6], but the novelty of this research is supplying the required cycle power through PV considering Izmir's climatic conditions.

2. SYSTEM DESCRIPTION

This study introduces an innovative integrated H_2 liquefaction cycle that effectively combines LNG regasification and solid oxide fuel cell (SOFC) operations. The designed framework leverages the cold energy from LNG, a 6-stage Joule-Brayton (J-B) process, an organic Rankine cycle (ORC) includes the working fluids H_2O and Refrigerant-290, CO_2-based power cycles, and PV to enhance overall efficiency. CO_2 serves as an optimal working fluid for supercritical cycles in power generation by utilizing heat recovery.

As a case study, it is considered that a PV system installed in Izmir, Türkiye, supplies approximately 23,455 kW of electricity to power the integrated process. In addition, Figs. 1 and 2 indicate the block flow and the process flow diagrams employed in the developed system, respectively. According to the process flow diagram (Fig. 2), H_2 initially enters heat exchanger HX1 through State 1 at a temperature of 25 °C, a pressure of 2100 kPa, and a mass flow rate of 1033 kmol/h.

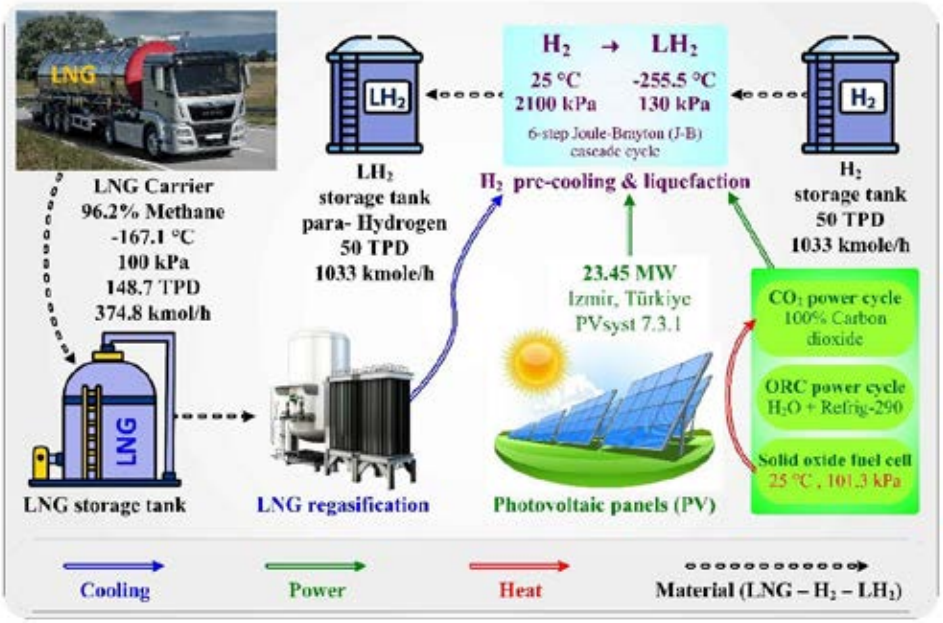

Fig. 1. The block flow diagram of the developed system.

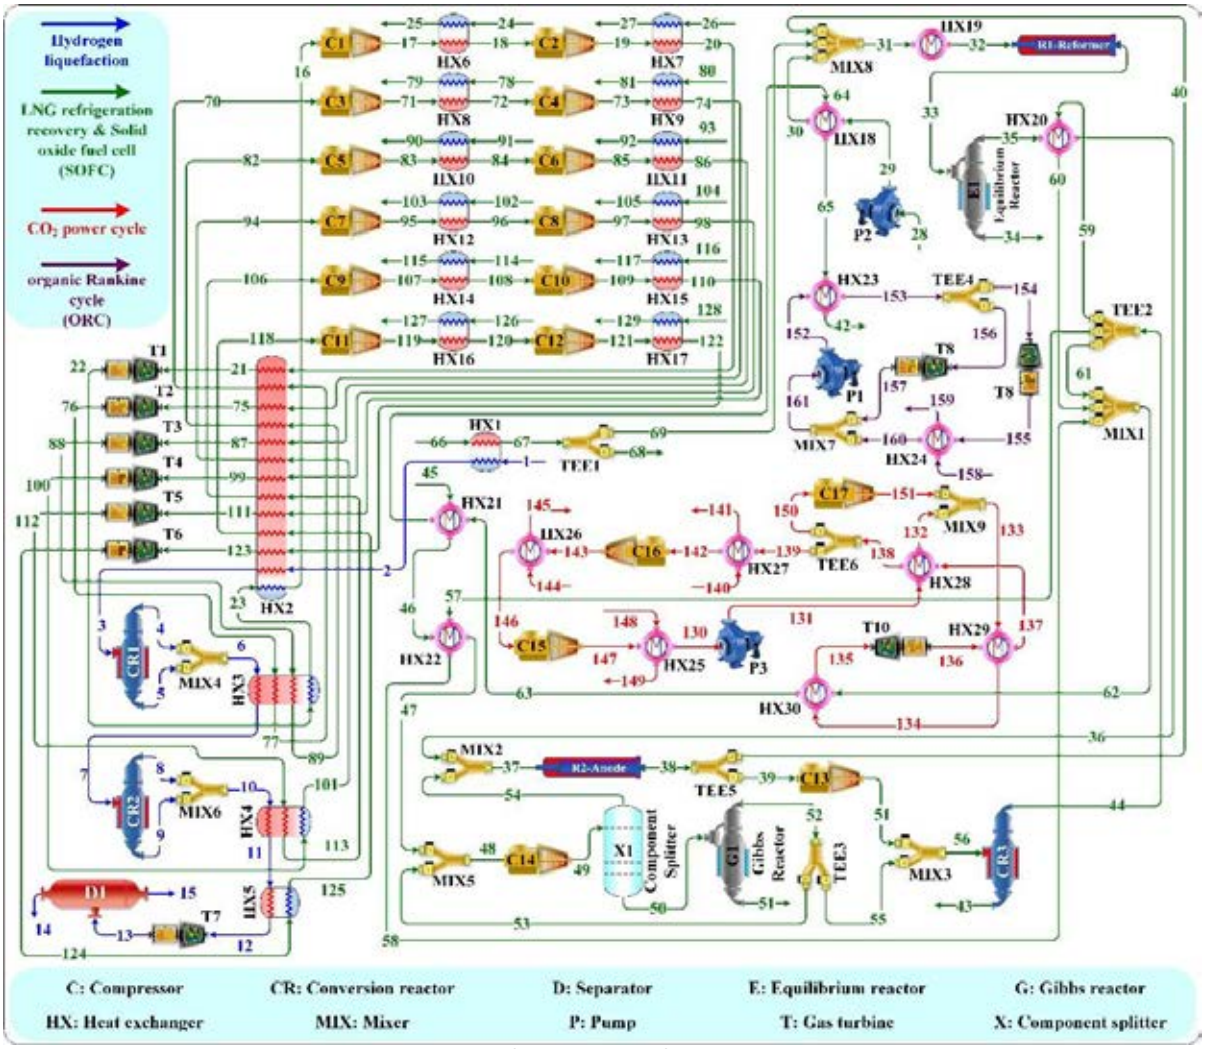

Fig. 2. The process flow diagram of the developed system.

In the final stage, liquefied hydrogen (LH_2) is released from the lower section of the D1 flash drum via state 15 at -255.5 °C and 130 kPa, maintaining a steady flow rate of 1033 kmol/h. The H_2 liquefaction process encompasses states 1 to 15, while states 16 to 129 correspond to SOFC and regasification of LNG operations. Furthermore, states 130 to 151 and 152 to 161 are linked to the CO_2 power unit and the ORC subsystem.

3. MODELING AND SIMULATION

With growing energy demand worldwide, solar power, particularly photovoltaic cells, plays a key role in converting renewable energy using the PV effect [2]. The International Energy Agency (IEA) defines essential efficiency metrics for evaluating on-grid PV systems [8]. Eq. 1 shown the final system yield (YF) is a key measure of on-grid energy output over time, calculated by the ratio of AC energy output to the peak power capacity of the PV unit's maximum power under standard test conditions (STC).

Eq. 2 shown the PV structure's efficiency is assessed using critical Indicators: final yield (YF) in kWh/kWp, energy yield (E_{AC}) in kWh/kWp, peak power output (P_{PV}) under STC, and reference yield (YR). under STC, Eq. 5 shown the total energy loss and the YA denotes DC energy output per kWh of nominal capacity per kWp. PR compares final yield to reference yield. Array absorber loss, determined by Eq. 6, represents the difference among yield of reference and yield of array, while efficiency of inverter, calculated using Eq. 7, is the ratio of AC power output to the array's of PV for DC power, and overall PV structure performance, derived from Eq. 8, is the combined efficiency of the PV inverter and the PV module [2].

$$Y_F = E_{AC}/P_{PV} \quad (1)$$
$$Y_R = H_t(kWh\ m^{-2})/G_o(kW\ m^{-2}) \quad (2)$$
$$Y_A = E_{DC}/P_O \quad (3)$$
$$PR = Y_F/Y_R \quad (4)$$
$$L = Y_R - Y_F \quad (5)$$
$$L_C = Y_R - Y_F \quad (6)$$
$$\eta_{inv} = P_{AC}/P_{DC} \quad (7)$$
$$\eta_{system} = \eta_{PV} \times \eta_{inv} \quad (8)$$

Based on PV simulations, the monthly average global radiation in Izmir varies between 55.9 kWh/m² in December and 242.9 kWh/m² in July. The hottest month in Izmir is July, with a temperature of 29.5 °C, while January is the coldest month, with a temperature of 9.5 °C.

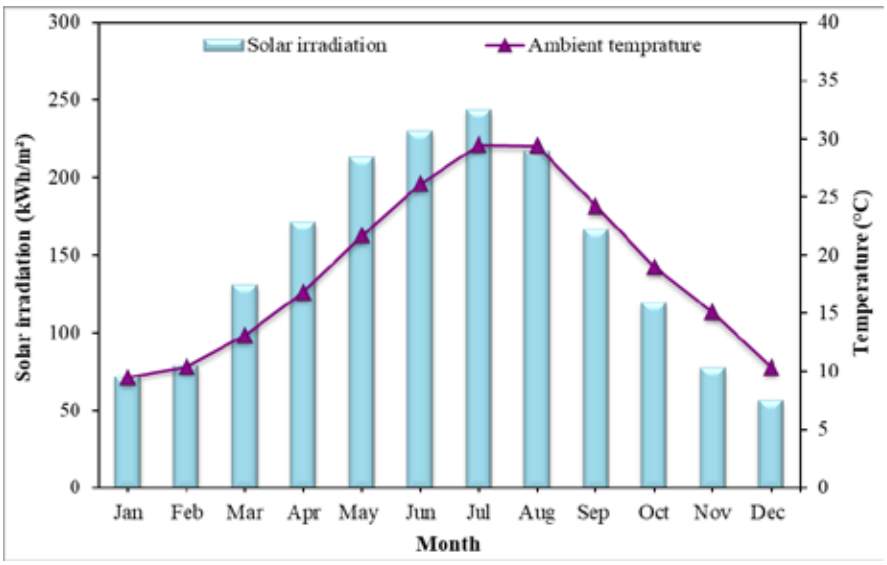

Fig. 3. Solar Irradiation and ambient temperature of Izmir.

4. RESULT AND DISCUSSION

In this research, PVsyst 7.3.1 software was used to model PV for Izmir, Türkiye (latitude 38.4237, longitude 27.1428), considering local weather conditions. This city is located on the western coast of Türkiye, bordering Balıkesir and Manisa to the north, Manisa to the east, Aydın to the south, and the Aegean Sea to the west.

Table 1 presents the specifications of the analyzed PV system. The research employed fixed-tilt PV with a 34º inclination angle in the PV structure.

Table 1. The specifications of the investigated PV system (a: module; b: inverter).

(a) PV module characteristics	
Length × Width × Thickness (mm)	1658 × 996 × 35
Weight (kg)	19.5
Number of Module	18
Manufacturer	Swiss Solar
Description and details	IBEX-60M-320

(b) PV inverter characteristics	
Width × Depth × Height (mm)	2600 × 800 × 2080
Weight (kg)	155
Number of Inverter	37
Manufacturer	Hyundai
Description and details	HPC-500HL-EU

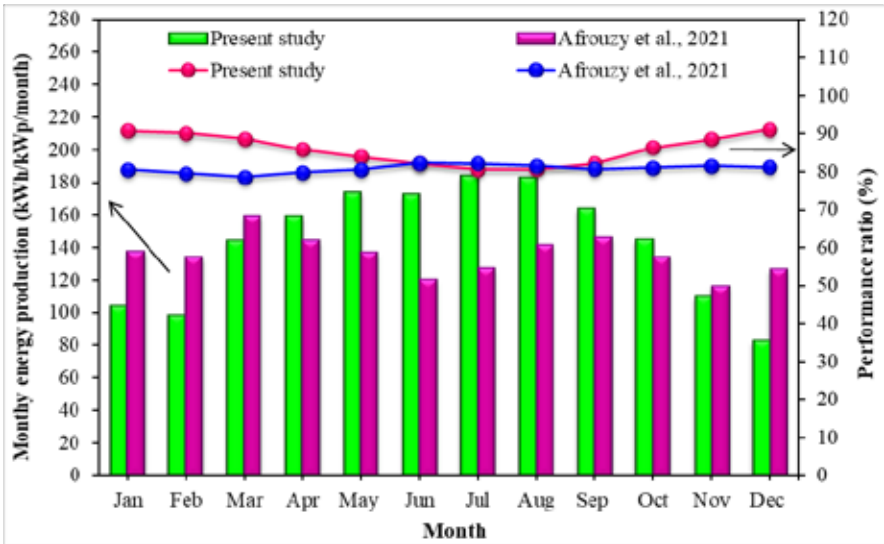

Fig. 4. Monthly energy production and yield for the proposed system and the reference model [8].

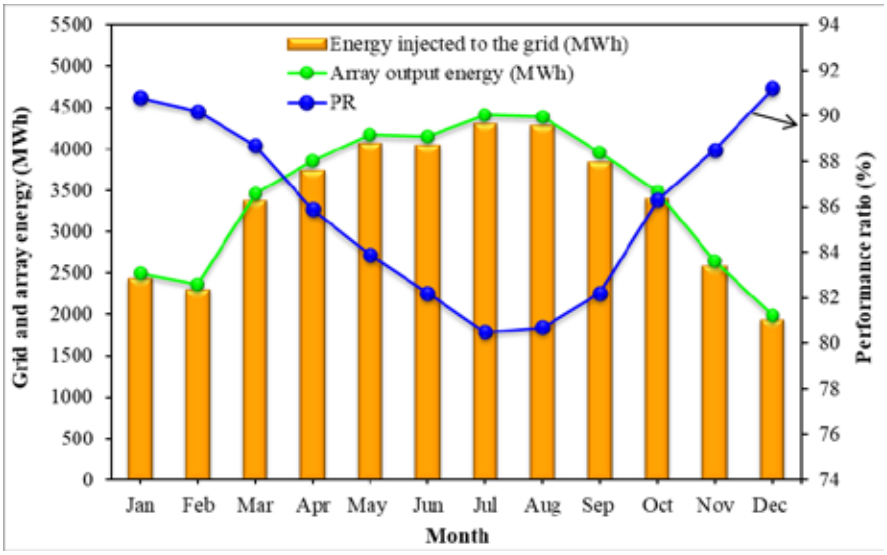

Fig. 5. Monthly PR, energy injected into the grid, and array energy production.

Fig. 4 compares the monthly yield of energy and output among the model of reference [8] and the suggested system. Fig. 5 depicts the PR, array of energy output, and the amount of energy injected into the grid. Also, illustrates the monthly solar energy injection across various structures throughout the year. The lowest PR was recorded in December at 80.5 %, while the highest value was observed in July, reaching 91.2 %.

Fig. 6 presents the simulated annual losses of the PV system. The mismatch loss was at its lowest in December, measuring 42.95 MWh, while it peaked in July at 95.87 MWh. Based on the results of the normalized annual energy in Izmir, the values of produced useful energy (YF), system loss (LS), and collection loss (LC) are 4.71, 0.11, and 0.72 kWh/kWp/year, respectively.

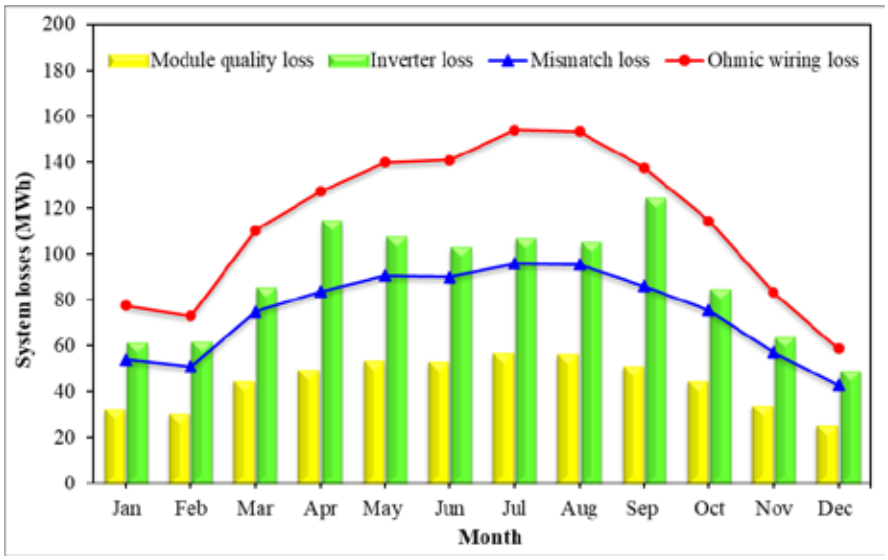

Fig. 6. The schematic represents annual system losses.

5. CONCLUSIONS

This study incorporates LNG regasification as a refrigeration source while utilizing solar energy to cover the system's power demand. The PV system with a capacity of 23.45 MW was integrated to provide the required power under the environmental conditions of Izmir. The main outcomes of the system assessment are described below:

- The proposed system successfully generates 50 TPD of LH_2.
- The LNG and NG flow rates amount to 374.70 kmol/h and 297.70 kmol/h.
- The monthly average global solar radiation in Izmir fluctuates between 55.9 kWh/m^2 in December and 242.9 kWh/m^2 in July. The PR reached its lowest level in December at 80.5%, while its peak value was recorded in July at 91.2%.
- Future research is encouraged to focus on advanced exergoeconomic assessments, detailed risk evaluations, and comprehensive environmental impact analyses to further optimize system performance and sustainability.

ACKNOWLEDGEMENT

This project has received funding from the European Union's Horizon Europe Research and Innovation Program under the Marie Skłodowska-Curie grant agreement No 101126655 (ECO-SPHERE Program). This project is also supported in part by a research grant from the Scientific and Technological Research Council of Türkiye (TÜBİTAK) under the grant number 123C459.

ABSTRACT
Posidonia oceanica (PO) can accumulate up to 125 kg/m^2 in Mediterranean coasts every year. This abundant biomass resource holds a great potential for biofuels and green chemicals. In this study, the first attempt of using PO is examined as a substrate for dark fermentative biohydrogen and volatile fatty acid (VFA) production. The impact of chemical (H_2SO_4), physical (ultrasound) and biological (cellulase) pretreatment methods was examined. The highest hydrogen production (10.8 L H_2/ kgVS) was obtained by acid pretreated PO, while enzymatic pretreatment showed the maximum VFA production as a 5140 mg/L. This is the first study in the literature to produce H_2 and VFA from pretreated PO and it showed promising results for further investigations.

Keywords: Posidonia Oceanica, Biohydrogen, Volatile Fatty Acid, Pre-treatment, Dark Fermentation

1. INTRODUCTION

The world's energy demand has steadily risen in recent decades due to population growth, urbanization, and industrialization. According to the International Energy Outlook 2017, global energy consumption is projected to increase by 28% from 2015 to 2040. Similarly, the International Energy Agency forecasts a 35% rise in energy demand between 2010 and 2035 [1]. Therefore, the global energy demand and environmental concerns associated with fossil fuels have intensified research into sustainable alternatives. Hydrogen, a clean energy carrier with high energy density and zero carbon emissions, is a promising solution. Hydrogen possesses a high energy density of 120 MJ/kg, making it a strong contender as a fossil fuel alternative. Large-scale implementation has the potential to reduce global CO_2 emissions by approximately 830 million tonnes per year [2]. Posidonia oceanica (PO) is an endemic marine seagrass species widely distributed across the Mediterranean Sea, forms extensive underwater meadows that play a crucial ecological role including carbon sequestration, sediment stabilization, oxygen production and serving as habitats for numerous marine organisms. It is the most abundant seagrass species in the Mediterranean Basin covering approximately 40,000 km^2 of the seabed [3,4]. However, significant seasonal accumulations of PO residues on coastal beaches pose both environmental and economic challenges due to their decomposition resulting in odors, aesthetic issues and high costs associated with their removal. A moderately wide (1 km) seagrass belt can produce more than 125 kg of dry seagrass litter per meter of coastline each year. Annually, these residues accumulate substantially highlighting the importance of finding efficient utilization methods. Utilizing PO for bioenergy production could effectively address these waste management challenges and contribute to renewable energy generation [4,5,6].

Lignocellulosic biomass is composed of three fundamental compounds which are cellulose (30-60% of dry matter), hemicellulose (14-40% of dry matter) and lignin (7-25% of dry matter). An essential step in biomass processing is pretreatment which plays a key role in breaking down the complex structure of lignocellulosic materials making them more accessible during fermentation. Since the composition of lignocellulosic biomass varies across species, selecting an appropriate pretreatment method is critical for optimizing bioenergy production [7]. In the case of PO, it's rigid lignocellulosic structure presents challenges for direct conversion into biofuels necessitating effective pretreatment strategies such as ultrasonic disruption (physical), enzymatic hydrolysis or chemical treatments to enhance its biodegradability and fermentable sugar release. Ultrasonic pretreatment employs disruption of the crystalline highly ordered structures of cellulose and lignin by using mechanical waves [8]. Enzymatic pretreatment depends on biological catalysts with cellulase hydrolysis efficiency influenced by biomass composition including cellulose crystallinity and the structural barriers of lignin and hemicellulose [9]. Chemical (Acid) pretreatment hydrolyzes hemicellulose and partially cellulose disrupting the lignocellulosic structure and making the biomass more porous [10].

Marine biomass, including PO residues, offers promising renewable energy potential through anaerobic digestion processes like dark fermentation. Dark fermentation is an anaerobic process of organic compound degradation carried out by strict or facultative anaerobic microorganisms in the absence of light resulting in biohydrogen production through proton reduction to dissipate excess electrons from organic matter oxidation in the culture medium. As primary byproducts of fermentation compounds such as alcohols, CO_2, and organic acids are also obtained [11]. Simultaneously it generates volatile fatty acids (VFAs) such as acetic, propionic, and butyric acids. These VFAs possess substantial

industrial value in biofuel production, bioplastics, and chemical synthesis, highlighting their economic and environmental relevance. The growing demand for VFAs have diverted the scientific focus to now co-produce these with biohydrogen [12].

This study aimed to evaluate the potential of PO residues for hydrogen and VFA production via optimized pretreatment methods and anaerobic dark fermentation. Analytical methods including spectrophotometry for sugar quantification and advance techniques for hydrogen and VFA measurements were employed. Ultimately, the study seeked to demonstrate the sustainable and economically viable valorization of PO residues, contributing to effective marine biomass management and renewable energy solutions in the Mediterranean region.

2. MATERIALS AND METHODS

Posidonia Oceanica was collected from the coast of Akçakaya Area, Çeşme, İzmir, Türkiye. Prior use of these material, it was soaked in tap water for 5 min to remove salt content. After that it was rinsed with distilled water, filtered and kept in owen at 40 ºC for drying. Dried materials were scaled (1 g VS) according to their proximate analysis (Table 1), then pre-treatments were applied according to Table 2. These contiditios were selected by the previous study of Pilavtepe et al. [3] to optimize sugar recovery for bioethanol production.

Table 1. Raw material and Inoculum Characteristics

Parameters	Unit	*Posidonia Oceanica*	Inoculum
Total Solid (TS)	(%)	14.339 ± 0.755	2.038 ±0,013
Volatile Solid (VS)	TS basis (%)	90.458 ± 0.435	56.371 ±1.511
pH			8.612
Fos/Tac			0.137

Table 2. Pre-treatments

Application	Conditions	Homogenisation
Acid	% H_2SO_4 (v/v), 120 Cº , 1 h, 100 ml dH_2O	Ultra-turrax 10000 rpm 3 min
Enzymatic	30 FPU (cellulase), 50 Cº, 96 h, 100 ml 0.1 M Citrate Buffer (pH=4,8)	
Ultrasound	800 W, 25 kHz, 2 h, 100 ml dH_2O, 20 Cº	

After pretreatment methods that applied to the raw material, supernatants were separatedby centrifugation (10000 rpm, 10 min, 4 Cº). Dark fermentation experiments were conducted in 130 ml in serum bottles with 50 ml working volume. Each reactor was filled with 10 ml of supernatant and 40 ml of mix inoculum which was obtained from various biogas plants. Inoculum was kept in dry owen for 1 h at 100 ºC to suppress methanogens and activate hydrogen producer. pH of all the reactors was adjusted to 6.5 by 2 M HCl solution. Before sealing the reactors with rubber butyl stoppers, headspace was flushed with nitrogen gas for 3 minutes to maintain anaerobic conditions. All reactors were kept in incubator with orbital shaker 37 ºC and 150 rpm, respectively. All reactors including controls were carried out in triplicates. Volumetric gas measurements were carried out with water displacement device. Gas concentrations were measured by Gas Chromatograph (TCD, Agilent, USA). VFA samples were collected from reactors 0,1,3,5 and 7th day then measured in gas chromatography prior methyl tert-butyl ether extraction (FID, Scion, Netherlands). Carbohydrate fractions were measured by HPLC (RID, Agilent, USA). Structural changes of the of the pretreated solid samples were carried out with FTIR (600 and 4000 cm^{-1} with the spectral resolution of 0.5 cm^{-1},Shimadzu, Japan).

3. RESULTS AND DISCUSSION

All the reactors were monitored for gas production and VFA production for 7 days. Biohydrogen production was occurred in all reactors except control within the first 24 hours. Biohydrogen yields of the PO are given in Figure 1. Maximum biohydrogen production was obtained from acid pretreated PO as 10.8 L H_2/ kgVS. According to the carbohydrate analysis of the supernatant, acid pretreatment also resulted in the highest sugar release. Enzymatically pretreated PO showed the second highest biohydrogen and sugar production. Ultrasound pretreatment produced the lowest amount of hydrogen and sugar, respectively. Lignocellulosic structure of raw PO consist on cellulose, hemicellulose and lignin. This pretreatment conditions are selected for loosen the lignin structure for to degrade other polymers for obtaining sugars [13]. In this case, acidic pretreatment is seemed to be promising way to stimulate sugar releasing from PO. On the other side, inoculum pretreatment to suppress methanogens was not entirely successful because methane production was detected in 4th day which means hydrogenotrophic methanoges survived and consumed H_2 and CO_2.

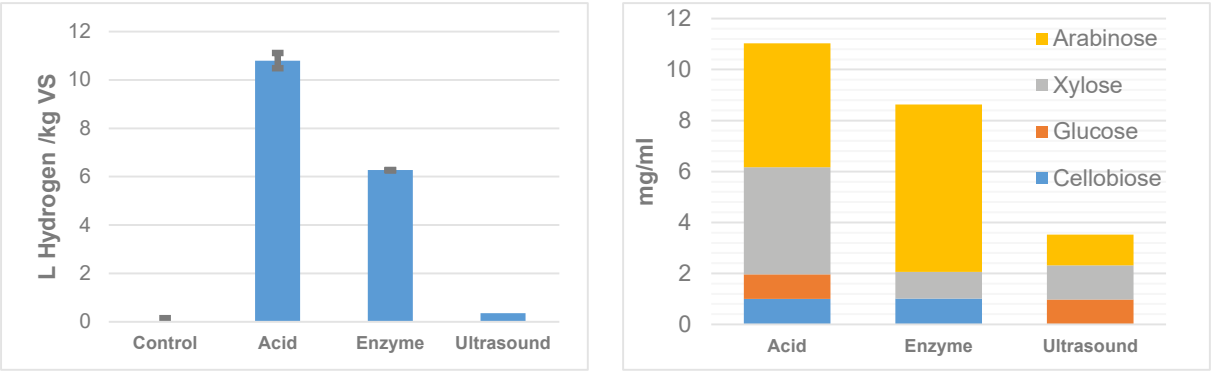

Fig. 1. Biohydrogen and sugar yields of pretreated *Posidonia Oceanica*

Figure 2 presents the VFA profiles that obtained from the dark fermention tests carried out under different pretreatment conditions. The dominant VFAs were acetic, propionic, butyric, isobutyric and isovaleric acid. The enyzmatic pretreated PO resulted in the highest VFA accumulation with the concentration peaking 5140 mg/L on day 7. The second-best performing VFA accumulation observed in the same pretreatment on day 3 as 5042 mg/L. The ultrasound pretreatment had little effect on VFA production as seen by the almost similar profile with the control without PO added.

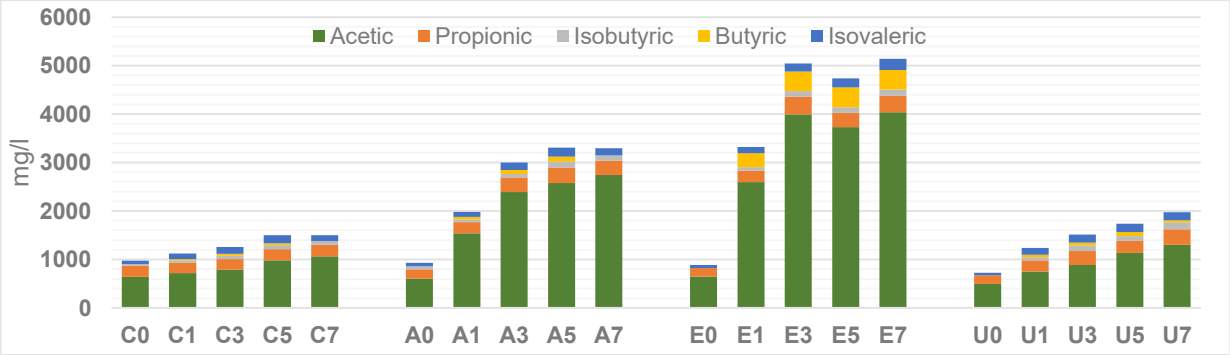

Fig. 2. Volatile fatty acid profiles during the dark fermentation of control, acid, ultrasound and enzyme pretreated Posidonia Oceanica residues (C: Control, A: Acid, E: Enzyme, U: Ultrasound).

FTIR spectral characterization of raw, acid, enzyme and ultrasound pretreated lignocellulosic PO was carried out in the region range of 600–4000 cm−1. Figure 3 showed the IR spectra of raw and pretreated dried samples.

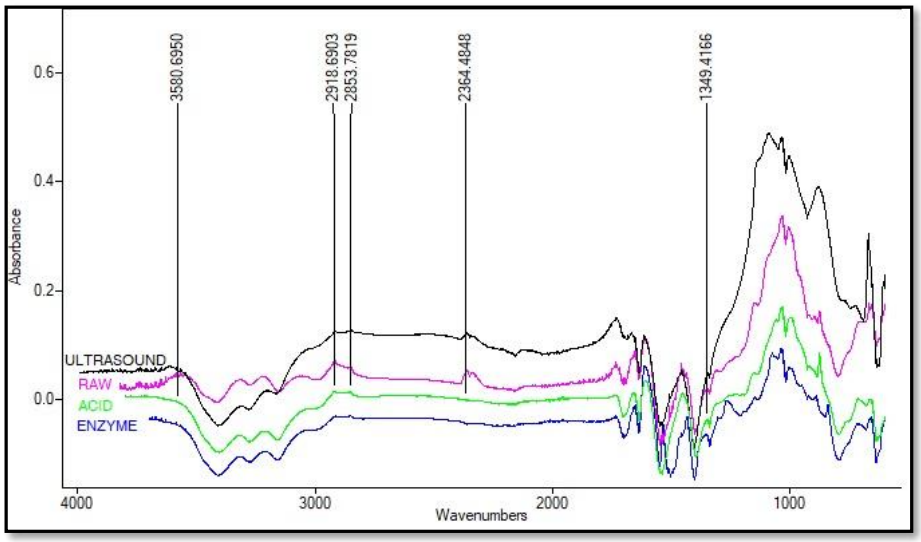

Fig. 3. FTIR spectra of Posidonia Oceanica (raw, acid, enzyme and ultrasound pretreated)

The peak around 1035 cm−1 corresponds to aromatic C–H deformation (present in lignin), C–O deformation in primary alcohol and stretching of non conjugated C=O bond (lignin and hemicellulose). The band around 2363 cm−1 corresponds to C–H stretching of lignin polymer. The band around 3318 and 3815 cm−1 corresponds to O–H stretching of lignin and hemicelluloses polymer [14]. The result showed that again the effectiveness of pre-treatment of PO by the spectrum profiles.

4. CONCLUSIONS

In this study, different physical, chemical and biological pretreatment methods that applied to seagrass Posidonia Oceanica to produce dark fermentative hydrogen and production. The highest hydrogen production (10.8 L H_2/ kgVS) was obtained from acidic pretreated PO. Besides, enzymatically pretreated PO showed maximum VFA production potential and mainly consisted of acetic, propionic and butyric acid. This is the first study in the literature to investigate H_2 and VFA from PO. Future optimization strategies, such as different pretreatment conditions and inoculum modifications, may enhance PO's potential as a sustainable biomass source for green hydrogen and chemical production.

NOMENCLATURE

TCD	Thermal conductivity dedector
FID	Flame ionisation dedector
FTIR	Fourier transform infrared spectroscopy
FPU	Filter paper unit (1 µmol of glucose equivalent per min)
Fos/Tac	Fos (such as acetic acid, propionic acid, and butyric acid) to Tac (total alkalinity or total bicarbonate alkalinity)
HPLC	High performance liquid Chromatography
RID	Refractive index dedector

ABSTRACT
In this study, sustainable hydrogen production using solar energy was carried out. An Evacuated Tube Solar Collector (ETSC) was utilized as the collector. Graphene – Al_2O_3 hybrid nanofuild was selected as the heat transfer fluid in the collector. The electricity was produced using Organic Rankine Cycle (ORC). The hydrogen production was performed by a Proton Exchange Membrane (PEM) electrolyzer. As a result of the study, the efficiencies of ETSC, ORC and PEM were investigated, and the values were found 82%, 16%, and 59% respectively. The hydrogen production rate in the PEM electrolyzer was determined as 0.0216 kg/h, 0.1296 kg/day and 3.88 kg/month. The effect of hybrid nanofluid usage on hydrogen production was investigated.

Keywords: Hydrogen production, Proton exchange membrane, Evacuated tube solar collector, Hybrid nanofluid, Organic Rankine Cycle

1. INTRODUCTION

In recent years, energy consumption has increased, and environmental problems such as global worming and the climate crisis have been observed. The main cause of these issues is the use of fossil fuels [1]. To reduce the consumption of fossil fuels and conventional energy sources, the utilize of renewable energy has been promoted. Solar energy is an abundant, economical, and renewable energy source. Hydrogen is the another fuel with high energy conversion efficiency, higher heating value, and no carbon emissions during combustion. Additionally, hydrogen is used for energy transportation and as an environmentally friendly fuel for vehicles, electricity production [2].

In the literature, solar energy has been investigated for green and sustainable hydrogen production. Atiz et al. [3] studied hydrogen production using solar energy, spesifically with an evacuated tube solar collector (ETSC). This system includes an evacuated tube solar collector (ETSC), a solar pond, an Organic Rankine Cycle (ORC), and a Proton Exchange Memebrane (PEM) electrolysis system. The system was analyzed utilizing Engineering Equation Solver (EES) software. The energy and exergy efficiencies were 5.92% and 18.21%, respectively. The daily hydrogen production was 3204 g. Karabuga et al. [4] studied solar energy-driven hydrogen production. An evacuated tube solar collector was selected as the collector. The thermal energy obtained from solar radiation was converted into electrical energy using an ORC. A PEM electrolyzer was utilized for hydrogen production. The thermodynamic analysis results showed energy and exergy efficiencies of 51.28% and 16.30%, respectively. Ghasem Khani et al., [5] designed hydrogen production system base on a solar-powered ORC and a PEM electrolyzer. Energy and exergy analyses of the system were carried out using EES software. The results of the research showed that energy and exergy variations in a double-pressure ORC system. Li et al., [6] studied a system consisting of a solar pond, an Abrobed Power Cycle (APC), an ORC, a PEM electrolyzer. The results of APC and ORC systems were compared. Additionally, an economic assessment of the system was conducted. The optimum energy and exergy efficiencies were found to be 42.44% and 27.54 respectively. Rejeb et al., [7] designed multi-generation sytems focusing on novel electricity, heat, and green hydrogen production. The system design includes a solar photovoltaic thermal collector, an ORC, a PEM electrolyzer, and liquefied natural gas (LNG). Thermodynamic analysis was performed using EES software. The research results showed that the system's exergy efficiency was 16.24%.

Furthermore, the usage of nanofluid in the solar collector enhanced the heat transfer rate and hydrogen production. Sathish et al. [8] designed a hydrogen production system that includes solar energy. This system consisted of an evacuated tube solar collector, a hybrid nanofluid (Al_2O_3 - SiO_2 - water), an Organic Rankine Cycle, and a PEM electrolyzer. The use of hybrid nanofluid with different volume concentrations (0.5%, 1%, 1.5%, and 2%) in the evacuated tube collector increased energy gains by 13.22%, 21.37%, 30.38%, and 48.52%, respectively, compared to water. ORC efficiency improved with increasing nanofluid concentrations 12.29% (0.5% vol.), 23.10% (1% vol.), 34.15% (1.5% vol.), and 48.40% (2% vol.). Hydrogen production in the PEM electrolyzer reached 2156.7 g at %2 vol. concentration, and overall system efficiency was 71.3%. In another similar study, Sathish et al. [9] designed a hydrogen production system using different hybrid nanofluids in an evacuated tube solar collector, ORC, and PEM electrolyzer. The researches selected magnesium oxide (MgO) and multi-walled carbon nanotubes (MWCNT) as nanoparticles, and thermal oil as the base fluid in the hybrid nanofluid. The nanoparticle concentration of the hybrid nanofluid was set 0.1% vol., each nanoparticle contributing 0.05% vol. The research results demonstrated the benefits of hybrid nanofluid usage in the solar system. While collector efficiency increased by 80.5% with hybrid nanofluid integration, exergy efficiency improved from 12.4% to 36.8%. The PEM electrolyzer's energy and exergy efficiencies were recorded 44.4% and 10.5%,

respectively.

In the solar-based electrical production system's the Organic Rankine Cycle (ORC) is used. The selection of a refrigerant for the ORC is an important factor affecting system efficiency. Kajurek et al. [10] studied the selection of refrigerants for the ORC. A low-temperature heat source in the range of 30 - 100 °C was designed for a 1kW electric power output ORC system. Ten different refrigerant (R134a, R152a, R227ea, R236fa, R245 fa, R290, R600a, R717, R1234yf, and R1234ze) were selected in the study. As a result of the analysis, ammonia was found to be the best refrigerant, achieving 5.68% efficiency. Another study was conducted by Ndame Ngangue et al. [11], focusing on the selection of a working fluid for the ORC system. Seven different refrigerants were examined in the ORC. The refrigerants were selected based on their Global Warming Potential (GWP) and Ozone Depletion Potential(ODP). Thermodynamic analysis results showed that R717 was the most suitable working fluid.

The literature review indicates that the solar energy-based hydrogen production process is enhanced by hybrid nanofluid. An evacuated tube solar collector is used to obtain heat from solar energy. The selection of the ORC system refrigerant is crucial for efficiency. The research gap in the literature focuses on the impact of graphene – Al_2O_3 hybrid nanofluid and R717 refrigerant usage on hydrogen production. For this purposes, a solar energy-based hydrogen production system was designed in this study. Solar energy was collected using an evacuated tube solar collector. Graphene - Al_2O_3 hybrid nanofluid was selected as the heat transfer fluid. The heat obtained solar energy was converted into electrical energy using a Organic Rankine Cycle (ORC) with ammonia as the refrigerant. A proton exchange membrane (PEM) electrolyzer was used for hydrogen production. This solar energy-based hydrogen production system was analyzed thermodynamically. The thermodynamic performance of the system was investigated utilized by Engineering Equation Solver (EES) from F-Chart Software [12].

2. SYSTEM DESCRIPTION

A solar energy-based hydrogen production system was designed. The system includes an evacuated tube solar collector, an Organic Rankine Cycle, and a PEM electrolyzer. The system design was shown in Fig. 1.

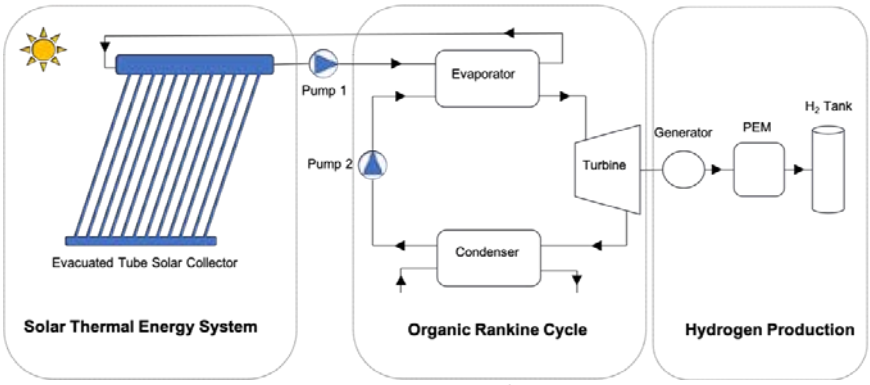

Fig. 1. Energy system design of hydrogen production

2.1. Evacuated Tube Solar Collector (ETSC)

An evacuated tube solar collector (ETSC) was selected as the solar collector. The heat transfer fluid in the collector is a hybrid nanofluid. Solar radiation was determined to be 850 W/m^2, which represents the average solar radiation during summer in the southern region of Türkiye [13,14]. The properties of the ETSC are as follows: a area of 11.92 m^2, 120 tubes, transmissivity of glass is 0.92, absorptivity is 0.91, and glass emissivity is 0.8 [9]. The heat obtained from solar energy and the collector efficiency [9] were calculated using equation (1) and equation (2).

$$Q_u = A_c F_R [I_T(\tau\alpha) - U_L(T_i - T_0)] \quad (1)$$

$$\eta = \frac{Q_u}{A_c I_T} \quad (2)$$

2.2. Nanofluid

Graphene - Al_2O_3 hybrid nanofluid was selected. The concentration of the hybrid nanofluid was determined by the proportion of graphene – Al_2O_3 nanoparticles (0.25% - 0.75%), totaling 1%. The material properties of water, graphene, and Al_2O_3 in the are presented in Table 1.

Table 1. Properties of water [15], graphene [16] and Al_2O_3 [17]

Parameters	Water	Graphene	Al_2O_3
Particle size (nm)	-	5 - 10	30 - 40
Specific heat capacity (J/kg·K)	4180	0.7	0.8
Density (kg/m^3)	997	2200	3790
Thermal conductivity (W/m·K)	0.617	4000 - 5000	765

The concentration, density, and specific heat capacity of the hybrid nanofluid [18] were calculated using equations (3), (4), and (5).

$$\emptyset_T = \emptyset_{np1} + \emptyset_{np2} \tag{3}$$

$$\rho_{hnf} = \emptyset_{np1}\rho_{np1} + \emptyset_{np2}\rho_{np2} + (1 - \emptyset_T)\rho_{bf} \tag{4}$$

$$c_{hnf} = \frac{\emptyset_{np1}\rho_{np1}c_{p,np1} + \emptyset_{np2}\rho_{np2}c_{p,np2} + (1-\emptyset_T)\rho_{bf}c_{p,bf}}{\rho_{hnf}} \tag{5}$$

2.3. Organic Rankine Cycle (ORC)

The heat energy obtained from the solar collector was converted into electrical energy in the Organic Rankine Cycle. The refrigerant of the ORC, R717 (ammonia), was selected due to its high performance. The heat obtained in the evaporator, net work, and energy efficiency of the ORC was determined using equations (6), (7), and (8) [8].

$$\dot{Q}_E = \dot{m}_R\left(h_{E,out} - h_{E,in}\right) \tag{6}$$

$$\dot{W}_{net} = \dot{W}_T - \dot{W}_P \tag{7}$$

$$\eta = \frac{\dot{W}_{net}}{\dot{Q}_E} \tag{8}$$

2.4. Hydrogen Production

Hydrogen was produced using a Proton Exchange Membrane (PEM) electrolyzer. The PEM electrolyzer generated hydrogen from water using an electrical input 1.2 kW. The hydrogen production rate was determined by measuring the flow rate and mass of the produced hydrogen. Hydrogen was generated over a 6-hour operational period per day and stored in compressed gas cylinders. The efficiency of the PEM electrolyzer was determined using equation (9) [19].

$$\eta_{PEM} = \frac{\dot{m}_{H_2}LHV_{H_2}}{\dot{W}_{PEM}} \tag{9}$$

3. RESULTS AND DISCUSSION

This study investigated hydrogen production in a solar energy system combining ETSC and ORC. A graphene - Al_2O_3 hybrid nanofluid was utilized to enhance heat transfer. The ORC was used to generate of electricity for the PEM electrolyzer. R717 (ammonia) was selected as the refrigerant in the ORC. The hybrid nanofluid properties were measured as 1025 kg/m^3 for density and 4063 J/kgK for specific heat capacity. The heat obtained from solar energy in the collector was 8.4 kW, and the efficiency of the evacuated tube solar collector was calculated to be 82%. The results of the ORC components are presented in Table 2, where the energy values of the evaporator, turbine, condenser, and pump are displayed. The energy efficiency of the ORC was calculated as 16%.

Table 2. Energy values of ORC equipment

System equipments	Energy (kW)
Evaporator	7.214
Turbine	1.216
Condenser	6.010
Pump	0.012

Hydrogen production in the PEM electrolyzer was determined to be 0.0216 kg/h hydrogen produced. The efficiency of PEMe was calculated as %59. The total daily and monthy hydrogen production was 0.1296 kg and 3.88 kg, respectively. For comparison, the literature data on solar based hydrogen production and the results of the this study are presented in Table 3. The efficiencies of the ETSC and PEM in this study were higher than those reported in previous studies. The use of a hybrid nanofluid in the ETSC proved to be effective in achieving high thermal efficiency.

Table 3. Comparison of the previous studies with current investigation

Component efficiency	Present study	Atiz et al. [3]	Karabuga et al. [4]	Sathish et al. [9]
ETSC (%)	82	n.a.	56.82	72.1
ORC (%)	16	25.4	21.48	n.a.
PEM (%)	59	n.a.	50.49	51.4

4. CONCLUSIONS

In this study, a thermal energy system was designed for green and sustainable hydrogen production. Solar energy was utilized trough an evacuated tube solar collector (ETSC). A graphene – Al_2O_3 hybrid nanofluid was used as the heat transfer fluid in the collector. Electiricity was generated using an Organic Rankine Cycle (ORC), and a PEM electrolyzer was employed for hydrogen production. As a result of this study, the efficiencies of the ETSC, ORC, and PEM were 82%, 16%, and 59%, respectively. The hourly, daily and monthly hydrogen production values were 0.0216 kg/h, 0.1296 kg/day, and 3.88 kg/month. The integration of a hybrid nanofluid in the ETSC for hydrogen production enhanced heat trasnfer performance. Hence, the use of a hybrid nanofluid in the ETSC, in conjuction with the ORC and PEM electrolyzer, proved to be an optimal choice for hydrogen productions.

ABSTRACT
The growing energy demand and depletion of fossil fuels have increased interest in clean hydrogen production. This study focuses on the thermodynamic analysis of the Claude cycle for hydrogen liquefaction. A mathematical model was developed to evaluate the system's performance under varying operating conditions. Using energy and exergy analyses, the study examines the effects of split ratio on second-law and exergy efficiencies considering different operating parameters. The results showed that the highest exergy efficiency of 30% was observed at a split ratio of 0.5. These findings contribute to the improvement of the performance of the Claude cycle for hydrogen liquefaction.

Keywords: Hydrogen liquefaction, Claude cycle, mathematical modeling, liquid hydrogen

1. INTRODUCTION

A large share of global energy consumption relies on fossil fuels, including coal, gasoline, and oil; thus, advancing and integrating zero-emission alternatives like green hydrogen is essential for sustainability. Hydrogen is emerging as a key energy carrier due to its potential for achieving net-zero emissions, as water splitting does not produce harmful byproducts. Its advantages, such as ease of storage and transportation, make it a promising solution for various industrial and energy applications. However, the large-scale adoption of green hydrogen requires the development of efficient production and storage technologies. Hydrogen is typically stored as either liquefied hydrogen (LH_2) or compressed hydrogen (CH_2), both of which significantly reduce its volume, enhancing portability and making it suitable for various storage environments Bian et al. [1]. Among these methods, liquefaction remains a crucial technology for hydrogen storage and transportation due to its high energy density and compatibility with large-scale applications.

Several studies have focused on improving hydrogen liquefaction efficiency by optimizing thermodynamic cycles. For instance Baker and Shaner [2], examined the pre-cooled dual-pressure Claude cycle and reported an energy consumption of 10.85 kWh/kgH_2 with an exergy efficiency of 36%. Similarly, Yang et al. [3] investigated the Joule-Brayton refrigeration cycle, achieving an energy consumption of 11.05 kWh/kgH_2 for large-scale production of 300 tons/day, whereas Krasae-In [4] analyzed a mixed refrigerant Brayton cycle, demonstrating improved efficiency with an energy consumption of 5.91 kWh/kgH_2. These studies highlight the ongoing efforts to enhance hydrogen liquefaction performance through different cycle configurations and operational strategies.

This study aims to conduct a thermodynamic analysis of the Claude cycle in the hydrogen liquefaction process. By evaluating the performance of various cycle components, this study assesses both the second law and exergy efficiencies under different operating parameters. These findings are expected to contribute to the performance improvement of hydrogen liquefaction technologies.

2. MATERIALS AND METHODS

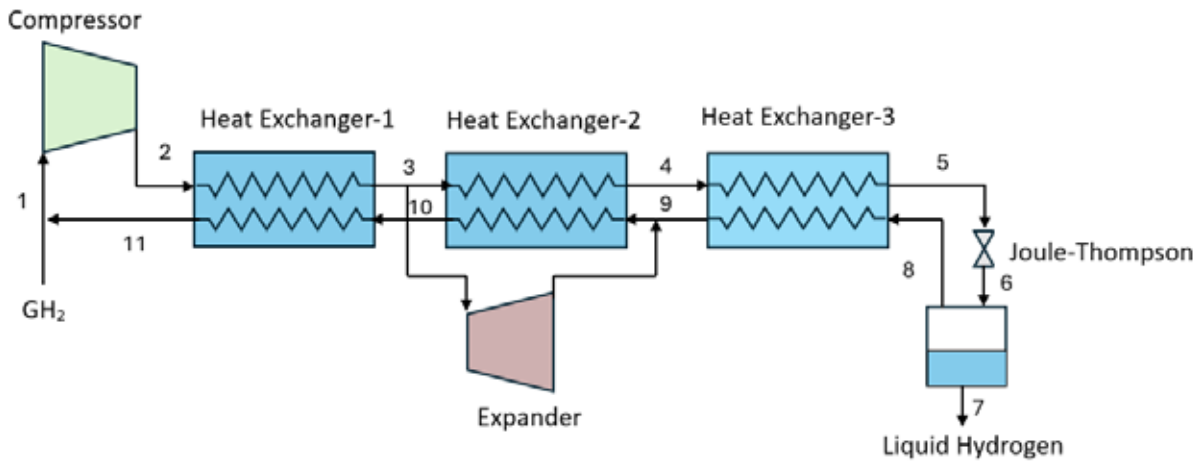

Fig. 1. Schematic of the Claude cycle

The hydrogen liquefaction system described in this study using the Claude cycle is shown in Fig.1. as a process flow diagram. The system's working principle is as follows: The first step involves compressing gaseous hydrogen (GH_2) with a compressor to raise its temperature and pressure. The high-pressure hydrogen leaving the compressor enters the heat exchanger-1, where it exchanges heat with cooling streams that are flowing counter-flowing, lowering the temperature. The hydrogen is further cooled in heat exchanger-2 as part of the cooling process. This step involves expanding a part of the high-pressure hydrogen through an expander, drastically reducing the hydrogen's temperature. This hydrogen stream is transferred to the Joule-Thomson valve after passing through heat exchanger-3, where it is further cooled. As the hydrogen expands via this valve, some of it performs a phase change and collects in the liquid hydrogen storage tank. Redirecting the remaining gaseous hydrogen to the heat exchangers, which precools the incoming hydrogen, improves the system efficiency.

The main assumptions of the thermodynamic models are as follows.

- The system operates under steady-state conditions.
- Kinetic and potential energy effects are neglected.
- Pressure drops across heat exchangers and separator are ignored.
- Heat losses from the turbine, heat exchanger, tank, and valve are neglected.

Table 1. Input Parameter

Input parameter	Symbol	Value
Pressure at the compressor inlet	P_1	100 kPa
Temperature at the compressor inlet	T_1	278 K
Pressure at the compressor outlet	P_2	10000 kPa
Temperature at the heat exchanger-1 outlet	T_3	160 K
Temperature at the heat exchanger-2 outlet	T_{10}	125 K
Isentropic efficiency of the turbine	η_t	0.80
Split ratio	x_s	0.5
Compressor efficiency	$\eta_{compressor}$	0.7

Mass and energy rate balances

The mass flow rate of the makeup hydrogen is equal to the liquefied hydrogen mass flow rate, expressed as:

$$\dot{m}_{makeup} = \dot{m}_{liq}$$

The mass flow rate at State 11 is obtained by applying the mass balance around CV1:

$$\dot{m}_{11} = \dot{m}_2 - \dot{m}_{liq}$$

From the definition of split ratio, the flow through the turbine is given by:

$$\dot{m}_{turbine} = \dot{m}_2 \cdot x_s$$

where x_s represents the split ratio, indicating the proportion of hydrogen that undergoes expansion through the turbine. By applying the first law of thermodynamics to Heat Exchanger 1, the following energy balance equation is derived:

$$\dot{m}_2 \cdot (h_2 - h_3) = \dot{m}_{11} \cdot (h_{11} - h_{10})$$

The ideal compressor work per kilogram of hydrogen is given by:

$$\dot{W}_{comp,ideal} = \dot{m}_2 \cdot (T_2 \cdot (s_2 - s_1) - (h_2 - h_1))$$

The work produced by the turbine per kilogram of H_2 is given by:

$$\dot{W}_{turbine} = \dot{m}_{turbine} \cdot (h_3 - h_9)$$

The actual compressor work per unit mass of hydrogen is calculated as:

$$\dot{W}_{comp,actual} = \frac{\dot{W}_{comp,ideal}}{0.7}$$

Total work required to produce liquid per kg of H_2 is given by the compressor-turbine work:

$$\dot{W}_{net} = \dot{W}_{comp,actual} + \dot{W}_{turbine}$$

The heat input required for compression per kg of H_2 is then:
$\dot{Q}_{comp} = \dot{W}_{comp,actual} - \dot{m}_2 \cdot (h_2 - h_1)$

The actual enthalpy at state h_9 is given by:
$h_9 = h_3 - \eta_{turbine} \cdot (h_3 - h_{9isentropic})$

Where η_t is the turbine efficiency, and $h_{9isentropic}$ represents the isentropic enthalpy at state 9.

Table 2. Exergy Rate Balance

Component	Exergy rate balance
Compressor	$0 = \dot{Q}_{comp} \cdot \frac{(1-T_0)}{T_1} - \dot{W}_{comp,actual} + \dot{m}_2 \cdot \left((h_1 - h_2) - T_0 \cdot (s_1 - s_2)\right) - \dot{E}x_{D,comp}$
Heat Exchanger-1	$\dot{E}x_{D,HX1} = \dot{m}_2 \cdot \left((h_2 - h_3) - T_0 \cdot (s_2 - s_3)\right) + \dot{m}_{11} \cdot \left((h_{10} - h_{11}) - T_0 \cdot (s_{10} - s_{11})\right)$
Heat Exchanger-2	$\dot{E}x_{D,HX2} = \dot{m}_2 \cdot (1 - x_s) \cdot ((h_3 - h_4) - T_0 \cdot (s_3 - s_4) + \dot{m}_{11} \cdot \left((h_9 - h_{10}) - T_0 \cdot (s_9 - s_{10})\right)$
Heat Exchanger-3	$\dot{E}x_{D,HX3} = \dot{m}_2 \cdot (1 - x_s) \cdot \left((h_4 - h_5) - T_0 \cdot (s_4 - s_5)\right) + (\dot{m}_2 \cdot (1 - x_s) - \dot{m}_{liq}) \cdot \left((h_8 - h_9) - T_0 \cdot (s_8 - s_9)\right)$
Valve	$\dot{E}x_{D,valve} = \dot{m}_2 \cdot (1 - x_s) \cdot \left((h_5 - h_6) - T_0 \cdot (s_5 - s_6)\right)$
Separator	$\dot{E}x_{D,sep} = \dot{m}_2 \cdot (1 - x_s) \cdot \left((h_6 - h_0) - T_0 \cdot (s_6 - s_0)\right) - \dot{m}_{liq} \cdot ((h_7 - h_0) - T_0 \cdot (s_7 - s_0)) - (\dot{m}_2 \cdot (1 - x_s) - \dot{m}_{liq}) \cdot \left((h_8 - h_0) - T_0 \cdot (s_8 - s_0)\right)$
Turbine	$\dot{E}x_{D,turbine} = \dot{m}_{turbine} \cdot \left((h_3 - h_9) - T_0 \cdot (s_3 - s_9)\right) - \dot{W}_{turbine}$

Performance assesment parameters
The second-law efficiency of the cycle is defined as:
$$\eta_{2.law} = -\frac{((h_7 - h_1) - T_1 \cdot (s_7 - s_1))}{\dot{W}_{net}}$$

The total exergy destruction ($\dot{E}x_{D,Total}$) in the system is given by:
$$\dot{E}x_{D,Total} = \dot{E}x_{D,comp} + \dot{E}x_{D,HX1} + \dot{E}x_{D,HX2} + \dot{E}x_{D,HX3} + \dot{E}x_{D,valve} + \dot{E}x_{D,sep} + \dot{E}x_{D,turbine}$$

This equation represents the summation of exergy destruction across all components of the system, including the compressor, heat exchangers, valve, separator, and turbine.

Exergy flow into the system ($\dot{E}x_F$) is expressed as the net work multiplied by -1. This indicates that the work is being supplied to the system as part of the energy balance.

Finally, the overall exergy efficiency of the system is determined as:
$$\varepsilon = 1 - \left(\frac{\dot{E}x_{D,Total}}{\dot{E}x_F}\right)$$

3. RESULTS AND DISCUSSION

Second-law efficiency ($\eta_{2.law}$) and exergy efficiency (ε), both of which are examined as functions of the parameter x_s, are used in this study to analyze the Claude cycle's performance. The effect of x_s on these efficiencies is shown graphically in Fig.2a illustrates how second-law efficiency ($\eta_{2.law}$) varies with respect to x_s. The findings show that as x_s grows, $\eta_{2.law}$ increases linearly. At x_s =0, the efficiency is roughly 0.232 at first. $\eta_{2.law}$ improves to about 0.252 as x_s approaches 0.5. Fig. 2b shows how exergy efficiency (ε) changes with x_s.The exergy efficiency begins at about 0.278 at x_s =0 and rises to about 0.305 at x_s =0.5. According to this enhancement, raising x_s results in better use of the energy resources that are accessible reducing the overall exergy destruction in the process.

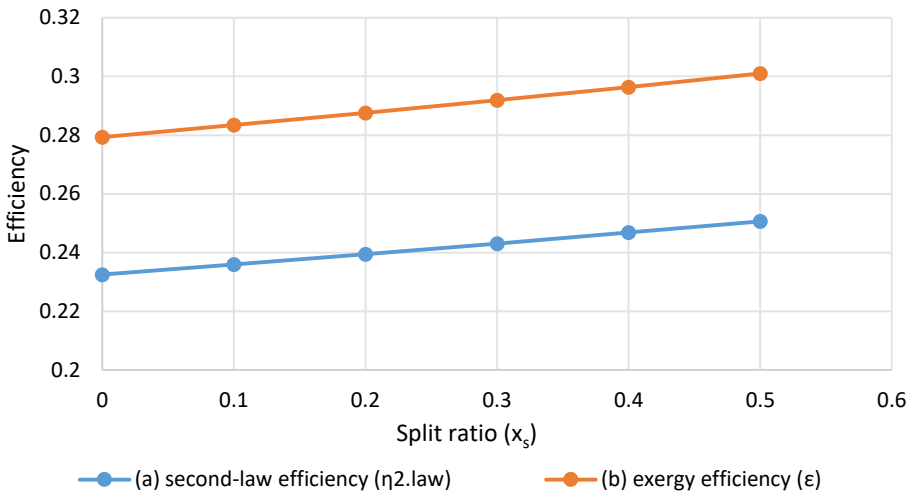

Fig. 2. The effect of x_s on (a) second-law efficiency ($\eta_{2.law}$) and (b) exergy efficiency (ε).

4. CONCLUSIONS

The damage caused by fossil fuels to the world and the increasing demand for green energy have led to a growing interest in hydrogen production. This study illustrates the thermodynamic analysis of the Claude cycle in relation to hydrogen liquefaction. Energy and exergy balances were solved and the effect of split ratio on second law efficiency and exergy efficiency was studied. A thermodynamic model was developed using Engineering Equation Solver (EES), and detailed parametric analyses were performed to explore the system's performance under various conditions. The results provide valuable insights into optimizing the hydrogen liquefaction process, offering a pathway toward more efficient and sustainable energy solutions. The main findings of this study is as follows:

- Second-law efficiency($\eta_{2.law}$) increases with the parameter x_s, showing a steady rise from approximately 0.23 to 0.252 as x_s increases.
- Exergy efficiency (ε) improves similarly, increasing from 0.275 to 0.305 with rising x_s, indicating better system performance.

ABSTRACT

The maritime sector is accelerating its transition toward sustainable energy solutions in response to international regulations targeting net-zero greenhouse gas (GHG) emissions by 2050. Hydrogen has emerged as a promising clean energy carrier, particularly in liquid form, due to its high gravimetric energy density. In maritime applications, hydrogen can be used both as a fuel for ship propulsion and as cargo transported in bulk. However, the cryogenic nature of liquid hydrogen (LH_2) introduces complex storage challenges, especially in harsh maritime environments. This study presents an investigation into material selection for the design of liquefied hydrogen tanks used in maritime applications. Insulation methods, which play a critical role in LH_2 storage tanks, are examined from both passive and active perspectives. Also, other key considerations such as tank geometry, and structural integrity under extreme temperature fluctuations are examined. By addressing these factors, the study aims to support the development of safe, efficient, and scalable hydrogen storage systems that are in line with the maritime sector's decarbonisation goals by providing a comprehensive review.

Keywords: Hydrogen Storage, Liquified Hydrogen Storage, Material Selection, Maritime Applications, Insulation Methods

1. INTRODUCTION

As the maritime industry seeks to decarbonize in line with international goals, hydrogen has emerged as a key alternative fuel due to its clean combustion and high energy content on a gravimetric basis. Among its various storage forms, liquid hydrogen (LH_2) is particularly promising for long-range and large-scale marine applications because of its high volumetric density [1]. However, the cryogenic nature of LH_2, typically stored at -253°C, poses serious engineering challenges, especially in terms of insulation [2]. Maintaining hydrogen in its liquid state under dynamic marine conditions requires highly efficient thermal protection systems to mitigate boil-off gas (BoG) generation and ensure safety and efficiency [3].

The design of LH_2 containment systems must therefore integrate advanced insulation strategies that minimize heat ingress from the ambient environment. Passive insulation methods can be classified as solid-state thermal insulation and radiative thermal insulation methods, are widely used due to their effectiveness and lack of reliance on external power [3,4]. For example, Yu et al. [5] demonstrated that multi-layer insulation (MLI) combined with vapor-cooled shields (VCS) and liquid nitrogen-cooled shields (LH_2CS) can reduce heat leakage by over 80%, achieving daily evaporation rates as low as 0.002% in a 4000 m³ LH_2 tank. Similarly, Liu et al. [6] showed that forced-evaporation VCS combined with rigid polyurethane foam can reduce insulation layer thickness by nearly 60%, highlighting the potential for space-efficient and thermally effective designs in marine LH_2 transport tanks. These technical advancements are increasingly important given that insulation materials and tank designs must not only be efficient but also be compliant with international maritime safety regulations. The International Maritime Organization (IMO) , particularly through the International Code for the Construction and Equipment of Ships Carrying Liquefied Gases in Bulk (IGC Code- MSC.370(93)) and the International Code of Safety for Ships using Gases or other Low-flashpoint Fuels (IGF Code- MSC.391(95)), establishes broad safety frameworks, but these are primarily centered on LNG rather than hydrogen [7,8].

Despite these advancements, regulatory guidance tailored to LH_2 insulation in maritime environments remains limited compared to LNG. Interim guidelines such as MSC.420(97) and MSC.565(108) provide a framework for bulk carriage of LH_2 and the safety amendments of ships using fuel cell power installations released as MSC.1/Circ.1647, yet comprehensive standards for insulation systems are still evolving [9–11]. In the absence of fully mature codes, studies like those of Park et al. [12], which investigate novel vacuum insulation membranes capable of withstanding cryogenic deformation and maintaining structural integrity, offer valuable insights. Consequently, this study aims to critically examine insulation strategies for LH_2 tanks in maritime applications, with an emphasis on material selection, structural integration, and performance under harsh operational conditions.

2. MATERIAL AND METHOD

The use of LH_2 either in bunkering or in bulk transportation in maritime vessels introduces several potential hazards. Due to its colourless, odourless, and highly flammable nature, hydrogen poses unique challenges when combined with the harsh and dynamic marine environment conditions. These hazards can generally be categorised into physical, chemical, and physiological [13]. A detailed classification of these hazard types is presented in [13]. Therefore, when designing hydrogen storage tanks for maritime applications, it is essential to consider these risk factors. IMO has specified different types of tanks to ensure safety and efficiency in the storage of LNG gases used in maritime applications for bulk transportation or bunkering (Fig. 1). According to IMO's IGC, tank types can be categorized as independent tanks (type-A, type-B, type-C), membrane tanks, integral tanks, semi-membrane tanks [8]. In the IGF Code, tank types can be categorized as independent (type-A, type-B, type-C) and membrane tanks [7].

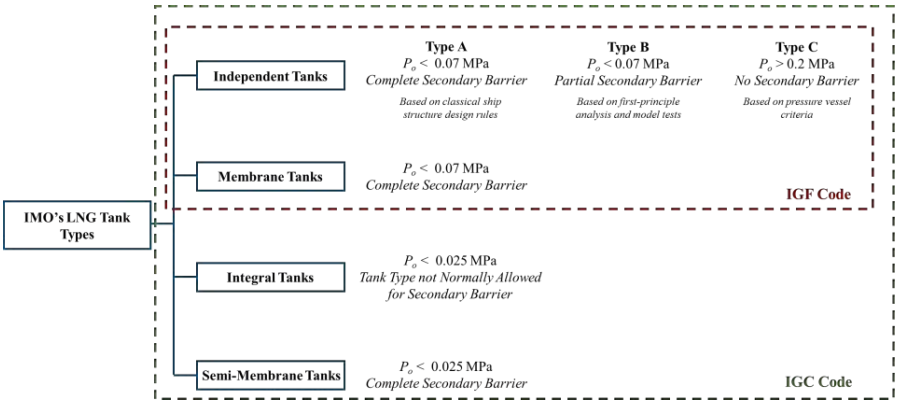

Fig. 1. Classification of the IMO's Tank Types [7,8]

To maintain cryogenic temperatures, LH_2 tanks are typically composed of three main layers: the primary barrier, vacuum space, and a secondary barrier. The primary barrier directly contains the liquid hydrogen, while the vacuum layer minimizes heat transfer by conduction, convection, and radiation. The secondary barrier, required in certain containment systems, serves to temporarily hold leaks and protect the ship's structure from extreme cold [6,12]. This multilayered configuration is standard in both spherical and cylindrical LH_2 tank designs (Fig. 2).

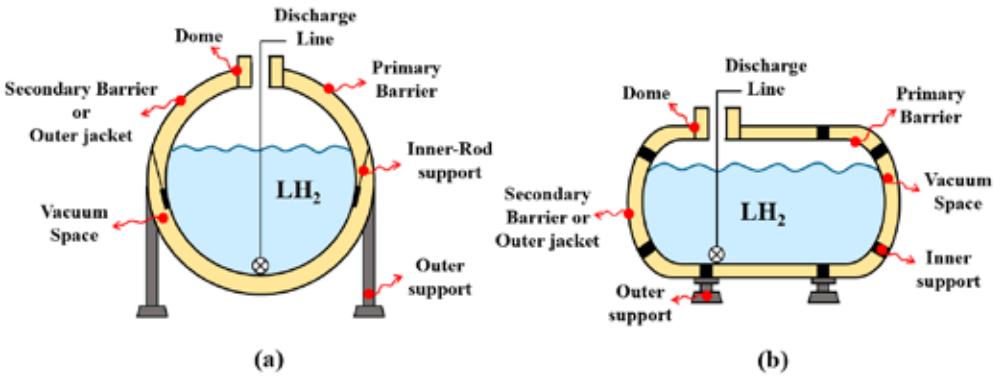

Fig. 2. Schematic of the (a) spherical, (b) cylindrical tanks

A secondary barrier is generally required when the primary barrier is not structurally integrated into the ship's hull. However, if leakage risk is low and the tank is positioned outside enclosed hull spaces, a full secondary barrier may not be necessary, partial barriers can offer localized protection. As outlined in MSC.565(108), revised interim guidelines propose a configuration where insulation is applied outside the primary barrier and inside the secondary barrier, with a dedicated gap in between to prevent condensation or solidification of hydrogen gas on the cold inner shell (Fig. 3).

Despite the improvements suggested in the IMO regulations, several studies in literature still employ type-C tanks for LH_2 storage applications. In the study by Alkhaledi et al. [14], the design focused on a large-scale LH_2 carrier named JAMILA, equipped with four massive type-C tanks (each ~70,600 m^3), yielding a total cargo capacity of 282,400 m^3 and carrying 20,000 tonnes of hydrogen at 0.5 MPa. The tanks were mechanically designed with a significant wall thickness (0.434 m aluminium with 4.4% Cu) to ensure structural integrity under pressure, while a 1 m thick polyurethane foam insulation layer limited boil-off to just 0.1% per day. The design aimed to eliminate onboard refrigeration, using boil-off

hydrogen to power the ship's propulsion system via a 50 MW combined-cycle gas turbine. The concept achieved good stability characteristics and energy efficiency, demonstrating the feasibility of large LH_2 marine transport.

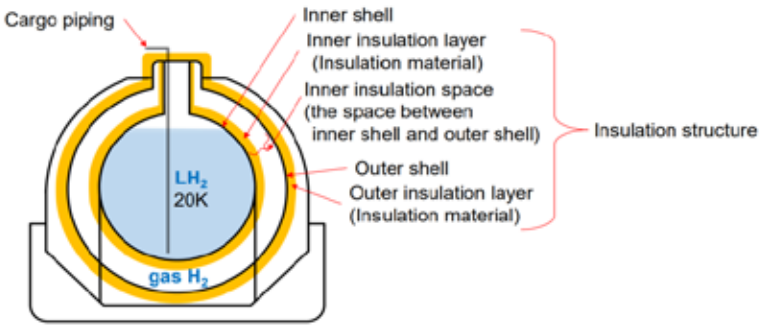

Fig. 3. Illustration of cargo containment system for hydrogen gas [10]

2.1. Insulation Methods and Material Selection in the LH_2 Tanks

Insulation methods can be classified fundamentally as passive and active insulation methods. Passive insulation methods (PIMs) can be implemented by either creating a vacuum layer on the outer surface of the LH_2 tank or by using high-performance materials, to minimise heat loss caused by thermal transfer. The most common PIM is to create a vacuum area outside the tank. The main aim of the vacuum area is minimising heat transfer resulting from convection. To support that and solid-state thermal insulation materials can be added into the vacuum area to minimise the conduction heat transfer. Solid-state thermal insulation methods can be classified as powder, foam, and fibre insulation [3]. These insulations describe the different physical forms of the insulation materials. In the absence of air or gas, conductive and convective heat transfer is minimal, and radiative heat transfer becomes predominant. To reduce the radiative heat transfer, MLI can be added in the vacuum area with or without solid-state thermal insulations methods [4].

Material selection for LH_2 tanks is a crucial part of system design, as these materials must operate reliably at very low temperatures and in direct contact with hydrogen. In addition to general cryogenic requirements, such as maintaining mechanical strength, toughness, and flexibility below -253°C, materials must also withstand specific challenges caused by hydrogen exposure such as hydrogen permeability, corrosion, thermal expansion, and most notably hydrogen embrittlement. Under this challenges, stainless steel is the most used cryogenic material [13]. Various stainless-steel alloys are developed by combining it with different elements to enhance properties such as strength, ductility, and corrosion resistance in LH_2 applications [15].

Thermal insulation material selection for LH_2 tanks in maritime environment must prioritize low thermal conductivity, cryogenic stability, and compatibility with the harsh marine environment. For powder insulation, chemical inertness, resistance to pressure and vibration, and low outgassing are key. Foam insulation should have a closed-cell structure, retain strength at cryogenic temperatures, and resist moisture and hydrogen degradation. Fibre insulation requires low density, mechanical flexibility, and vacuum compatibility. In MLI systems, reflective materials must offer high reflectivity, low emissions, and cryogenic stability, while spacer materials should minimize conduction and be lightweight, strong, and chemically compatible. Hybrid approaches, such as combining MLI with HGMs or glass fibers, show promise in reducing boil-off rates significantly [3,4]. In Table 1, several studies from literature are given for maritime vessels.

Table 3. Specification of the components in marine vessels using liquid hydrogen storage tanks

Authors	Tank Type	Insulation Method	Insulation Material	Primary Barrier Material	Secondary Barrier Material	Aim of H_2 Usage	Boil of Gas Rate
Tamura et al. [16]	Type-B (Prismatic)	N/A	N/A	N/A	Partial secondary barrier	Cargo	N/A
Moreno-Blanco et al. [17]	Cryo-compressed vessel	MLI	Metalized plastic	Aluminum lined composite	Metallic jacket	Fuel	N/A
Lee et al. [18]	C-Type	Foam	Polyurethane	N/A	N/A	Cargo	N/A
Park et al. [12]	N/A	Foam	Polyurethane	N/A	Flexible vacuum membrane	Cargo	N/A
Liu et al. [6]	Type-C	Foam, VCS	Polyurethane	AISI 316L Stainless Steel	N/A	Fuel	Heat ingress reduced by 85.86%
Li et al. [19]	N/A	MLI, VCS, VDMLI	Mylar, Dacron	N/A	N/A	N/A	Reduction by up to 50.43% (HLF)

3. CONCLUSION

This study examined the design criteria for LH_2 storage tanks in maritime applications, aiming to address gaps in the literature regarding their use onboard ships. Key focus areas included bunkering and bulk transport scenarios, insulation methods, and material selection. IMO's codes and related amendments were reviewed to identify applicable regulatory requirements, while insulation strategies were categorized as solid-state or radiative based on current literature. Although IMO does not mandate a specific tank type for LH_2, studies show that type-C tanks are commonly favored due to their effectiveness in minimizing BoG rates. As a next step, the study will explore current innovations and emerging trends in LH_2 technologies for maritime use.

ABSTRACT
In this article, the F110-GE129 afterburning turbofan engine was modelled, and its thermodynamic performance was examined by considering that NH_3/H_2 and JP8 fuels perform under identical operating conditions. The thrust force was calculated as 129 kN in JP8 fuel and 116 kN in NH_3/H_2 fuel. The energy efficiency and thrust efficiency of the afterburning turbofan engine were calculated as 27.03% and 29.70%, respectively, when using JP8 fuel and 26.54% and 28.98%, respectively, when using NH_3/H_2 fuel.

1. INTRODUCTION
The bypass turbofan engine is widely used in civil and military aviation. These engines' working system produces high thrust/power by passing the air fluid drawn from the fan through the fan channel designed around the engine at a certain bypass ratio at high speed. Thus, the turbofan engine produces high thrust force with low fuel consumption. Turbofan engines used in the military field need high and fast thrust force in short distances and it is desired to do this with high thermodynamic performance. However, values below the desired engine performance can be obtained. Increasing the thrust force and power in a turbofan engine is difficult and complex. Because in military aircraft, it is desired to increase the speed to supersonic speeds. In this case, high bypass ratios are not used in these engines because they will create friction [1]. However, engineers and airline companies have done many studies to increase this data. One of these is to add an afterburner to a turbofan engine.

This paper aims to investigate both the thermodynamic performance of the afterburning turbofan engine and the thermodynamic feasibility of a new fuel formed by blending environmentally friendly fuels such as ammonia and hydrogen fuels to reduce emissions.

2. SYSTEM DESCRIPTION
The GE-F110 afterburning turbofan engine is a low bypass, two shaft, and mixed flow fighter jet engine. The turbofan engine consists of a 3-stage fan, a 9-stage high-pressure compressor, The schematic diagram of the afterburning turbofan engine used in military aircraft is presented in Fig. 1.

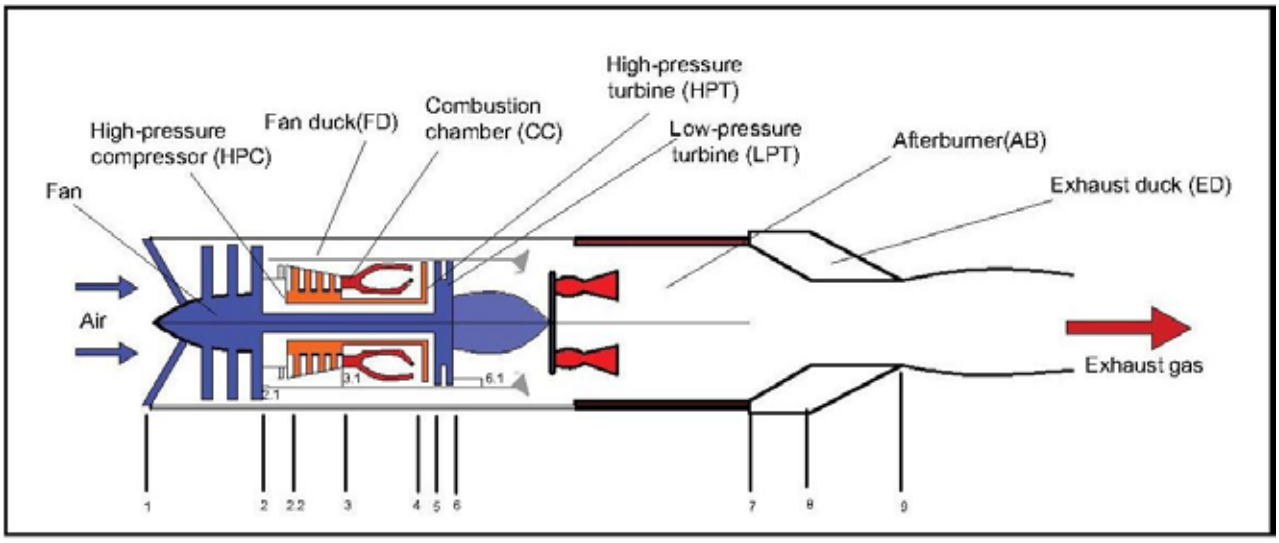

Fig. 1. Simplified version of the F110-GE-129 turbofan engine.

3. PARAMETRIC EQUATIONS FOR AN AFTERBURNING TURBOFAN ENGINE

In this section, a mathematical model has been developed to determine the performance parameters of the afterburning turbofan engine, including specific fuel consumption, thrust, thrust efficiency, thermal energy, and thermal efficiency. These equations are expressed as follows.

Thrust of an afterburning turbofan engine [3,4];

$$ET = [(\dot{m}_9 V_9) + (A_{ED} P_9)] - [(\dot{m}_1 V_1) + (A_{fan} P_1)] \quad (1)$$

Afterburning turbofan engine thrust power [5];

$$\dot{W}_p = ETV_1 \quad (2)$$

Thrust efficiency of afterburning turbofan engine [2,6];

$$\eta_{ET} = \frac{\dot{W}_p}{\frac{V_9^2}{2}\dot{m}_9 - \frac{V_1^2}{2}\dot{m}_1} \quad (3)$$

Thermal efficiency of afterburning turbofan engine [2, 6];

$$\eta_{th} = \frac{\frac{V_9^2}{2}\dot{m}_9 - \frac{V_1^2}{2}\dot{m}_1}{\dot{Q}_{in}} \quad (4)$$

3.1. Hydrogen-Ammonia Mixture Fuel

For this reason, the ammonia/hydrogen mixture has been investigated in numerous studies as an alternative fuel. The applicability of ammonia/hydrogen mixture as a fuel to eliminate the properties of ammonia gas such as its high autoignition temperature, low laminar burning speed and the presence of nitrogen that is harmful to the environment is supported by studies obtained from the literature.

4. RESULTS AND DISCUSSIONS

In this study, performance analysis is compared using different fuels in the afterburning turbofan engine. Operating conditions are assumed to be the same in the analyses. The calculated thrust force and specific fuel consumption of an afterburning turbofan engine using different fuels are shown in Fig. 2.

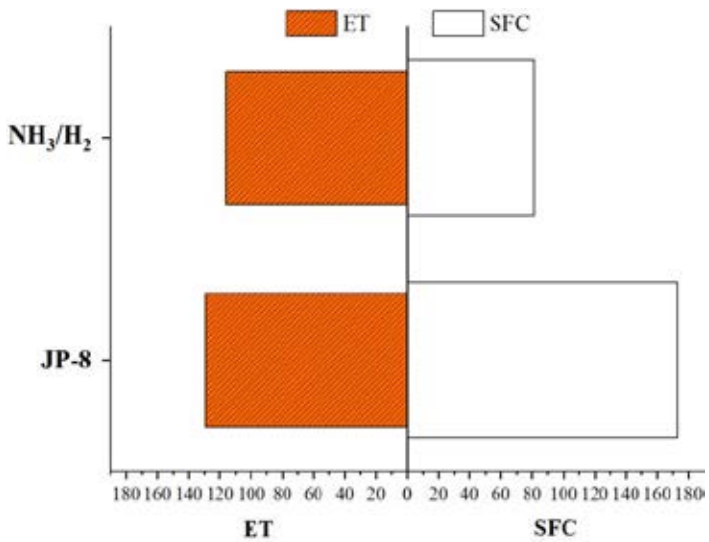

Fig. 2. Thrust force and specific fuel consumption values of afterburning turbofan engine.

Thrust is an important performance parameter in afterburning turbofan engines. As given in Figure 2, the thrust of the afterburning turbofan engine studied in this paper is 129 kN. However, to produce this thrust force, the SFC value is high with 173.37 kg/kN.h. In this study, the thrust force and SFC value are calculated assuming that the NH_3/H_2 mixture fuel, as an alternative fuel to reduce high fuel consumption, operates under the same conditions. Accordingly, the thrust force is obtained as 116 kN and the SFC value as 81.64 kg/kN.h. The thrust force is 10.1% lower compared to JP8 fuel.

5. CONCLUSION

In this essay, the results of the thermodynamic performance analysis made with the data obtained from the literature of the F110-GE129 turbofan engine are compared with the analysis results of the NH_3/H_2 fuel. The inferences from the analysis data are as follows:

- While the thrust of the afterburning turbofan engine using JP8 fuel is 129 kN, this value is obtained as 116 kN when NH_3/H_2 fuel is used.
- The SFC value of the afterburning turbofan engine is 173.37 kg/kN.h when using JP8 fuel, while this value decreased to 81.64 kg/kN.h when using NH_3/H_2 fuel.
- The thrust efficiency and thrust power of the afterburning turbofan engine are worked out as 17458.55 kW and 27.03% in JP8 fuel, and 15646.18 kW and 26.53% in using NH_3/H_2 fuel, respectively.

ABSTRACT
Solar-powered water splitting offers various benefits for sustainable energy consumption. This study focuses on developing a new photo-catalytic-conventional hybrid electrolysis reactor to produce sustainable hydrogen and improve system efficiency. ZnS is commonly utilized in photocatalytic water breakdown for hydrogen production due to its quick electron-hole pair creation and inexpensive cost. ZnS catalyst concentration is 1% (w/v). At 800 W/m^2 and 25-55 °C, the maximum hydrogen generation rate from ZnS suspension was 0.24 µg/s at 40 °C, indicating potential photo-corrosion or oxidation in aqueous environments at high temperatures. Measured Cl_2 gas production on the anode side was found to be 2.95 g/h. The overall hydrogen generation rate for the hybrid reactor was obtained to be 0.74 µg/s.

Keywords: Solar energy, hydrogen, hybridized water electrolysis, photocatalytic water splitting

1. INTRODUCTION

As the worldwide energy sector undergoes rapid transformation in response to climate change and the demand for sustainability, hydrogen has emerged as an important factor in the transition away from fossil fuels. In contrast to conventional energy sources, hydrogen may serve as a clean, efficient, and adaptable energy carrier that offers a path to decarbonizing sectors that are challenging to electrify directly, including heavy industrial, aircraft, and long-haul transportation.

Photocatalytic water splitting is a promising sustainable hydrogen generation technology. However, it remains in its early stages of development. A photocatalytic system harnesses solar energy to divide water in an individual semiconductor cell. The photo-catalyst in the solution should have excellent stability and cost-effectiveness for large-scale use. Zinc sulphide (ZnS) and cadmium sulphide are examples of efficient and cost-effective photo-catalysts [1]. This research focuses on the performance of a solar reactor for splitting heterogeneous water. The photochemical/electrocatalytic-conventional hybridized reactor combines solar technology with electrolysis to produce hydrogen more efficiently.

Fig.1. A schematic of the proposed system's layout

A study by Baniasadi (2012) [2] conducted a study on an experimental apparatus designed and built to simulate processes in photo-catalytic and electro-catalytic water-splitting systems. The study utilized ZnS and CdS photo-catalysts to simultaneously enhance quantum yield and exergy efficiency. The production rate has increased by nearly 30% relative to the performance of ZnS. Han et al. (2025) [3] developed spherical ZnS@ZnO heterojunctions in situ by a simple one-step hydrothermal growing procedure. The impact of ZnO content on the H_2 generation rate of the composite was examined. ZOS-4, the composite formed after 4 hours of reaction, has the greatest photocatalytic hydrogen generation rate of 18.81 mmol $h^{-1}g^{-1}$.

ZnS is a semiconductor with a wide bandgap (~3.6 eV) that is renowned for its robust photocatalytic activity when exposed to ultraviolet (UV) radiation. When dispersed in an aqueous solution, ZnS particulates can effectively absorb UV light to generate electron-hole pairs, thereby triggering the redox reactions required for hydrogen evolution when used in suspension form. The holes oxidize water or sacrificial agents (e.g., methanol or sodium sulphide) to maintain charge neutrality, while the photogenerated electrons reduce water or protons (H^+) to produce hydrogen gas (H_2). Nevertheless, the rapid recombination of charge carriers and the reliance on UV light, which accounts for a mere fraction of the solar spectrum, restrict the potential of ZnS.

The photocatalytic suspension system can be incorporated with a conventional electrolysis cell to resolve these challenges and improve overall efficiency, resulting in a hybrid configuration. The electrolyzer's external voltage is partially reduced by the photocatalytic activity of ZnS in this configuration. This reduces the total energy input and enables the system to continue hydrogen production in low-light or non-illuminated conditions, as the conventional cell can continue operation using electrical energy from renewable or grid sources. The hybrid approach is a promising solution for scalable and continuous green hydrogen production, as it also provides extended functionality throughout the day, enhanced hydrogen yield, and greater operational flexibility.

2. SYSTEM DESCRIPTION

The hybrid hydrogen reactor is depicted in Figure 1 in operation, illuminated by the solar simulator with ZnS suspension. The process of photocatalytic hydrogen production involves the illumination of ZnS, which is suspended in basic solutions containing sulphide ions under a solar irradiation level (800 W/m^2).

The reactor is composed of two distinct electrolysis cells: the conventional cell and the photocatalytic cell. The primary components of the PC are an anode, a cation exchange membrane, and a photocathode. The common anode for both cells is the critical component of the investigation. The bipolar plate was selected as the anode electrode type due to the presence of two active surfaces during the electrolysis process. Three distinct electrolytes are employed: $NaCl_{sat}$, ZnS suspension, and KOH. Furthermore, the membrane facilitates the selective passage of Na^+ ions from the anode to the cathode partition, thereby neutralizing the presence of OH^- ions in the cathode compartment. To facilitate the irradiation of the photocathode, the reactor is equipped with transparent windows made of acrylic glass. The following equation may characterize the chemical process of hydrogen production in the hybrid electrolyzer:

For the Photocatalytic cell:

$$Overall\ reaction = 2H_2O + 2Cl^- \xrightarrow{hv} 2H_2 + 2OH^- + Cl_2 \quad (1)$$

$$Anode = 2Cl^- \rightarrow Cl_2 + 2e^- \quad (2)$$

$$Photocathode = 2H_2O + 2e^- \rightarrow H_2 + 2OH^- \quad (3)$$

For the conventional cell:

$$Overall\ reaction = 2H_2O \rightarrow 2H_2 + O_2 \quad (4)$$

$$Anode = 2H_2O \rightarrow O_2 + 4OH^-_{aq} + 4e^- \quad (5)$$

$$Cathode = 4OH^-_{aq} + 4e^- \rightarrow 2H_2 + 2H_2O \quad (6)$$

The following equations are used to compute comprehensive energy and exergy efficiencies of the hybrid system:

$$\eta_{overall} = \frac{\dot{m}_{Cl_2} h_{Cl_2} + \dot{m}_{PC} LHV_{H_2} + \dot{m}_{Con} LHV_{H_2}}{\dot{Q}_{in} + \dot{W}_{in,total}} \quad (7)$$

and

$$\Psi_{overall} = \frac{\dot{m}_{Cl_2} ex_{Cl_2} + \dot{m}_{PC}\left(ex_{PC} + ex^{ch}_{H_2}\right) + \dot{m}_{Con}(ex_{Con} + ex^{ch}_{H_2})}{Ex^{\dot{Q}}{}_{in} + W_{in,total}} \quad (8)$$

3. RESULTS AND DISCUSSIONS

The catalyst concentration is determined to be 1% (w/v) of ZnS. An increased electron concentration and improved performance under elevated solar radiation conditions are the result of a greater number of photons within the band gap energy of ZnS being accessible per unit of time. The impact of ZnS inclusion on hydrogen production in the PEC cell under high solar intensity at various operational temperatures is illustrated in Figure 2. An average standard deviation of 0.001 µg/s for the PEC cell is achieved by conducting each experimental trial three times at three distinct operating temperatures (25, 40, and 55 °C) under an 800 W/m^2 solar radiation intensity and a mass flow rate of 35 mL/min.

Operating at a temperature of 40°C, the maximum hydrogen generation rate was 0.24 µg/s. The quantity of active electrons available for hydrogen generation is reduced as a result of the faster recombination of electron-hole pairs at higher temperatures. Nevertheless, ZnS may be subjected to photo-corrosion or oxidation in an aqueous

environment at elevated temperatures, resulting in a decrease in active sites. The dissolution of sulphur or the formation of Zn $(OH)^{-2}$ layers may obstruct active sites, thereby reducing the catalytic effectiveness. The quantity of hydrogen produced at 55°C is less than that at 40°C. As a result, the efficiency of the system experiences a significant decrease as the operational temperature exceeds 50°C because of the synergistic effects of recombination, catalyst degradation, and bubble formation.

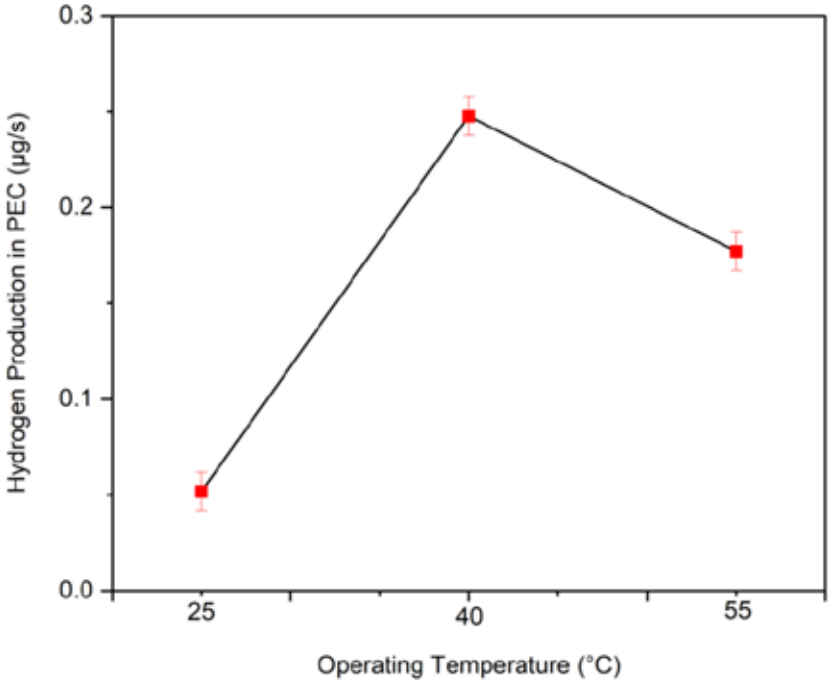

Fig. 2. The impact of ZnS suspension on hydrogen production in the PEC cell under high solar intensity at various operational temperatures.

The Cl_2 gas generation rate measured using a U-manometer was 2.95 g/h, whereas the hydrogen synthesis rate was determined to be 0.52 µg/s at 40°C. So, the overall hydrogen production rate in the hybrid reactor was found to be 0.74 µg/s.

4. CONCLUSIONS

The hybrid system offers several benefits, including generating significantly more hydrogen and operating without solar radiation. The maximal hydrogen generation rate was 0.24 µg/s when the PEC cell was operated at a temperature of 40°C and under 800 W/m^2. The hydrogen was produced using a 1% (w/v) ZnS suspension. The hydrogen synthesis rate was determined to be 0.52 µg/s at 40°C, while the Cl_2 gas generation rate was 2.95 g/h as measured by a U-manometer. Therefore, the overall hydrogen production rate of the hybrid reactor was determined to be 0.74 µg/s.

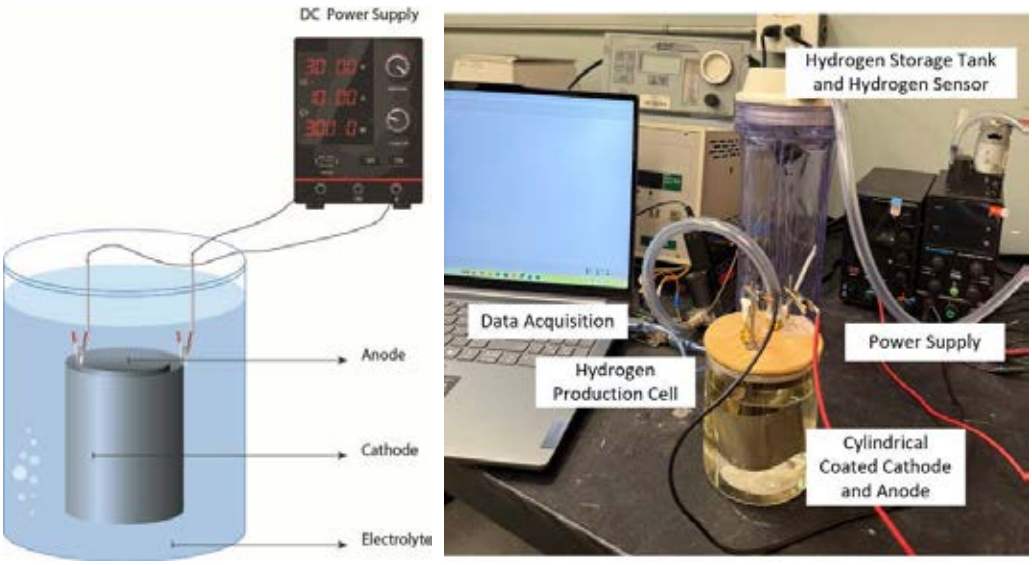
ABSTRACT
Electrolysis is a process that separates water into hydrogen and oxygen using an electric current. This study examines the effect of electrode surface area on hydrogen production in a cylindrical electrolysis system with copper-coated cathodes under a 3 V applied voltage. The experiments were conducted with six different electrode surface areas, and the highest hydrogen production (~42 mg) was observed at X3. After this point, production decreased, possibly due to gas accumulation or ion transfer limitations. These results highlight the importance of electrode surface optimization for improving hydrogen generation efficiency.

Keywords: Hydrogen, Coated Electrode, Electrolysis.

1. INTRODUCTION
Hydrogen generation via electrolysis occurs by applying an electric current to an electrolyte solution, causing water to split into hydrogen and oxygen gases [1]. The efficiency of this process is influenced by electrode materials, design, and operational conditions. Copper-coated electrodes are commonly used due to their excellent electrical conductivity, durability, and catalytic properties, making them beneficial for enhancing electrolysis efficiency.
A cylindrical electrode arrangement helps improve mass transfer, ensures even current distribution, and minimizes energy losses, ultimately increasing hydrogen output [2]. In electrolysis, hydrogen is generated at the cathode, where positively charged ions gain electrons, while oxygen is released at the anode. Optimizing the electrode surface area and configuration plays a key role in improving performance, offering a scalable solution for hydrogen production [3]. In this study, a new cylindrical electrolysis is developed to employ various copper-coated electrodes tested under various operating conditions for improved hydrogen production rates.

2. SYSTEM DESCRIPTION
The electrolysis reactor in this study features a cylindrical electrode design, where the outer electrode functions as the cathode and the inner electrode serves as the anode. The copper-coated cathode facilitates electron flow, improving hydrogen generation efficiency. A uniform gap between the electrodes ensures smooth ion movement within the electrolyte, reducing resistance and enhancing overall performance. When an external power source supplies direct current to the system, the electrolysis process begins. At the cathode, water molecules undergo reduction, producing hydrogen gas, while oxidation at the anode results in oxygen gas release. The cylindrical structure maximizes electrode surface utilization and supports stable gas bubble detachment, improving system stability and efficiency.



a) b)

Fig. 1. Electrolysis Reactor with Cylindrical Electrodes
a) Novel structure of the Electrolysis Reactor; b) The present Electrolysis Reactor

The electrolysis reactions occurring in the system are as follows:

Overall Reaction:
$2H_2O_{(l)} \rightarrow 2H_{2(g)} + O_{2(g)}$

Anode Reaction:
$2H_2O_{(l)} \rightarrow O_{2(g)} + 4H^+ + 4e^-$

Cathode Reaction:
$4H^+ + 4e^- \rightarrow 2H_{2(g)}$

3. RESULTS AND DISCUSSION

Fig. 2 shows the relationship between electrode surface area and hydrogen production at 3V. Initially, as the surface area increases, hydrogen production also rises, reaching its highest level (~42 mg) at X3. This suggests that a larger surface area enhances electrochemical activity. Beyond X3, production decreases at X4 and then increases slightly at X5 and X6, though it does not surpass the peak at X3. The decline after X3 may result from factors such as gas accumulation on the surface or changes in ion flow. Overall, the trend indicates that hydrogen production does not continuously increase with surface area but instead reaches an optimal level before stabilizing.

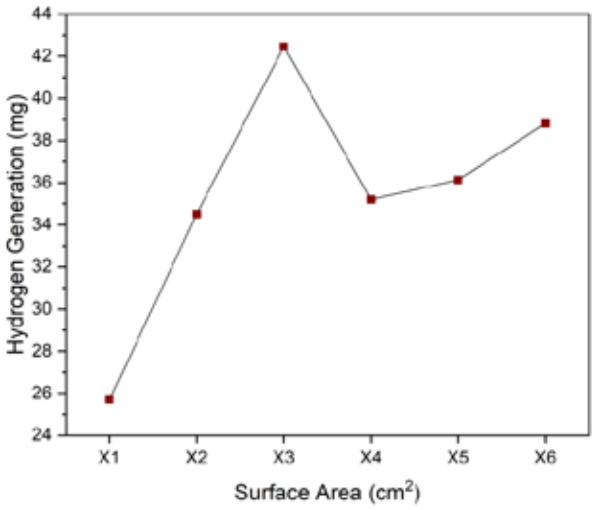


Fig. 2. Effect of Electrode Surface Area on Hydrogen Production at 3V (X1:80 cm^2, X2:130 cm^2, X3: 180 cm^2, X4: 230 cm^2, X5: 280 cm^2 and X6: 330 cm^2)

4. CONCLUSIONS

The study results show that electrode surface area plays a key role in hydrogen production. Hydrogen generation increases as surface area expands, reaching its highest level at X3 (~42 mg). After this point, production declines and varies, which may be influenced by factors such as gas buildup on the electrode, changes in ion movement, or variations in electrical resistance. These findings suggest that while a larger surface generally improves efficiency, an optimal level exists beyond which performance may decrease. Adjusting electrode design and operating conditions could help improve hydrogen generation in future applications.

ABSTRACT
This study investigates the efficiency of hydrogen production via alkaline electrolysis using coaxial cylindrical electrodes with a scrubber-wire cathode. A three-dimensional (3D) cathode structure composed of 316 steel wire is utilized, with the cathode mass varied between 2g and 4g while maintaining a constant volume. The primary objective is to assess the impact of cathode mass on hydrogen production rate and energy efficiency. The experimental results indicate that while the hydrogen production rate for both configurations followed similar trends, the total hydrogen production is higher for the 2g cathode (5.02 mg) compared to the 4g cathode (2.35 mg). Furthermore, the energy efficiency for the 2g cathode reached 78.3%, significantly surpassing the 69.6% efficiency observed for the 4g cathode. The reduced efficiency of the 4g cathode is attributed to increased ohmic losses and bubble coalescence, which hinder mass transport. These findings highlight the importance of optimizing cathode mass in electrolysis systems to balance hydrogen production rate and energy consumption, ultimately enhancing the economic feasibility of hydrogen generation.

Keywords: Hydrogen; hydrogen production; alkaline electrolysis, 3D electrode

1. INTRODUCTION

Hydrogen has emerged as a promising energy carrier in the global pursuit of sustainable and clean energy solutions, offering a versatile means to decarbonize all sectors, including transportation, industrial manufacturing, power generation, and residential applications. Although hydrogen is the most abundant element in the universe, it is rarely found on Earth in its molecular form (H_2) for direct use, as it is typically bound in compounds like water or hydrocarbons, with rare exceptions such as underground hydrogen deposits. Hydrogen's potential lies in its ability to store and deliver energy with zero carbon emissions when produced using renewable resources [1]. The challenge of producing hydrogen efficiently, economically, and sustainably remains a significant obstacle to its widespread adoption.

In electrolysis processes, the cost of the cathode material, electrochemical characteristics, and specific surface area all contributed to its effective hydrogen recovery for use [2]. Due to their high electrical conductivity, biocompatibility, and hydrogen evaluation reaction potential, a variety of metal-catalyst electrodes, including Pt, stainless steel, nickel alloys, tungsten carbide, MoS_2, and iron, have been utilized for water electrolysis in the last 10 years [3]. Moreover, several geometries are used as cathode electrodes such as plates, rods, brush, felt, 3D printed electrodes, and foam [4]. Coaxial electrode configuration for water electrolysis can be a significant alternative to manage the gas evolution and electrolyte circulation inside the cell [5]. However, among these electrode types, plate and rod electrodes often suffer from limited surface area, reducing reaction efficiency. Brush and felt electrodes, while offering higher surface area, may experience structural degradation over time and exhibit non-uniform current distribution. 3D-printed electrodes, though customizable, can be costly and may have material compatibility issues in harsh electrolytic environments, while foam electrodes, despite their porous nature, often face challenges related to mechanical stability and potential clogging.

Therefore, there is a critical need for cost-effective and three-dimensional electrode materials that enhance hydrogen production efficiency while maintaining durability and scalability. In this regard, the use of a scrubber-wire cathode in electrolysis-based hydrogen production offers several potential advantages. Its high surface area-to-volume ratio enhances electrochemical activity, promoting increased hydrogen evolution reaction efficiency. The interconnected wire structure facilitates improved mass transfer, reducing diffusion limitations and ensuring uniform current distribution. Additionally, the open and porous design minimizes gas bubble accumulation, thereby decreasing ohmic resistance and improving overall system performance. Compared to conventional cathode materials, scrubber-wire electrodes are typically cost-effective, easily scalable, and mechanically robust, making them a promising alternative for sustainable and high-efficiency hydrogen production.

In closing, this paper experimentally explores the use of wire-mesh-type three-dimensional electrodes in an alkaline environment. The effect of various design and operating conditions are tested. The hydrogen production rate and energy efficiency of the electrolysis process are used for performance assessment.

2. MATERIALS AND METHODS

This study employs a concentric electrode configuration in the electrolysis cell, comprising a cylindrical anode, separator, and three-dimensional cathode. 316 anealled steel sheet is used as the anode material. The 3D electrode (cathode) is produced from 316 stainless steel pads. The amount of the cathode material is parametrically studied to be 2 and 4 g, while keeping its volume constant. Thus, the effect of the electrode porosity is investigated parametrically. A DC power supply is used for power input for the electrolysis cell. A thermocouple (Vernier stainless steel temperature probe, ±0.2°C) and conductivity sensor (Vernier conductivity sensor, ±4% µS/cm) are placed inside the electrolysis cell. To measure the

electricity current flows through the electrodes, a Vernier current probe (±0.31 mA) is included in the experimental setup. An electrochemical hydrogen sensor (±1 ppm) has been used for measuring the hydrogen production rate. A vacuum pump is installed in the setup to collect the production gases and send them to the collection vessel. A fan is used to create a uniform gas mixture to detect hydrogen. Vernier LabQuest and Arduino UNO are used for data logging. The data is recorded every second. The experiments are carried out for 30 minutes. Each experiment is repeated three times without changing the electrolyte solution. After each set of experiments, the KOH solution is replaced with a new one. The conductivity of the 2 M KOH solution varied from 320.1 to 324.2 μS/cm during the experiments. Also, no significant change in electrolyte temperature is observed.

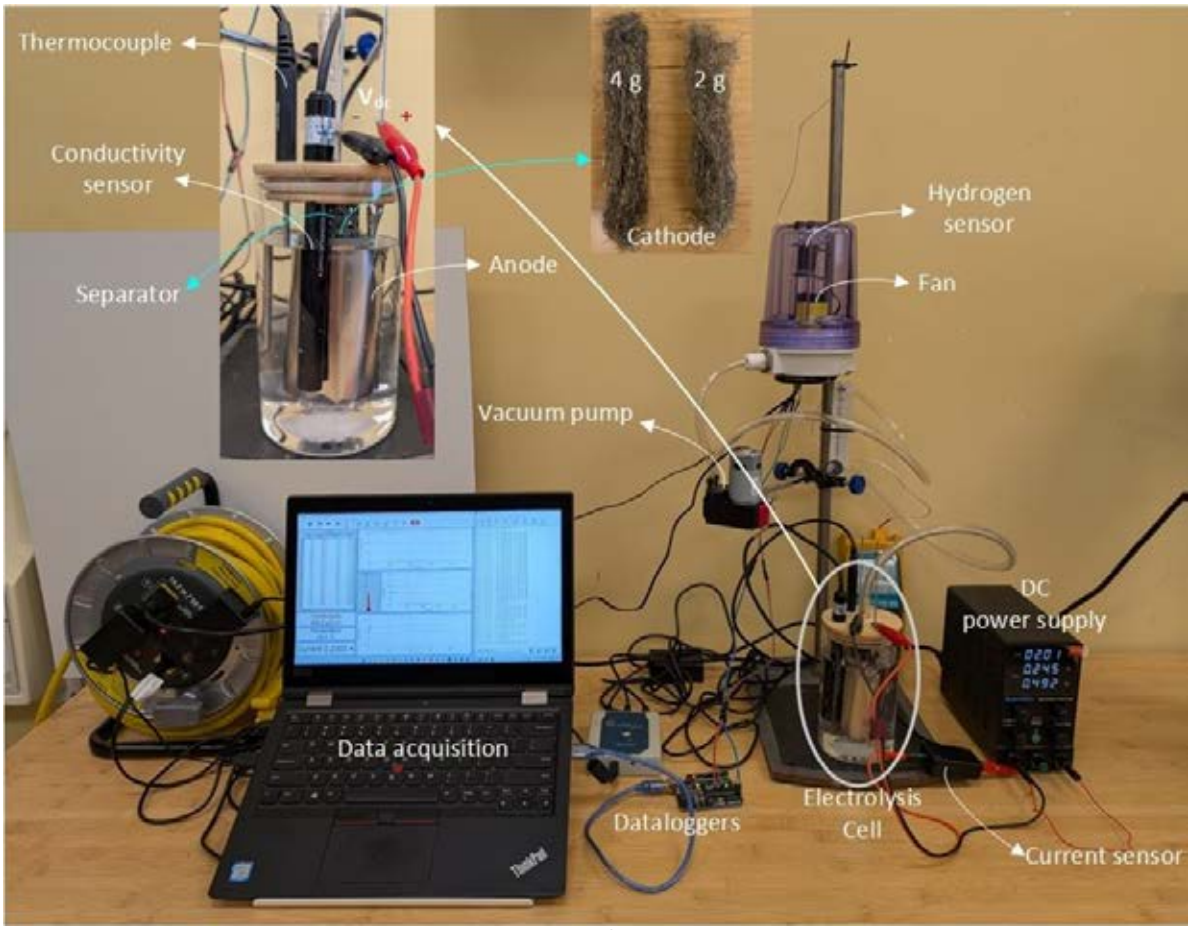

Fig. 1. The photography of the experimental setup

3. RESULTS AND DISCUSSION

The results of the present work are first assessed over the hydrogen production rate. Fig. 2 demonstrates the hydrogen production rate for 2 g and 4 g of cathode materials. Although the hydrogen production rate profiles are similar, the total hydrogen production is observed to be 2.35 and 5.02 mg for 4g and 2g of mesh mass, respectively. The average hydrogen production rate is also measured as 190 and 210 ppm concerning the mass of the cathode material. Fig. 2 illustrates the hydrogen production rate over time for the electrolysis of a 2 M KOH solution at 2 V, utilizing coaxial cylindrical electrodes with scrubber-wire cathodes of 2 g and 4 g masses. The data reveals a clear correlation between cathode mass and hydrogen production. Initially, both configurations exhibit a gradual increase in hydrogen production, likely corresponding to the establishment of electrochemical equilibrium and the activation of the electrode surface. The 2 g cathode consistently demonstrates a higher hydrogen production rate throughout the experimental period compared to the 4 g cathode. This difference is particularly pronounced in the initial stages, suggesting that a larger cathode mass provides a greater mass-to-surface area ratio for electrochemical reactions, facilitating enhanced hydrogen evolution accordingly.

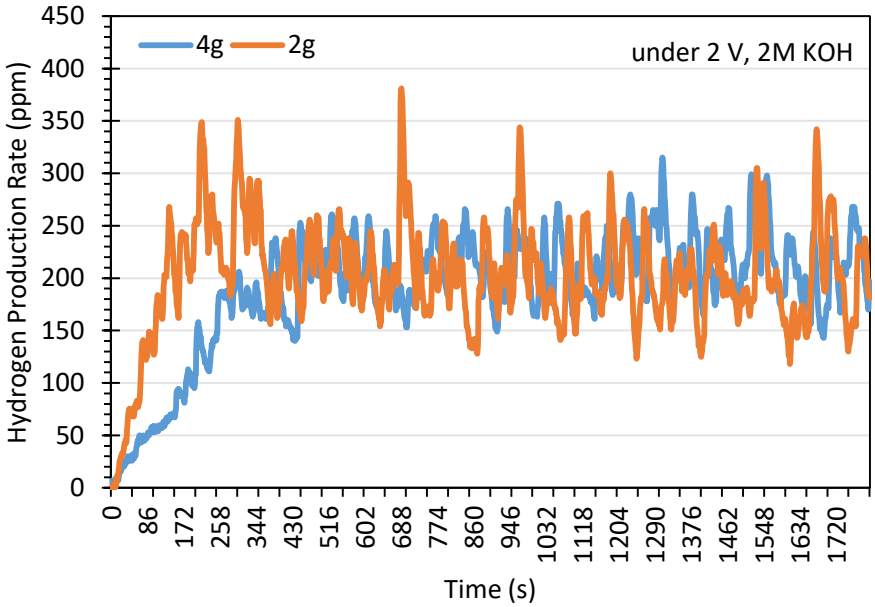

Fig. 2. Effect of the amount of cathode materials on the hydrogen production rates

Moreover, based on the total energy consumed for hydrogen production and total hydrogen production, the energy efficiency is calculated. Notably, the 2 g cathode demonstrates a significantly higher energy efficiency, reaching approximately 78.3%, compared to the 4 g cathode which exhibits an efficiency of around 69.6%. This highlights a crucial trade-off between production rate and energy efficiency in the design of electrolysis systems. While a larger cathode mass can enhance hydrogen output, it may compromise the overall energy efficiency of the process. Optimizing the electrode mass to balance production rate and energy consumption is therefore essential for achieving cost-effective and sustainable hydrogen production.

4. CONCLUSIONS

This study demonstrates that cathode mass plays a crucial role in determining the energy efficiency of hydrogen production in alkaline electrolysis. The experimental results reveal that the 2 g scrubber-wire cathode exhibits superior energy efficiency (78.3%) compared to the 4 g cathode (69.6%), despite similar hydrogen production trends. These results suggest that an optimized balance between electrode mass and effective surface area is necessary for enhancing the performance of electrolysis systems. Future research should explore the influence of additional parameters such as electrode geometry, electrolyte concentration, and operational voltage on hydrogen production efficiency.

ABSTRACT
Hydrogen is a clean and versatile energy carrier with the potential to play a crucial role in the transition to sustainable energy systems. The magnesium-seawater reaction offers a promising solution by enabling hydrogen production from an abundant and naturally available resource, providing an efficient and environmentally friendly alternative to conventional methods. Therefore, this study investigates hydrogen production through the magnesium-seawater reaction to evaluate its feasibility and potential as a sustainable energy solution. Since temperature is a crucial parameter in this process, its effect on hydrogen production performance has been examined in this study. As expected, the hydrogen production performance of the process increased with temperature (40, 60, and 70 °C), likely due to the enhanced reaction kinetics, improved magnesium corrosion rate, and accelerated hydrogen gas release in the magnesium-seawater system. The highest hydrogen production rate was achieved at 70 °C, reaching 5.78 mL/min/g Mg in 30 minutes, while the lowest rate was observed at 40 °C, yielding 4.06 mL/min/g Mg in the same duration. Overall, these results showed that the magnesium-seawater reaction is a promising method for hydrogen production, with temperature playing a key role in optimizing its efficiency and performance.

Keywords: Hydrogen production, Hydrolysis process, Magnesium-water reaction, Sustainability

1. INTRODUCTION
For the past couple of decades, hydrogen has been introduced as a fuel source in an attempt to transition from the use of fossil fuels into cleaner sources of energy. Hydrogen as a fuel source is versatile and can be used in different applications. However, the challenge is in producing hydrogen in a large-scale, efficient, and cost-effective way.
In this regard, magnesium was established as an on-demand, sustainable, and reliable source for hydrogen production. Over the years, scholars searched for different ways to control and enhance the hydrolysis reaction, whether by controlling the medium solution by adding promoters such as $AlCl_3$ or MgCl [1]. This study aimed to observe the reaction at very low temperatures from -40 °C to 0 °C with different solution promoters' percentages with ball-milled magnesium powder with no additives. It was conducted that the best production rate was at 0 °C proving that higher temperatures give better results than lower temperatures with the magnesium hydrolysis. In another study, the effect of the ball milling device, milling time, and the particle size of the magnesium powder were manipulated to improve the hydrolysis kinetics [2]. The best result was obtained with a single additive (graphite), reaching 95% yield in 5 minutes, while also investigating the effect of catalysts using metal chlorides on the hydrolysis.
Moreover, magnesium hydride hydrolysis was vastly investigated in many studies including using magnesium hydride due to its high hydrogen storage capacity [3]. The study aimed at optimizing the reaction by adjusting the flow rate of the solution and adding reactive such as graphite, solid citric acid, and aluminum sulfate obtaining a stable hydrogen production for 12 hours using a flow rate of 200 mL/min.
Different experimental setups were used in the literature such as drainage volumetric method, flow measurements, gravimetric method as well as gas chromatography. In this study, a novel setup was used for the hydrolysis reaction aiming at eliminating the waste using a distillation setup to collect the excess water byproduct, as well as collecting the magnesium hydroxide to be used in other applications such as industrial water treatment and paper industry. This study also focused on using commercially available equipment and abundant materials to make it cost-effective and accessible to all and could be done on a larger scale in the future.

2. EXPERIMENTAL PROCEDURE AND SET-UP
The proposed experimental setup used in this study is based on a distillation unit using a vigorous column, condenser, and collector for any excess water leaving the reaction (Fig. 1). The simulated seawater is first added to the flask, heated to a certain temperature using a hot plate and a temperature controller then the magnesium powder with an average particle size of 50 μm is added to the flask to start the reaction. Using a pump to supply the condenser with cold water to help with the condensation of steam byproduct. Also, there is a flow meter and a vacuum pump to make a stream for the hydrogen sensor to get the readings. All the parts used are commercially available and easy to use.

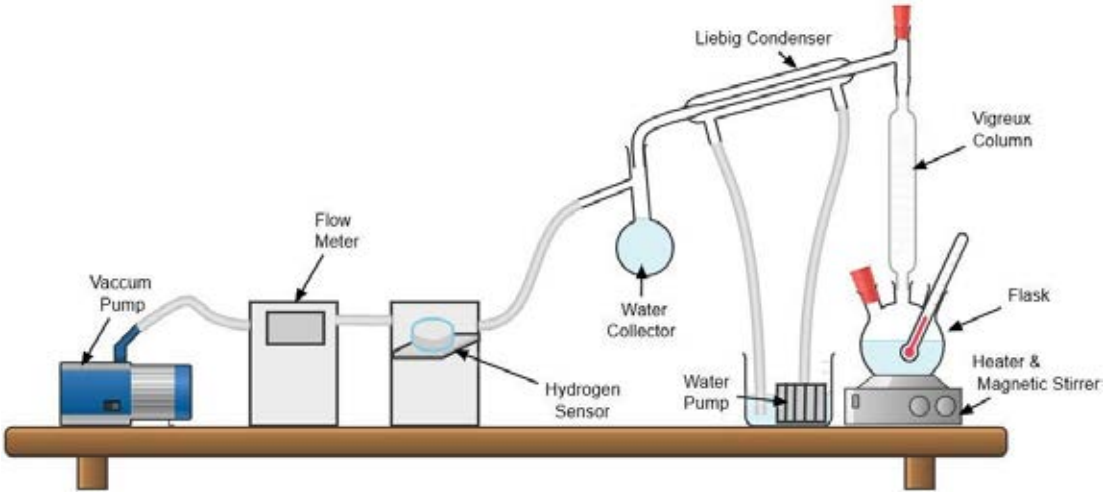

Fig. 1. Schematic illustration of the experimental set-up of the magnesium hydrolysis reaction.

3. ANALYTICAL METHODS

In this study, hydrogen measurements were conducted using the DF Robot Gravity Hydrogen Sensor (I2C&UART), which operates based on an electrochemical detection principle, providing real-time and continuous hydrogen concentration monitoring. The sensor data were continuously recorded throughout the experiments to ensure a precise evaluation of hydrogen production performance. Additionally, since temperature is a critical parameter in this process, a Digital Thermostat Temperature Controller was employed to regulate and maintain the desired experimental temperature. The temperature data were continuously monitored and recorded to ensure accuracy and reproducibility in the experimental conditions.

4. RESULTS AND DISCUSSIONS

In this study, the effect of different temperatures on hydrogen production was investigated, and the results are presented in Fig. 2. It is found that hydrogen production is highly sensitive to temperature. For example, at an operating temperature of 70 °C, it can be observed that the hydrogen production rate was the highest compared to 40 °C. The results indicate that hydrogen production increases with temperature, with the highest yield observed at 70 °C, reaching 5.78 mL/min/g Mg in 30 minutes. On the other hand, the lowest hydrogen production is recorded at 40 °C, with a yield of 4.06 mL/min/g Mg. This trend can be attributed to the fact that higher temperatures enhance the reaction kinetics, increasing the corrosion rate of magnesium in seawater and accelerating hydrogen gas release. Additionally, elevated temperatures improve the diffusion of reactants and reduce activation energy barriers, further promoting hydrogen production. However, beyond an optimal point, excessive heat may lead to increased side reactions or the formation of surface passivation layers on the magnesium, potentially limiting further improvements in hydrogen yield.

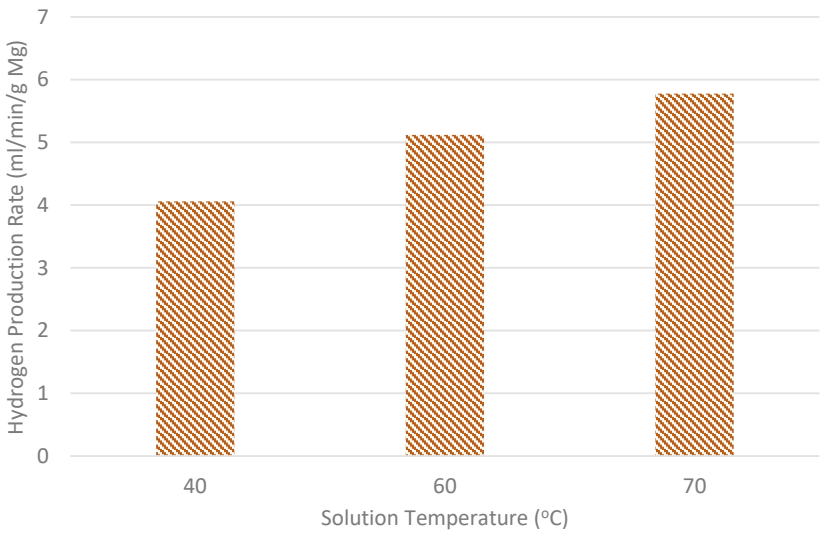

Fig. 2. Hydrogen production rate at different temperatures.

2

5. CONCLUSIONS

This study demonstrates the significant potential of the magnesium-seawater reaction for hydrogen production, highlighting the crucial role of temperature in optimizing the process. The results clearly show that hydrogen production increases with temperature, with the highest production rate of 5.78 mL/min/g Mg achieved at 70 °C. This enhancement can be attributed to improved reaction kinetics, accelerated magnesium corrosion, and increased hydrogen gas release. Overall, the findings suggest that the magnesium-seawater reaction, when carefully optimized, offers a sustainable and efficient method for hydrogen production, with temperature serving as a key parameter for maximizing performance.

APPLICATION OF SYNTHESIZED AMMONIUM FORMATE AS AN ELECTROLYTE IN STAINLESS STEEL-STAINLESS STEEL ELECTRODE H-CELL CONFIGURATION

*Cagri Gokhan Turk and Ibrahim Dincer.
Clean Energy Research Laboratory (CERL), FEAS, Ontario Tech University, Oshawa, Ontario, L1H 7K4, Canada
*E-mail: cagri.turk@ontariotechu.net

Abstract
This research studies the utilization of synthesized ammonium formate as an electrolyte in an H-cell setup with stainless steel electrodes. Electrochemical analyses were conducted across a range of temperatures (room temperature to 100°C). The highest stable voltage performance was recorded around 700 mV at 80°C and approximately 500 mV at 100°C, whereas significantly lower voltages (approximately 50-150 mV) were observed at lower temperatures (RT to 50°C). FTIR spectroscopy confirmed the synthesis accuracy through characteristic peaks, including NH_4^+, C=O, and C–O groups.

Keywords: Ammonium formate, Stainless stell electrode, FTIR Spectroscopy.

1. INTRODUCTION

Ammonium formate (NH_4HCO_2) is increasingly gaining attention as a promising electrolyte in electrochemical applications due to its inherent properties, such as notable ionic conductivity, high solubility, and considerable electrochemical stability under diverse operating conditions [1]. Electrolytes play a critical role in facilitating ionic transport and ensuring effective charge transfer within electrochemical systems, thus significantly impacting system efficiency and stability [2]. Stainless steel electrodes, commonly used in electrochemical experiments, offer benefits such as high corrosion resistance, durability, and economic feasibility, making them suitable candidates for wide-ranging electrochemical setups [3]. Despite various electrolyte materials available, exploring novel solutions like synthesized ammonium formate remains crucial to improving overall electrochemical performance, particularly in energy storage, electrolysis, and fuel cell technologies. In the present study study, the primary objective is to evaluate the electrochemical effectiveness, stability, and performance of ammonium formate synthesized under controlled laboratory conditions using a stainless steel-stainless steel electrode H-cell configuration across a range of operating temperatures, thereby determining its suitability and potential as an electrolyte in broader electrochemical energy systems.

2.SYSTEM DESCRIPTION

The experimental setup consisted of an H-cell with stainless steel electrodes separated by a membrane. Synthesized ammonium formate served as the electrolyte solution. Electrochemical performance, specifically voltage stability, was measured at various temperatures including RT, 30°C, 40°C, 50°C, 80°C, and 100°C. FTIR was employed to confirm the chemical and structural integrity of ammonium formate.

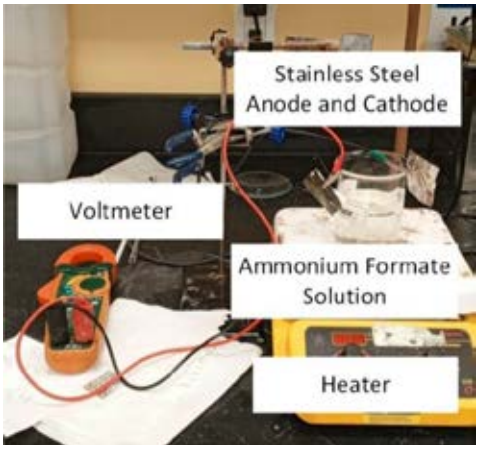

Fig. 1. Experimental Setup.

3. RESULTS AND DISCUSSION

The chemical structure and composition of the synthesized ammonium formate were examined to ensure the integrity of the electrolyte material. In Figure 2, the FTIR spectrum reveals key absorption bands that confirm the presence of characteristic functional groups. Specifically, absorption near 1400 cm^{-1} corresponds to NH_4^+ bending vibrations, the band around 1600 cm^{-1} is attributed to C=O stretching, and the signal near 1350 cm^{-1} indicates C–O stretching. These distinct peaks validate the successful synthesis and chemical stability of the ammonium formate, supporting its suitability as a robust electrolyte component.

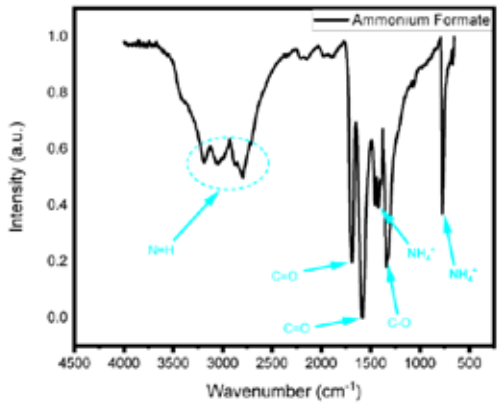

Fig. 2. The FTIR Spectroscopic Analysis of Synthesized Ammonium Formate.

Figure 3 illustrates the voltage-time profiles at different operational temperatures. Stable voltage outputs around 700 mV at 80°C and approximately 500 mV at 100°C indicate substantial electrolyte effectiveness at elevated temperatures. Conversely, lower temperature tests (RT to 50°C) demonstrated notably lower voltage outputs ranging between approximately 50-150 mV, indicating a pronounced temperature dependency in electrochemical performance.

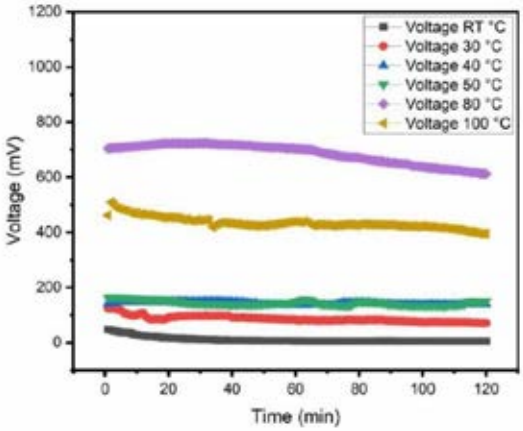

Fig. 2. The voltage-time Profiles of Ammonium Formate Electrolyte at Various Temperatures.

These observations are further supported by evidence indicating successful synthesis and preservation of the chemical structure, which is essential for stable electrolyte performance. The results strengthen the viability of ammonium formate as a potential electrolyte candidate, particularly for systems operating at elevated temperatures. The electrochemical data highlight the enhanced ionic mobility of the electrolyte at higher temperatures, directly linking temperature with improved electrochemical efficiency.

4. CONCLUSIONS

The synthesized ammonium formate demonstrated promising electrochemical stability and efficiency at higher operational temperatures within the stainless-steel H-cell configuration. Optimal voltage performances were observed at elevated temperatures (80°C and 100°C). The chemical integrity of ammonium formate was confirmed by FTIR analysis. These findings support ammonium formate's viability as an electrolyte candidate for stainless steel electrode-based electrochemical applications.

ABSTRACT
Anion Exchange Membrane (AEM) water electrolyzers have emerged as a promising alternative to Proton Exchange Membrane (PEM) due to their potential for cost reduction and long component life. In this study, a one-dimensional (1-D) mathematical model of an AEM water electrolyzer is developed and simulated using Electrolyzer Module in COMSOL Multiphysics. Through parametric analysis, this study investigates the effects of key operating parameters, such as KOH electrolyte concentration and membrane thickness. The primary focus is quantifying major overpotential mechanisms, particularly ohmic and activation overpotentials. The results show that the increasing membrane thickness raises ohmic losses and overall cell voltage, while higher KOH concentrations enhance performance by reducing resistance.

Keywords: AEM water electrolyzer, COMSOL Multiphysics, Modeling

1. INTRODUCTION

In today's world, where sustainability and global warming are gaining importance, the aim is to meet global energy needs with cleaner energy sources and carriers. Hydrogen is an alternative fuel with great potential to meet these demands, and it has merits such as high gravimetric energy density and high reactivity. Hydrogen must be produced using highly efficient methods and renewable energy sources to achieve this. Although there are many methods for hydrogen production, the most commonly used method without harming the environment is electrolysis. The electrolyzer technologies widely used are Proton Exchange Membrane Water Electrolyzer (PEMWE), Alkaline Water Electrolyzer (AWE), and Solid Oxide Electrolyzer Cell (SOEC). Combining the advantages of both PEMWE, which offers a fast response to load changes and high efficiency, and AWE, known for their cost-effectiveness and durability, Anion Exchange Membrane Water Electrolyzer (AEMWE) has recently emerged as a promising new type of electrolyzer [1]. As a relatively new technology, AEMWE still requires significant optimization and further development in various aspects. In this study, a 1-D mathematical model of AEMWE was developed; and parametric studies were performed to investigate the effects of membrane thickness, KOH solution concentration, and the use of NaOH or KOH as the solution on the electrolyzer performance.

2. MODEL DEVELOPMENT

Fig. 1 presents the schematic of the AEMWE used in the 1-D model. As seen in Fig. 1, electrochemical reactions occur on both the anode and cathode sides. The Oxygen Evolution Reaction (OER) occurs at the anode, where hydroxide ions (OH^-) produce oxygen gas (O_2), water (H_2O), and electrons. Simultaneously, at the cathode, the Hydrogen Evolution Reaction (HER) occurs, where water molecules use electrons to form hydrogen gas (H_2) and hydroxide ions. In this study, the boundary conditions for the 1D modeling of AEMWE are defined as follows: At x=0, the electric potential on the anode side is determined by the applied voltage (1.3–2 V). The operating temperature and pressure are set to 343 K and 101,325 Pa, respectively. At x=L, the electric potential is set to zero, serving as the system's reference (ground) potential. The model assumes a single-phase fluid, neglecting bubble effects. The experimental study [2] was tested with a single cell PBI-based membrane and Freudenberg H24C5 carbon gas diffusion layers so the modeling is based on these properties. The geometric and operating parameters used in the model are given in Table 1 [2].

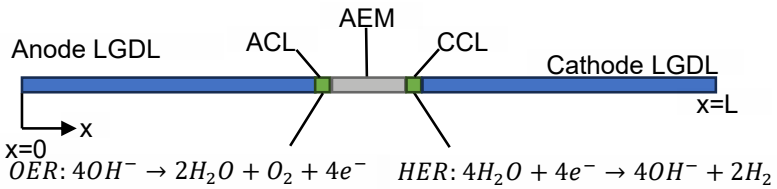

Fig. 1. Schematic diagram of the 1-D model

Table 1. Geometric and operating parameters

Parameter	Value	Unit	Parameter	Value	Unit
Membrane thickness	50	μm	Temperature	343	K
LGDL thickness	230	μm	Pressure	101325	Pa
Catalyst layer thickness	10	μm	KOH concentration	1000	mol/m^3
LGDL conductivity	100	S/m	Active Specific Surface Area	10^7	1/m
Anode exchange current density	12.2	A/m^2	Anodic transfer coefficient	0.343	-
Cathode exchange current density	13.1	A/m^2	Cathodic transfer coefficient	1.657	-

The cell voltage is defined in terms of the overpotentials as follows [3]:

$$E_{cell} = E_{eq} + \eta_{act} + \eta_{ohm} + \eta_{conc} \quad (1)$$

E_{cell} is the total voltage that must be applied (V), E_{eq} is the minimum theoretical voltage required for electrolysis to occur under ideal conditions (V), η_{act} is the activation overpotential (V), η_{ohm} is the Ohmic overpotential (V) (consisting of membrane, electrode, and electrolyte resistance losses), and η_{conc} is the concentration overpotential (V) occuring due to ion consumption or gas production.

2.1. Reversible Cell Voltage

The equilibrium potential is directly related to the change of Gibbs free energy of the reacting species, ΔG, as:

$$\mathrm{E_{eq}} = -\frac{\Delta \mathrm{G}}{\mathrm{nF}} \quad (2)$$

Since the free energy of the reacting species is concentration-dependent, the equilibrium potential also varies with concentration (activity) and is typically determined using the Nernst equation.

$$E_{eq} = E_{eq,ref} - \frac{RT}{nF} ln \prod_i \left(\frac{a_i}{a_{i,ref}}\right)^{v_i} \quad (3)$$

where $E_{eq,ref}$ (V) is the equilibrium potential, corresponds to a reference state where the activities of all species, a_i, are set to a predefined set of reference activities, $a_{i,ref}$. R, n, and F represents the universal gas constant ($\mathrm{J/mol \cdot K}$), the number of moles, and Faraday's constant (96,485.3 $\mathrm{C/mol}$), respectively.

2.2. Activation Overpotential

Activation overpotential is related to the rate of redox reactions occurring at the electrode surfaces. Butler-Volmer equation [4] gives the value of this overpotential as a function of the current density. The equation is described as:

$$i_{loc} = i_0 \left(exp\left(\frac{\alpha_a F \eta}{RT}\right) - exp\left(-\frac{\alpha_c F \eta}{RT}\right)\right) \quad (4)$$

where α_c denotes the cathodic charge transfer coefficient, α_a is the anodic charge transfer coefficient, and i_0 (A/m^2) is the exchange current density. The exchange current density is generally concentration-dependent.

2.3. Ohmic Overpotential

Ohmic overpotential refers to the potential loss due to internal resistances in ionic and electronic conductors in an electrochemical cell. This potential loss is calculated according to Ohm's Law [5]:

$$\eta_{ohm} = i\, R_{ohm} + h_m \frac{i}{\sigma_m} \quad (5)$$

where R_{ohm}, h_m and σ_m are ohmic resistance (Ωm^2), membrane thickness and conductivity of membrane, respectively. Ohmic resistance depends on the conductivity properties of both the electrolyte and electrode materials.

2.4. Continuity Equation

The continuity equation ensures mass conservation by accounting for the balance of species within the system.

$$\frac{\partial(\rho u)}{\partial x} = 0 \quad (6)$$

where u and ρ are velocity and density, respectively.

2.5. Momentum Equation

For steady, flow in the x-direction, considering only viscous and pressure forces:

$$\frac{d}{dx}\left(\mu\frac{du}{dx}\right)=\frac{dP}{dx} \tag{7}$$

where μ is the dynamic viscosity of the electrolyte. The momentum conservation equation describes the balance of forces acting on the fluid, ensuring the proper distribution of velocity and pressure within the system.

3. RESULTS AND DISCUSSIONS

In this study, the performance of an anion exchange membrane water electrolyzer was analyzed under different conditions, focusing on activation losses, membrane thickness effects, and electrolyte composition. Fig. 2 shows the relationship between the experimental data [2] and model data with cell voltage and current density. At low current densities (<0.5 A/cm²), the error rate is up to 9%. At medium current densities (0.5-2.5 A/cm²), the model and the experiment almost match. The error rates are usually around 1%, meaning the modeling is quite successful. At high current densities (>2.5 A/cm²), the model predicts a voltage slightly lower than the experimental data. Here, the error is again around 5%.This can be concluded that this difference is due to the increased formation of bubbles at higher current densities and the neglect of bubble formation in the model.

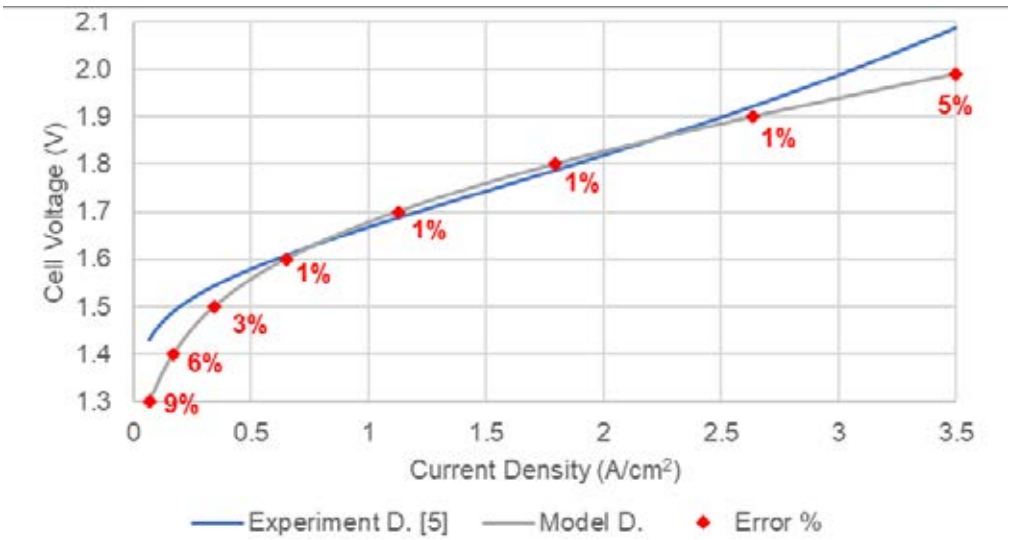

Fig. 2. Comparison of model data with experimental data [2]

In Fig. 3a, the polarization curve for a membrane thickness of 50 µm is presented, illustrating the contributions of different overpotentials to the overall cell voltage. The reversible voltage remains constant, representing the minimum theoretical voltage required for electrolysis. As the current density increases, both the ohmic and activation overpotentials contribute to a rise in the total cell voltage. The ohmic losses, which result from the resistance of the membrane and other cell components, show a linear increase with current density. Meanwhile, activation overpotentials, associated with the energy required to initiate electrochemical reactions, show a nonlinear trend at low current densities. The total cell voltage follows a rising trend as a result of these losses, emphasizing the importance of optimizing membrane properties and electrode kinetics to minimize energy consumption and improve electrolyzer efficiency. In Fig. 3b, polarization curves for different membrane thicknesses (25 µm, 50 µm, and 125 µm) are compared. In general, it is observed that the cell voltage increases as the membrane thickness increases. Thicker membranes offer more resistance to ion passage, decreasing ionic conductivity and thus increasing ohmic losses. Fig. 3c shows the polarization curves obtained when 1 M NaOH and 1 M KOH were used. As can be seen, the use of KOH at the same molarity results in lower cell potential compared to NaOH. This is due to the higher ionic conductivity of KOH. Lower cell voltage means lower energy loss and a more efficient electrolysis process. Therefore, KOH has the potential to improve electrolyzer performance compared to NaOH. Fig. 3d compares the polarization curves for different KOH concentrations (1 M, 3 M and 5 M). It is observed that the cell voltage decreases as the concentration increases. Higher electrolyte concentration reduces ohmic losses by increasing the conductivity of the solution. Especially at low current densities, the difference between different concentrations is insignificant, which becomes more significant as the current density increases.

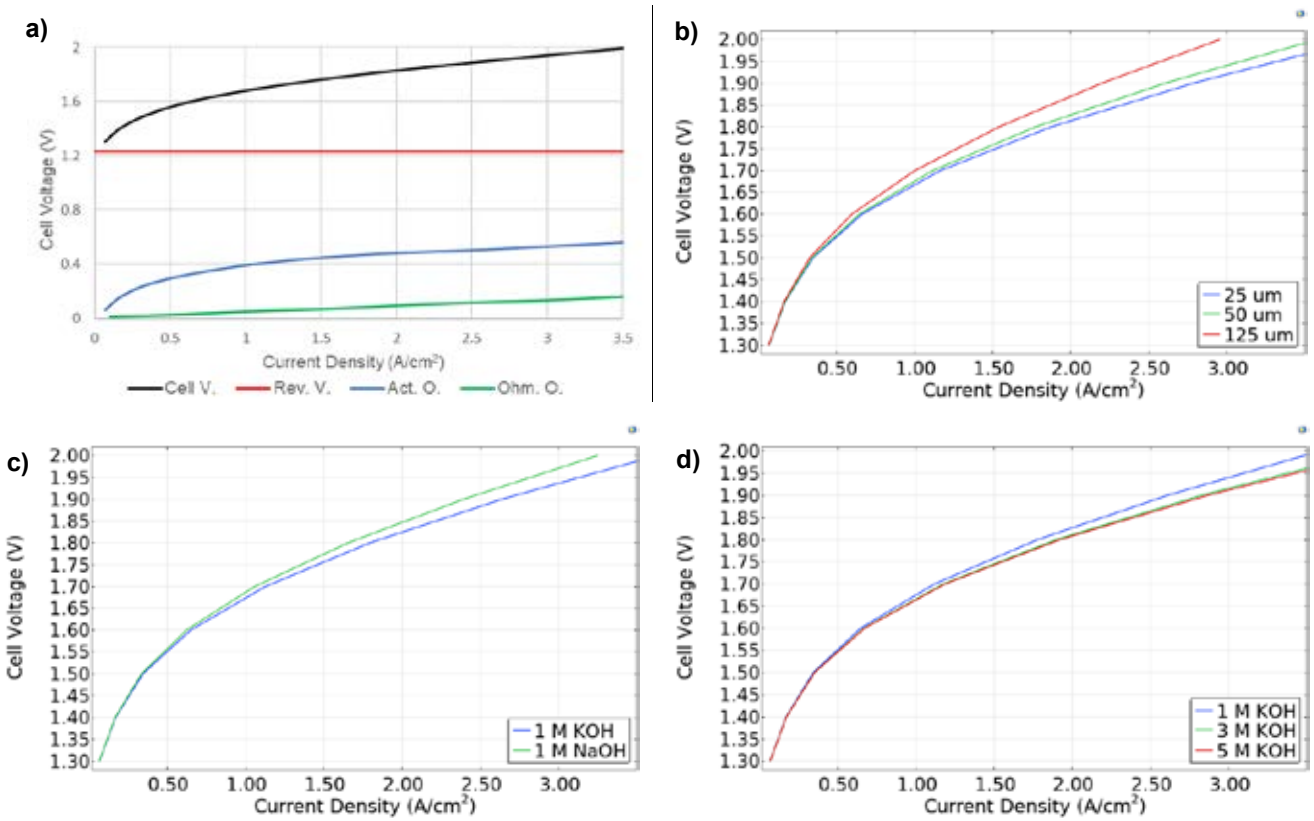

Fig. 3. a) Overpotentials effects and resulting cell voltage relative to current density, **b)** Polarization curves for different membrane thicknesses, **c)** Polarization curves for 1 M KOH and 1 M NaOH, **d)** Polarization curves for different KOH molarities.

4. CONCLUSIONS

In this study, 1-D model is developed to evaluate the performance of an AEMWE under different operating conditions. The results confirm that the model is consistent with the results observed in the literature [2]. The impact of membrane thickness on cell performance was also analyzed. The results indicated that increasing membrane thickness led to higher ohmic losses and an increase in overall cell voltage. Additionally, electrolyte composition significantly affects system performance, as seen in the comparison between NaOH and KOH solutions. Higher KOH concentrations resulted in lower cell voltage at a given current density, highlighting its higher ionic conductivity and lower resistance. These findings highlight the importance of optimizing membrane thickness to balance ionic conductivity and mechanical stability. Data obtained from this study can contribute to the optimization of AEMWE systems. However, further research is needed to improve the model by adding more detailed catalyst kinetics and additional experimental data for improved accuracy and validation.

5. ACKNOWLEDGEMENTS

The authors would like to thank The Scientific and Technological Research Council of Türkiye (TÜBİTAK) (Grant Number: 123M878) for their support and funding of the project.

ABSTRACT
Green hydrogen has been a trend as a key solution for the decarbonization of various sectors, offering a sustainable alternative to conventional fossil fuels. Despite its potential to drive the energy transition, green hydrogen applications are constrained by technical and economic challenges. This study aims to determine the optimal capacity values of solar and wind power plants for six districts (Çeşme, Dikili, Foça, Karaburun, Seferihisar, and Urla) in Izmir, adhering to a 200% oversizing limit based on the capacity of the electrolyzer system. While the Levelized Cost of Hydrogen (LCOH) values for the specified districts yielded similar results, Çeşme yielded the lowest value at 6.15 USD/kgH_2. Contrarily, Foça and Urla had the highest value at 6.27 USD/kgH_2. Identifying a 65 MW wind-powered 50 MW PEMWE system in Çeşme as the optimal configuration, a one-at-a-time (OAT) sensitivity analysis was conducted to investigate key cost drivers. The sensitivity analysis indicated that the scale index (SI) parameter significantly impacted LCOH. It was observed that the Scaled Purchase Cost (C_{SP}) value decreased significantly when the SI value was reduced from the baseline value of 90% to 75% and 60%. Finally, the modularity of the Proton Exchange Membrane Water Electrolyzer (PEMWE) was investigated. Increasing the number of modules led to a reduction in LCOH by 8.5%. The results offer practical insights into system sizing, cost drivers, and modularity for green hydrogen production.

Keywords: Techno-economic analysis, hybridization, modularity, sensitivity analysis, green hydrogen.

1. INTRODUCTION

As the decarbonization of the energy sector accelerates, green hydrogen produced from renewable sources is offered as an alternative to various sectors (e.g. steel industry, transportation, and heating) as a sustainable fuel. However, its production comes with a significant challenge, as it is not cost-effective compared to conventional fossil fuels. Therefore, identifying strategies to achieve a lower Levelized Cost of Hydrogen (LCOH) is essential for the future of green hydrogen. Solar and wind energy are the most commonly used renewable sources to produce green electricity [1]. Solar-wind hybrid power plants ensure a continuous energy supply by allowing them to benefit from each other. Due to the seasonal and economic variations in solar and wind energy sources, determining the optimal hybridization ratio is essential for cost-effective green hydrogen production. This study aims to analyze LCOH values by investigating the hybridization potential for six districts (Çeşme, Dikili, Foça, Karaburun, Seferihisar, and Urla) for a 50 MW Proton Exchange Membrane Water Electrolyzer (PEMWE) green hydrogen production system. Subsequently, a one-at-a-time (OAT) sensitivity analysis was performed to identify the critical input parameters of the LCOH, which was revealed to be SI. IRENA elaborated on the relationship between the manufacturing scale and the learning rate [2]. The variation of the Scaled Purchase Cost (C_{SP}) value in relation to the reduction of scale index (SI) was examined. In addition, the cost-effectiveness of the multi-module PEMWE system was investigated through a calculation that calculates the hydrogen production amount depending on the stack load by separating the specific energy consumption (SEC) of BoP and stack. This study focuses on optimizing the deployment of variable-capacity solar-wind hybrid power plants within the boundaries of İzmir. A key objective is to determine the most suitable location for these systems based on technical and economic factors. Additionally, the study aims to identify which parameter has the most influence on the LCOH. Finally, it examines how variations in the number of modules impact the LCOH. The findings of this study will provide valuable insights into determining the optimal green hydrogen production region among the considered districts, contributing to strategies for reducing green hydrogen production costs.

2. MATERIALS AND METHODS

2.1. Data Collection

The techno-economic analysis algorithm was developed in MATLAB. Reference capital cost and operational cost data were obtained from the IRENA [3], TNO Reports [4], and Khan's study [5]. The SI, the rate to predict the scaled purchase cost, was considered 90%. Annual electricity production data was collected from a website called Renewables-Ninja [6] for all districts of İzmir, excluding areas with a high degree of urbanization, and their average yearly capacity factor values are presented in Table 1. The renewable energy data are based on 2024 measurements in one-hour intervals. Reference costs for solar and wind energy and PEMWE are shown in Table 2, and the specifications of PEMWE are provided in Table 3. Crespi's industrial PEMWE's SEC curve [7] was used as a basis for the hydrogen production calculations.

Table 1. Average annual capacity factor values of the districts of İzmir.

District	Aliağa	Bayındır	Bergama	Beydağ	Çandarlı	Çeşme	Dikili	Foça	Karaburun	Kemalpaşa
Solar Ave. CF	25.71%	25.86%	24.71%	26.15%	25.71%	24.56%	25.61%	25.81%	25.92%	25.84%
Wind Ave. CF	46.63%	22.66%	37.52%	14.85%	48.24%	49.63%	48.82%	47.05%	48.38%	27.15%
	Kınık	**Kiraz**	**Menderes**	**Menemen**	**Ödemiş**	**Seferihisar**	**Selçuk**	**Tire**	**Torbalı**	**Urla**
Solar Ave. CF	25.16%	26.02%	25.94%	25.77%	25.94%	26.12%	25.95%	25.93%	25.90%	26.03%
Wind Ave. CF	39.26%	16.04%	32.89%	34.82%	18.12%	46.92%	27.59%	20.80%	28.24%	46.87%

Table 2. Input cost data for the study

	Value	Reference
Reference capital cost		
PEMWE	2000 USD/kW	[4]
Solar energy power plant	750 USD/kW	[3]
Wind energy power plant	1600 USD/kW	[3]
Reference O&M cost		
PEMWE	2.5% of total PEMWE equipment cost	[5]
Solar energy power plant	7000 USD/kW/y	[3]
Wind energy power plant	30000 USD/kW/y	[3]
PEMWE stack replacement cost	40% of the total stack equipment cost	[5]

Table 3. Technical data of the PEMWE of this study

	Value	Reference
Nominal SEC	55.5 kWh/kgH_2	[7]
Load range	20%-100% of the nominal load (stack)	(assumption)
Stack lifetime	50000 h	[2]
Degradation rate	0.19 %/1000 h	[8]

2.2. Hydrogen Production Modeling

Electricity production data of 1 kW solar and wind power plants were obtained as power plant capacity factor (CF_{pp}) and linearly scaled to calculate the electrolyzer capacity factor (CF_{el}) according to Eq. (1).

$$CF_{el} = \frac{E_{pp}}{E_{el}} \times CF_{pp} \quad (1)$$

where E refers to capacity.

Hydrogen production was calculated according to Eq. (2). This calculation is based on the SEC values that vary depending on the load, with separate consideration given to the energy use of the stack and the Balance of Plant (BoP). Stacks are assumed to degrade yearly, while BoP does not. As stack degradation progresses, SEC_{stack} increases, leading to a decline in hydrogen production performance over the years. The degradation rate changes yearly, while the SEC and CF values change hourly.

$$m_{H_{2(h,y)}} = \frac{1}{\left(1+r_{d_y}\right)\cdot SEC_{stack_{(h,y)}} + SEC_{BoP_{(h,y)}}} E_{el} CF_{el_{(h,y)}} \quad (2)$$

where $r_{d,y}$ refers to the degradation rate.

The modularity of the PEMWE system was further investigated to evaluate its impact on the LCOH. In this context, modularity divides the input electricity among multiple modules by applying a specific operational strategy: the Daisy Chain Allocation (DCA) [9]. This approach prioritizes the operation of modules sequentially. Specifically, Module 1 (M1) is supplied with electricity until it reaches its nominal load. Once M1 is fully loaded, M2 begins operating, followed by M3, M4, and so on.

2.3. Techno-economic Analysis

The techno-economic analysis conducted in this study focuses on two key cost metrics: capital expenditures (CAPEX) and operational expenditures (OPEX), which represent initial investment costs and ongoing operation and maintenance expenses, respectively. This study excludes the electrolyzer stack replacement costs from OPEX to see its impact on LCOH. The C_{SP} was calculated using Eq. (3), and the equipment cost of the asset was determined by multiplying the C_{SP} by its capacity, as shown in Eq. (4).

$$C_{SP} = C_{cap,ref}\ E_{ref}\ \left(\frac{E}{E_{ref}}\right)^{SI} \quad (3)$$

$$C_{eq} = C_{SP}E \quad (4)$$

where C refers to cost.

Land cost is another parameter representing an asset's total land procurement cost. It can be calculated as a percentage of the scaled purchase cost [5]. Finally, total capital costs are determined by summing the equipment and land procurement costs (Eq. (5)).

$$C_{CAPEX} = C_{eq} + C_{land} \quad (5)$$

OPEX is an annual cost parameter reduced due to a discount rate (r_{dis}). The total OPEX was calculated by summing these values (Eq. (6)).

$$\sum OPEX = \sum \frac{C_{op,ref}C_{eq}}{(1+r_{dis})^y} \quad (6)$$

LCOH is determined by dividing the total expenses by the total amount of hydrogen produced over the entire lifespan of the green hydrogen production facility (Eq. (7)).

$$LCOH = \sum_{y=1}^{L} \frac{CAPEX+OPEX_y}{m_{H_2 y}} \quad (7)$$

3. RESULTS AND DISCUSSION

Six districts with high solar and wind energy capacity factors were selected for this study, and they are compared for a 50 MW PEMWE system, with solar and wind power plants simulated at capacities of up to 200% of the electrolyzer's nominal capacity (i.e., up to 100 MW). Table 4 presents minimum LCOH values for considered districts. Çeşme district has the lowest, with 6.15 USD/kgH_2 for a 65 MW wind-only power plant. In contrast, Foça and Urla have the highest, with 6.27 USD/kgH_2 for 70 MW wind, combined with a 75 MW solar power plant. Çeşme's lower LCOH can be attributed to its higher wind energy CF, which ensures more consistent electricity generation, reducing the reliance on solar energy. District variations have minimal impact on minimum LCOH (≤ 0.12 USD/kgH_2). Therefore, site selection may prioritize land availability and transportation options over hydrogen production performance.

Table 4. Minimum LCOH results for each district

District	LCOH (USD/kg)	Solar - Wind Capacity (MW)
Çeşme	6.15	0 - 65
Dikili	6.16	0 - 85
Foça	6.27	75 - 70
Karaburun	6.19	70 - 70
Seferihisar	6.25	75 - 70
Urla	6.27	75 - 70

The optimal configuration for Çeşme (65 MW wind-only) was selected for further calculations. The OAT sensitivity analysis result in Figure 1 shows that the SI has the highest impact by far, with −37.35% to 68.25% impact for −20% to 20% input value variation. The SI's dominant influence indicates that manufacturing scale and technology maturity are the primary levers for LCOH. This underlines the importance of the economy of scale and the effect of the learning rate on cost-reduction strategies. In contrast, the other figure represents the C_{SP} curves that vary according to SI, referencing the wind energy power plant reference capital cost for Türkiye. Improvement in SI reflects C_{SP} as 506 USD/kW and 254 USD/kW, for 75% and 60% SI, respectively.

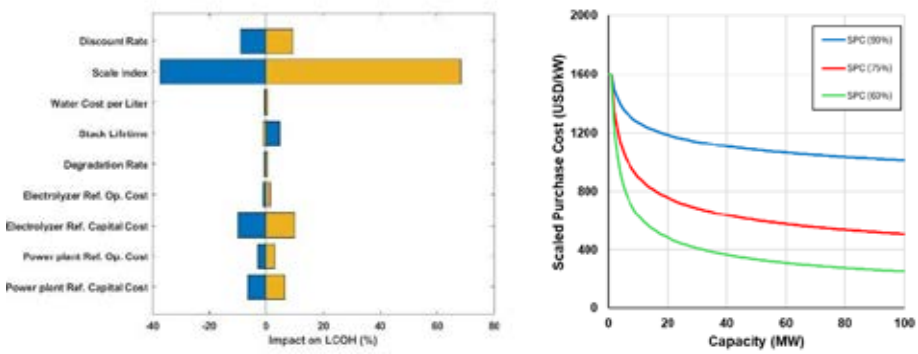

Fig. 1. Sensitivity analysis results (left) and C_{SP} curves of variable SI percentages (right)

Finally, the modularity of the PEMWE was investigated from 1 module to 400 modules. Results in Figure 2 show that using a DCA strategy for modularity can reduce the LCOH by 8.5% for the optimal configuration. The DCA strategy ensures that each module operates closer to its optimal efficiency point by leveraging the total system capacity distribution of the electrolyzer's modularity. While modularity enhances hydrogen production in this case, but its benefits may diminish in situations with lower availability of renewable energy.

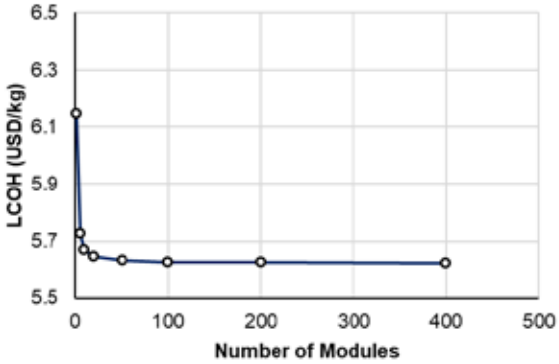

Fig. 2. The effect of changing the number of modules in the considered PEMWE system on the LCOH.

4. CONCLUSIONS

This study investigated the hybridization of solar and wind energy power plants for a PEMWE green hydrogen production system. Six districts are included, considering the solar and wind energy potential of the districts of İzmir. Minimum LCOH values for the six districts are presented for a 50 MW PEMWE system, considering zero to 200% solar and wind power plant oversizing. Results indicated that the Çeşme provides the lowest LCOH, and Foça and Urla provide the highest. LCOH is not highly varied for the six districts with high solar and wind energy potential. Therefore, different factors, such as land availability and transportation options, may be investigated for clarification to determine the most appropriate district. An OAT sensitivity analysis was conducted to determine the critical input parameters referencing the selected optimal case. This analysis presented the importance of SI. Therefore, C_{SP} curves for 60%, 75%, and 90% of SI were given, and a significant C_{SP} decrease was observed. Finally, modularization of the PEMWE system was also investigated, where the increase in the number of modules led to a reduction of LCOH. For future work, integrating a Battery Energy Storage System (BESS) will be considered to further improve the average capacity factor by storing the excess electricity. In addition, financial improvements will be considered for the techno-economic model to obtain more accurate long-term estimations.

ABSTRACT
This study presents a computational investigation of a hydrogen-fueled two-dimensional gas turbine combustor operating at cruise flight conditions (FL390). The combustor geometry was adapted from the literature and meshed with high quality (average skewness: 0.13, orthogonal quality: 0.95). Real engine-derived boundary conditions, including a hydrogen fuel mass flow of 0.3286 $kg.s^{-1}$ and an air flow rate of 13.20 $kg.s^{-1}$, were applied. Numerical simulations were performed using the RNG k–ε turbulence model and eddy dissipation combustion model in ANSYS Fluent. Temperature, velocity, pressure, turbulence kinetic energy, and species distributions were analyzed. The results revealed a maximum flame temperature of approximately 3045 K and a velocity exceeding 1000 $m.s^{-1}$ near the nozzle exit. Efficient hydrogen oxidation was confirmed by high H_2O concentrations and a sharp drop in H_2 mass fraction. NO formation was concentrated in the post-flame region, with a peak mass fraction of 0.031. The absence of CO_2 and unburned hydrocarbons highlights the clean-burning nature of hydrogen.

Keywords: CFD, cruise altitude, emission analysis, hydrogen combustion, jet engine

1. INTRODUCTION
The aviation industry faces increasing pressure to reduce environmental impact and transition toward sustainable propulsion systems [1]. Gas turbine combustors play a crucial role in determining thermal efficiency, emission levels, and operational stability. With conventional aviation fuels being associated with significant carbon-based emissions and long-term resource depletion, the exploration of alternative fuels such as hydrogen has gained notable traction [2]. Hydrogen offers several advantages including high flame speed, absence of carbon-based combustion byproducts, and a broad flammability range, rendering it a promising candidate for decarbonized aviation propulsion [3]. Nevertheless, hydrogen combustion presents several technical challenges [4]. Due to its low ignition energy and high diffusivity, hydrogen-air flames are susceptible to instabilities such as flashback and blow-off, especially under lean or premixed conditions [5–7]. This necessitates the development of advanced combustion chamber geometries and optimized mixing strategies to ensure safe and efficient operation. Various stabilization techniques, such as swirl-induced recirculation, jet-based stabilization, and micro-mixing configurations, have been employed to improve flame stability and combustion efficiency [8,9]. Recent studies have investigated the implementation of hydrogen in gas turbine combustors under diverse operating conditions. Kahraman et al. [10] demonstrate that hydrogen combustion can achieve higher pressure recovery and lower CO_2 emissions compared to Jet-A, though NO_x emissions may increase depending on excess air ratios. Lu et al. [11] explored the stability window of hydrogen-enriched fuels, highlighting the role of flue gas recirculation and inlet temperature in mitigating flashback risk. Liu et al. [12] emphasize the importance of radiative heat transfer and turbulence–radiation interaction in swirling flames, which significantly affect temperature distribution and NO_x formation. Meanwhile, Sun et al. [13] analyzed the influence of equivalence ratio on flame shape and vortex evolution in jet-stabilized combustors, identifying critical flow features that dictate flame anchoring behavior.

In the context of high-altitude flight, particularly at cruise conditions such as FL390, combustor performance becomes even more sensitive to thermal loading and pollutant formation [14]. This study aims to numerically investigate the combustion behavior of a 2D hydrogen-fueled combustor operating under cruise altitude conditions, using real jet engine boundary data. By evaluating key flow and reaction fields—such as temperature, pressure, velocity, turbulence kinetic energy, and species mass fractions—the study provides insights into hydrogen flame behavior and pollutant emissions in a representative aviation-relevant setting.

2. MATERIALS AND METHODS
In this study, a numerical investigation was conducted to evaluate the combustion characteristics of a two-dimensional hydrogen-fueled combustor operating under cruise altitude conditions. The computational domain was designed based on simplified yet representative combustor geometry with a single fuel inlet and two separate air inlets (primary and secondary). Numerical simulations were performed using validated turbulence and combustion models to capture the coupled flow, heat transfer, and chemical reaction phenomena. The modeling strategy and simulation parameters are detailed in the following subsections, including the description of the numerical model, governing equations, and boundary conditions employed in the CFD (computational fluid dynamics) analysis.

2.1. Numerical Model

The computational domain used in this study was adopted from the work of Kahraman et al. [10], who modeled a tubular combustor inspired by a Rolls-Royce Nene-type gas turbine [15,16]. The two-dimensional axisymmetric geometry features a single hydrogen fuel inlet along with two air inlets—primary and secondary. The domain dimensions are 620 mm in length and 145 mm in maximum height, as shown in Fig. 1. The simulation domain was discretized using a structured mesh, resulting in 57,166 nodes and 56,137 elements. The mesh quality metrics indicate excellent resolution, with an average skewness of 0.13299 and an orthogonal quality of 0.95328. According to ANSYS meshing criteria, skewness values below 0.25 and orthogonal qualities above 0.95 are considered excellent, ensuring reliable numerical convergence and solution stability [17]. The mesh configuration, displayed in Fig. 1. To resolve the near-wall regions and capture velocity and thermal gradients, five inflation layers were applied along all solid boundaries. The CFD simulations were performed using the ANSYS 2022 R2 Fluent software. The realizable RNG k–ε turbulence model was selected to account for the effects of turbulent flow within the combustion chamber due to its proven performance in similar geometries and reacting flow environments. Further details regarding the governing equations, chemical reaction mechanisms, and boundary conditions applied in the model are provided in the following subsection.

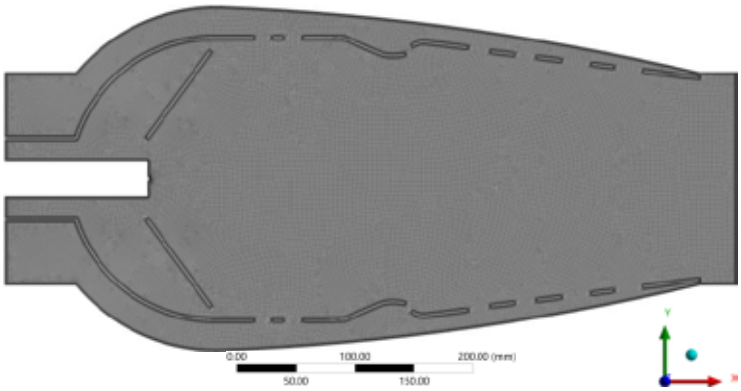

Fig. 1. Mesh structure of the hydrogen-fueled combustion chamber.

2.2. Governing Equations and Boundary Conditions

The numerical simulations were conducted by solving the steady-state, compressible Navier–Stokes equations along with species transport and energy conservation equations. The realizable RNG k–ε turbulence model and the eddy dissipation combustion model were used to capture turbulent mixing and hydrogen-air combustion behavior. The ideal gas law was used as the equation of state, with temperature-dependent material properties. Wall surfaces were assumed to be adiabatic with no-slip conditions. All boundary conditions were defined based on flight level FL390, extracted from real jet engine operational data. The ambient air enters the domain at a total temperature of 228.9 K and a density of 0.3348 $kg.m^{-3}$, while the fuel-air ratio is 0.0249. The hydrogen fuel inlet was defined with a mass flow rate of 0.3286 $kg.s^{-1}$ and the total air mass flow was 13.20 $kg.s^{-1}$. The air and fuel streams were introduced through velocity inlets with a turbulence intensity of 5%. The combustor outlet was modeled as a pressure outlet with a zero-gradient condition. A symmetry boundary condition was imposed along the central axis of the domain.

3. RESULTS AND DISCUSSION

Figure 2 presents the CFD results for the hydrogen-fueled combustor operating at FL390. The temperature distribution (Fig. 2a) indicates a peak flame temperature of approximately 3045 K, located slightly downstream of the primary air inlet. Compared to Kahraman et al. [10], where peak temperatures ranged around 2650 K at similar engine speeds, the elevated flame temperature observed here is attributed to higher hydrogen purity and reduced dilution effect under cruise-specific boundary conditions. The velocity contour (Fig. 2b) shows a maximum flow velocity exceeding 1000 $m.s^{-1}$ near the nozzle exit, which aligns with the accelerated expansion due to thermal gradients. The static pressure distribution (Fig. 2c) illustrates a gradual drop toward the outlet, consistent with combustion-induced expansion. The turbulence kinetic energy (Fig. 2d) peaks near the fuel-air mixing region, ensuring flame anchoring through recirculation effects. Species mass fraction contours reveal effective combustion. The H_2 mass fraction (Fig. 2e) drops sharply in the reaction zone, while H_2O (Fig. 2f) peaks correspondingly, validating efficient hydrogen oxidation. Similarly, O_2 (Fig. 2g) and N_2 (Fig. 2h) exhibit expected dilution patterns. Notably, NO formation (Fig. 2i) is localized in the high-temperature post-flame zone, with a peak mass fraction of ~0.031, consistent with thermal NO mechanisms. Compared to Kahraman et al. [10], where NO peaked around 0.026 under similar equivalence ratios, this slight increase is a trade-off for higher combustion efficiency.

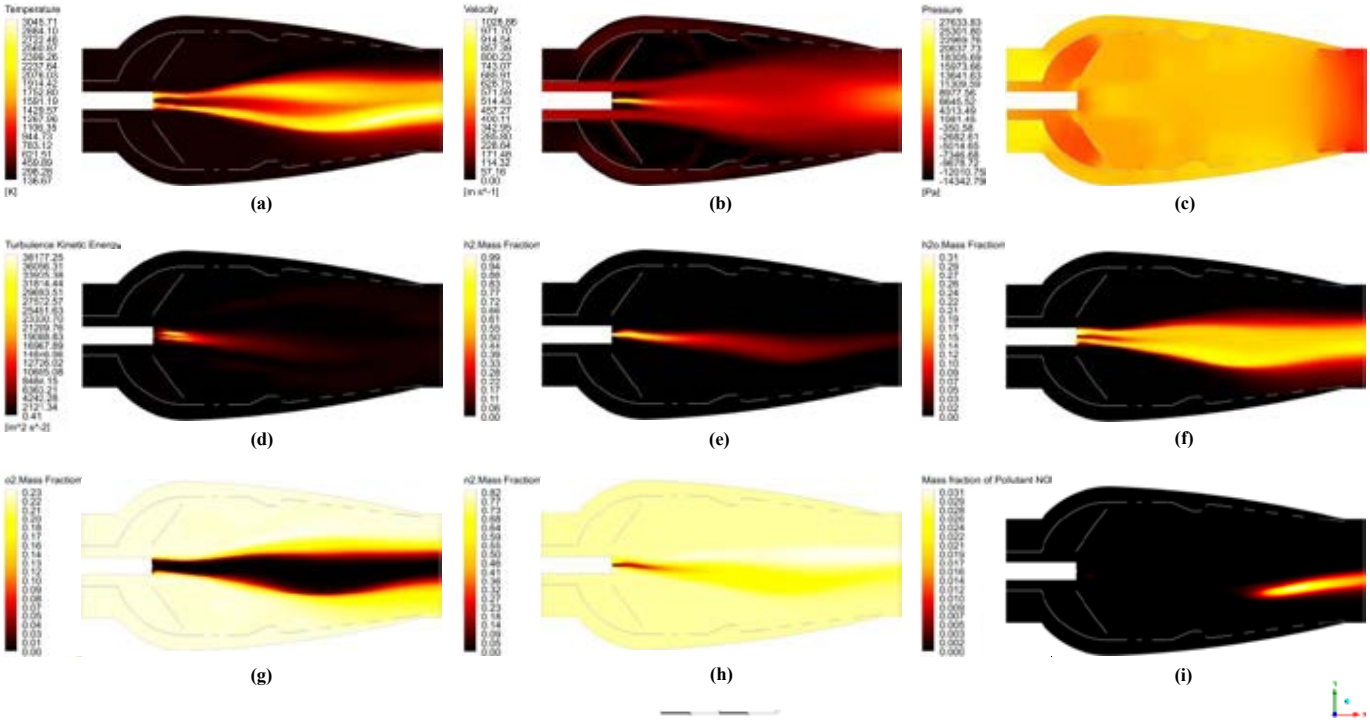

Fig. 2. CFD contours of the hydrogen-fueled 2D combustion chamber at cruise altitude: (a) Temperature distribution [K], (b) Velocity magnitude [m.s^{-1}], (c) Static pressure [Pa], (d) Turbulence kinetic energy [m^2.s^{-2}], (e) H_2 mass fraction, (f) H_2O mass fraction, (g) O_2 mass fraction, (h) N_2 mass fraction, (i) Mass fraction of pollutant NO.

4. CONCLUSIONS

- A 2D hydrogen-fueled combustor operating at FL390 was successfully simulated using real engine boundary conditions.
- Peak flame temperature reached approximately 3045 K, indicating efficient hydrogen-air combustion with complete H_2 oxidation.
- NO formation was localized and remained within acceptable limits, with a maximum mass fraction of ~0.031, comparable to previous studies.
- No CO_2 or unburned hydrocarbon emissions were observed, confirming the zero-carbon nature of hydrogen combustion.
- Mesh quality and turbulence treatment (RNG k–ε) contributed to stable and accurate CFD predictions.
- The results highlight hydrogen's strong potential for low-emission, high-efficiency aviation propulsion under cruise conditions.

ACKNOWLEDGEMENT

The authors declare that they have no conflict of interest. Also, this research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors.

ABSTRACT
This study presents a numerical investigation of a gas turbine combustor fueled by a 50–50 mass fraction blend of ammonia and kerosene, evaluated under cruise flight conditions corresponding to FL390. The combustor geometry was based on a validated two-dimensional axisymmetric configuration, and real jet engine operating conditions were applied as boundary inputs. Simulations were performed using ANSYS Fluent with the RNG k–ε turbulence model and eddy dissipation combustion model. The results indicate a peak flame temperature of approximately 1934 K, with NH_3 rapidly consumed near the flame front and $C_{12}H_{23}$ persisting downstream. Velocity reached ~200 m.s^{-1}, while turbulence levels remained moderate. Species mass fraction contours showed distinct behaviors for each fuel component, with oxygen excess evident along the axial region. Emission analysis revealed a maximum NO mass fraction of ~3.8 × 10^{-7}, while NOx and CO_2 levels remained within controlled limits. These outcomes align with prior research, suggesting that NH_3–hydrocarbon blends can support stable combustion with reduced carbon emissions, albeit with thermal NO formation.

Keywords: Ammonia combustion, CFD, cruise altitude, emission, fuel blend

1. INTRODUCTION
Decarbonizing the aviation sector has become a strategic priority as emission regulations tighten and sustainability goals intensify [1–4]. Gas turbine engines, being the dominant propulsion system in commercial aircraft, are central to these efforts [5–9]. While hydrogen has gained attention for its zero-carbon emissions and high reactivity, challenges related to storage, safety, and combustion instability under practical conditions remain unresolved [10–12]. As a result, hybrid fuel strategies combining hydrogen-free alternatives with conventional fuels are gaining momentum. Ammonia (NH_3) is a carbon-free, hydrogen-rich energy carrier with high volumetric energy density and ease of liquefaction [13–15]. However, its low reactivity and high ignition temperature often result in incomplete combustion and elevated NO_x emissions when used alone. On the other hand, conventional jet fuels such as dodecane ($C_{12}H_{23}$), a surrogate for Jet-A, offer high reactivity and well-established performance in turbine systems. A balanced blend of NH_3 and $C_{12}H_{23}$ can potentially leverage the clean-burning characteristics of ammonia and the combustion stability of kerosene-based fuels. Some studies have demonstrated that ammonia–hydrocarbon blends can reduce carbon emissions while maintaining reliable flame stabilization and thermal efficiency under gas turbine conditions. Recent advancements have focused on enhancing ammonia's combustion characteristics, such as blending with more reactive fuels to improve flame propagation and stability [16]. Wei et al. [17] show that adding high-reactivity fuels to ammonia can enhance flame propagation speed, heat release rate, and overall combustion efficiency. For instance, blending ammonia with methanol has been investigated using jet ignition systems, resulting in improved flame stability and reduced emissions. Specific research on ammonia and dodecane blends has been conducted to understand their combustion mechanisms and potential as alternative fuels. A skeletal chemical kinetic mechanism for n-dodecane/ammonia combustion was developed to facilitate computational studies, providing insights into ignition characteristics and pollutant formation [18]. Despite the potential benefits, challenges remain in utilizing ammonia–hydrocarbon blends. These include optimizing combustion strategies to balance efficiency and emissions, addressing material compatibility issues due to ammonia's corrosive nature, and ensuring safe handling and storage. Some reviews have discussed these challenges and the progress made in ammonia combustion research, emphasizing the need for continued innovation to realize ammonia's potential as a sustainable fuel [19].

In this study, a numerical simulation was conducted on a two-dimensional gas turbine combustor fueled by a 50–50 mass-based blend of ammonia and Jet-A. Real engine-derived boundary conditions corresponding to flight level FL390 were applied. The objective is to assess the thermal behavior and pollutant formation characteristics of the hybrid fuel, including NO and CO_2 emissions, flame structure, and combustion efficiency under realistic cruise conditions.

2. MATERIALS AND METHODS
This study presents a numerical investigation of the combustion characteristics of a two-dimensional gas turbine combustor fueled by a hybrid blend of ammonia and dodecane. The combustor geometry and mesh structure were based on a previously validated configuration, while the operating conditions were derived from real jet engine data corresponding to cruise altitude (FL390). A 50–50 mass-based fuel mixture was introduced through a central injector,

accompanied by primary and secondary air inlets. Computational simulations were conducted using ANSYS 2022 R2 Fluent, incorporating appropriate turbulence and combustion models to capture the complex interaction between fluid flow, heat transfer, and chemical reactions. Detailed descriptions of the numerical model setup, governing equations, and applied boundary conditions are provided in the following subsections.

2.1. Numerical Model

The computational domain employed in this study was adapted from the combustor configuration introduced by Kahraman et al. [20], originally inspired by a Rolls-Royce Nene-type gas turbine. The geometry features a two-dimensional axisymmetric layout comprising a single central fuel inlet and two separate air inlets designated for primary and secondary airflow. The total length and maximum height of the domain are 620 mm and 145 mm, respectively. To resolve the domain accurately, a structured mesh was generated using ANSYS Meshing. The final mesh includes 57,166 nodes and 56,137 elements, ensuring high spatial resolution, especially in regions of steep gradients such as the flame zone and near-wall layers. A five-layer inflation zone was applied along all solid boundaries to enhance near-wall accuracy. The mesh quality metrics confirm suitability for reactive flow simulations: average skewness was 0.13299 and orthogonal quality averaged 0.95328, both classified as "excellent" based on ANSYS best practices. The mesh structure is illustrated in Fig. 1. ANSYS Fluent 2022 R2 was used to perform the simulations. The realizable RNG k–ε turbulence model was employed due to its effectiveness in predicting swirling and recirculating flows commonly encountered in combustor environments. Further modeling details, including governing equations and boundary condition specifications, are discussed in the following subsection.

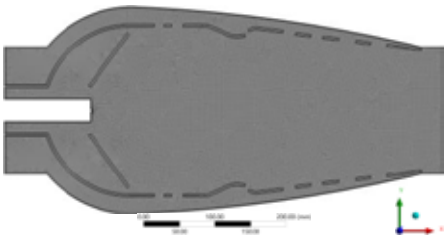

Fig. 1. Mesh structure of the hydrogen-fueled combustion chamber.

2.2. Governing Equations and Boundary Conditions

The CFD simulations were conducted by solving the steady-state, compressible form of the Navier–Stokes equations, which include the conservation of mass, momentum, energy, and species transport. The general governing equations used in the numerical model are as follows:

Continuity equation:

$$\frac{\partial \rho}{\partial t} + \nabla.\rho\vec{v} = 0 \tag{1}$$

Momentum equation:

$$\frac{\partial(\rho\vec{v})}{\partial t} + \nabla.(\rho\vec{v} \times \vec{v}) = -\nabla p + \nabla\tau + \rho\vec{g} \tag{2}$$

Energy equation:

$$\frac{\partial(\rho E)}{\partial t} + \nabla.(\vec{v}(\rho E + p)) = \nabla.(k_{eff}\nabla T) + S_E \tag{3}$$

Species transport equation:

$$\frac{\partial(\rho Y_i)}{\partial t} + \nabla.(\rho\vec{v}Y_i) = -\nabla.\vec{J_i} + R_i \tag{4}$$

Here,

ρ is the density, $\vec{v}$ is the velocity vector, p is pressure, E is the total energy, Y_i is the mass fraction of species i, $\vec{J_i}$ is the diffusion flux, and R_i represents the net rate of production due to chemical reactions. The viscous stress tensor τ, effective thermal conductivity k_{eff} and source term S_E account for viscous dissipation and heat release. Combustion was modeled using the Eddy Dissipation Model, which assumes that the reaction rate is controlled by the turbulent mixing of fuel and oxidizer. The realizable RNG k–ε turbulence model was employed to capture the effects of swirling and recirculating flows within the combustor. The working fluid was treated as a compressible ideal gas, with temperature-dependent thermophysical properties. Radiation heat transfer and soot formation were neglected due to the moderate operating temperature and low carbon content of the blend.

Real engine-derived inputs corresponding to FL390 were applied to all boundaries:

- Fuel inlet (NH_3–$C_{12}H_{23}$ mixture): 50–50 mass-based blend injected at a fixed mass flow rate of 0.3286 kg.s^{-1} and temperature of 298 K.
- Air inlets (primary + secondary): Primary air mass flow rate of 13.20 kg.s^{-1} and secondary air mass flow 6.50 kg.s^{-1} at 228.9 K, distributed between the two air ports.

- Turbulence intensity: Set to 5% at all inlets.
- Outlet: Modeled as a pressure outlet at 0 Pa gauge pressure, allowing free exit flow.
- Walls: Treated as adiabatic and no-slip.

3. RESULTS AND DISCUSSION

Figure 2 illustrates the flow, thermal, and chemical characteristics of the combustor operating with a 50–50 mass fraction NH_3–$C_{12}H_{23}$ blend at FL390 conditions. The peak flame temperature (Fig. 2a) reaches approximately 1934 K, lower than typical kerosene combustion due to the reduced reactivity of ammonia. Similar moderate temperature peaks in ammonia-based blends were reported by Valera-Medina et al. [4], emphasizing ammonia's flame-cooling effect. The velocity contour (Fig. 2b) reveals an axial acceleration of the flow, reaching a maximum velocity of approximately 200 $m.s^{-1}$ at the nozzle exit. The pressure field (Fig. 2c) indicates a steady decrease along the combustor axis, consistent with combustion-driven expansion. Figure 2d illustrates relatively low turbulence kinetic energy, particularly near the flame zone, suggesting limited shear and mixing intensity between the fuel and oxidizer streams. This is typical in partially pre-vaporized or low-reactivity fuel blends. Fuel distribution is visualized in Figures 2e and 2f. The NH_3 mass fraction drops sharply in the primary reaction region, whereas $C_{12}H_{23}$ persists longer into the chamber, indicating its slower vaporization and oxidation. The O_2 mass fraction (Fig. 2g) remains significant along the axis, implying that excess air is present, likely due to incomplete mixing or lean regions in the flow. Water vapor (Fig. 2h), primarily a product of NH_3 combustion, shows moderate levels centered along the flame front. In contrast, CO_2 concentration (Fig. 2i), originating from dodecane decomposition, is more evenly distributed across the combustion chamber. This dual-profile is a result of the chemical differences between nitrogenous and carbonaceous fuels in the blend. Pollutant formation is depicted in Figures 2j and 2k. The NO mass fraction peaks around 3.8×10^{-7} near the high-temperature post-flame region, while NO_x appears at much lower levels. These values align with findings by Li et al. [21], who noted that NO_x emissions from ammonia–hydrocarbon blends are influenced more by thermal effects than by fuel-N pathways at moderate temperatures.

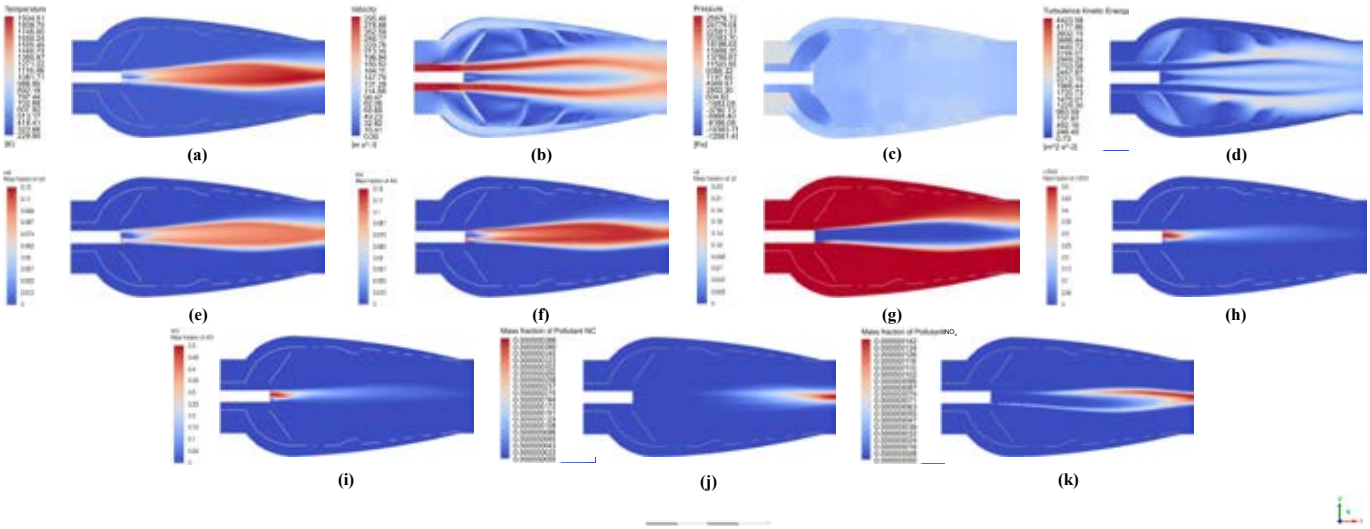

Fig. 2. Contours of the gas turbine combustor fueled by an NH_3–$C_{12}H_{23}$ blend at cruise altitude: (a) Temperature distribution [K], (b) Velocity magnitude [$m.s^{-1}$], (c) Static pressure [Pa], (d) Turbulence kinetic energy [$m^2.s^{-2}$], (e) NH_3 mass fraction, (f) $C_{12}H_{23}$ mass fraction, (g) O_2 mass fraction, (h) H_2O mass fraction, (i) CO_2 mass fraction, (j) NO mass fraction, (k) NO_x mass fraction.

4. CONCLUSIONS

- A 2D gas turbine combustor was numerically analyzed using a 50–50 mass fraction blend of NH_3 and $C_{12}H_{23}$ under FL390 cruise flight conditions.
- The simulation yielded a maximum flame temperature of ~1934 K, indicating moderate thermal intensity suitable for steady combustion.
- NH_3 was consumed rapidly near the flame front, while $C_{12}H_{23}$ remained dominant further downstream, reflecting differing combustion behaviors of the blended fuels.
- The formation of NO peaked at a mass fraction of ~3.8×10^{-7}, while NO_x levels remained relatively low, suggesting that pollutant formation was thermally driven and spatially confined.
- CO_2 distribution confirmed complete oxidation of the carbon-containing component, with no indication of unburned hydrocarbons in the post-flame region.
- The hybrid NH_3– $C_{12}H_{23}$ fuel demonstrated stable combustion, moderate emissions, and promising characteristics as a cleaner alternative to conventional jet fuels.

- Further studies are recommended to investigate variations in blending ratios, ignition behavior, and emission mitigation strategies for real engine implementation.

ABSTRACT
The growing demand for renewable energy is driven by the depletion of fossil fuels, increasing CO_2 emissions, and the rising need for energy. Hydrogen, as a clean energy carrier, plays a crucial role in future energy scenarios. Among hydrogen production technologies, photocatalytic hydrogen evolution (PCHER) remains at the research stage, with challenges such as low quantum efficiency, slow charge separation and transfer, recombination, and particle size limitations. In this study, a novel $Ni_2P/g\text{-}C_3N_4/Ti_3C_2$ quantum dot (QD) photocatalyst was synthesized to enhance photocatalytic hydrogen production. Ni_2P was obtained through the phosphorization of metal salt, $g\text{-}C_3N_4$ was synthesized via the thermal decomposition of urea, and Ti_3C_2 quantum dots were prepared using the hydrothermal method. The designed photocatalyst aims to improve visible light utilization and address key efficiency limitations in PCHER. This work contributes to the development of sustainable hydrogen production and provides a promising approach for future renewable energy applications.
Keywords: Photocatalytic Hydrogen Production, $g\text{-}C_3N_4$, Ti_3C_2 Quantum Dot, Nickel Phosphite.

1. INTRODUCTION

In a photocatalytic hydrogen production system, a semiconductor-based photocatalyst absorbs solar energy and converts it into usable energy for water splitting. Semiconductors are materials that possess a specific band gap (BG), which separates the conduction band (CB) from the valence band (VB) by a distinct energy level. Upon exposure to sunlight, electrons from the valence band of the photocatalyst are excited, jumping to the conduction band, leaving behind electron holes (h^+) in the valence band. These electron holes drive the oxidation of water (producing O_2), while the excited electrons in the conduction band promote the reduction of water (resulting in H_2 formation). This process regenerates the photocatalyst, allowing redox reactions to take place within the electrolyte.

For efficient photocatalytic hydrogen generation, the conduction band level of the semiconductor must be more negative than the standard redox potential for the H^+/H_2 reaction (0.0 V vs. SHE, not considering overpotentials). Likewise, the valence band level needs to be more positive than the standard potential for the O_2/H_2O reaction (1.23 V vs. SHE, again, without accounting for overpotentials). From a thermodynamic perspective, the semiconductor's band gap should exceed 1.23 eV to enable photocatalytic hydrogen production. However, in practical scenarios, factoring in overpotentials and energy band alignment, the band gap should ideally be above 1.8 eV. Due to the complexity and challenges of overall water splitting, most reported photocatalysts primarily focus on the half-reaction of H_2 production[1].

Since the first discovery of monolayer graphene in 2004 [2], two-dimensional (2D) materials have attracted significant interest. Due to their ability to enhance photocatalytic activity and suppress charge carrier recombination, researchers have particularly focused on materials such as $g\text{-}C_3N_4$ [3], black phosphorus[4], and transition metal dichalcogenides[5]. Among 2D carbon-based nanomaterials, $g\text{-}C_3N_4$, graphene, and carbon nanotubes exhibit unique properties, including quantum confinement effects, efficient visible light absorption, tunable energy levels, superior charge transport capabilities, large surface area, easy accessibility, and high quantum efficiency. These distinctive properties make them highly suitable for a range of photocatalytic applications. However, the practical use of $g\text{-}C_3N_4$ in photocatalytic water splitting is significantly constrained by the rapid recombination of photoexcited electrons and holes. To enhance the separation efficiency of these charge carriers, several structural modifications have been investigated, such as crystallinity improvement, heteroatom doping, heterojunction engineering, and cocatalyst incorporation [6]. Among these methods, cocatalyst incorporation is recognized as an effective means to enhance charge separation.

Various cocatalysts, including Pt, MoS_2, and graphene-based materials, assist in trapping photoinduced electrons, thereby reducing charge recombination [7]. Among these options, Pt exhibits the highest efficiency in photocatalytic hydrogen evolution. However, its widespread application is restricted by its high cost and limited availability. Consequently, the exploration of cost-effective cocatalysts is essential to support the advancement of semiconductor-based photocatalysts for industrial-scale applications.

MXenes have become one of the most intriguing two-dimensional (2D) materials, finding applications in various fields such as electromagnetic shielding, batteries, power generation, and catalysis[6]. Compared to the widely studied graphene, 2D MXenes exhibit remarkable electrical conductivity, suggesting their potential to replace conventional graphene-based materials in various applications [7]. Despite the advantages of 2D MXenes, a literature indicate that hybrid materials synthesized with zero-dimensional (0D) MXenes exhibit significantly higher photocatalytic hydrogen production rates. The superior optical and catalytic activity of 0D MXene quantum dots (QDs) has been attributed to their size-dependent properties, low Fermi level, defects, and surface functional groups.

To overcome key limitations in semiconductor-based photocatalysis, such as electron-hole recombination and short

charge carrier lifetimes, MXenes are frequently utilized as cocatalysts. Dong et al.[8] synthesized a Ti_3C_2 QD-modified 3D/2D TiO_2/g-C_3N_4 hybrid, achieving a photocatalytic hydrogen production rate of 5540.21 μmol h^{-1} g^{-1}. They also reported that Ti_3C_2 QD cocatalysts enhanced the hydrogen evolution rate of 3D/2D TiO_2/g-C_3N_4 by nearly two fold. Given these advantages, we aims to synthesize 0D Ti_3C_2 QDs as an efficient cocatalyst for photocatalytic applications.
Metal phosphides are typically formed by the combination of metal and phosphorus elements. The electronegativity of the phosphorus (P) atom in metal phosphides facilitates the conversion of positively charged hydrogen ions in the electrolyte to hydrogen gas. Transition metal phosphides (such as Ni_2P, FeP, CoP, MoP, and Cu_3P), which possess high conductivity and low overpotentials, are widely considered as promising candidates for both photocatalysis and electrocatalysis in hydrogen production reactions [9].In one study, it was reported that the nickel in Ni_2P acts as a hydride acceptor, while phosphorus serves as a proton-accepting site, synergistically accelerating H_2 formation [10].
A thorough literature review reveals that the application of 2D/0D g-C_3N_4/Ti_3C_2 QD photocatalysts in photocatalytic hydrogen production with Ni_2P cocatalysts has not been reported. Therefore, the Ni_2P/g-C_3N_4/Ti_3C_2 QD catalyst were designed as entirely novel and innovative.

2. MATERIALS AND METHODS

2.1. Synthesis of catalysts

The synthesis of g-C_3N_4 and Ti_3C_2 QDs were carried out according to Y. Li et al. method [11]The synthesis of Ni_2P was carried out according to the procedure described by K. Wang et al.[12]. Ni_2P with different weight percentages (%0.5, %1.0, %3.0, %5.0, %10.0, and %15.0) was obtained by grinding g-C_3N_4 in a mortar for 30 minutes.
A 40 mL aqueous solution of Ti_3C_2 QD at 50 mg/L concentration was mixed with 100 mg of the Ni_2P/g-C_3N_4 binary hybrid, which showed the highest hydrogen production rate, for 24 hours on a stirrer. The resulting suspension was centrifuged at 5000 rpm for 30 minutes and then dried in a vacuum oven at 60°C. Ni_2P/g-C_3N_4/Ti_3C_2 QD (%2.0 wt) was obtained. Similarly, ternary hybrid was prepared with different weight percentages (%4.0, 6.0, 8.0, and 10.0) to synthesize the optimum Ni_2P/g-C_3N_4/Ti_3C_2 QD catalyst.

2.2. Photocatalytic Performance Tests

The photocatalytic reactor was designed with a quartz glass upper part that allows UV-Vis light to pass through, equipped with gas inlet and outlet as well as water inlet and outlet. Initially, optimizations were carried out using 10 mg of catalyst to minimize the amount before determining the optimum quantity. The catalyst was transferred into the reactor with a 10% triethanolamine (TEOA) aqueous solution as the electrolyte. The temperature of the reactor was continuously controlled by water flow. During the reaction, the catalyst was mixed using a magnetic stirrer. The gas produced in the reaction was carried through a microfluidic pressure sensor connected to the system, which was used to measure the hydrogen quantity. Additionally, the gas was characterized by using gas chromatography. The light source was positioned to illuminate the entire photocatalyst, and its intensity was adjusted to 100 mW/cm² using a light meter. To prevent errors from changes in light intensity over time, the light intensity was measured before each photocatalytic reaction to ensure the stability of the light source.

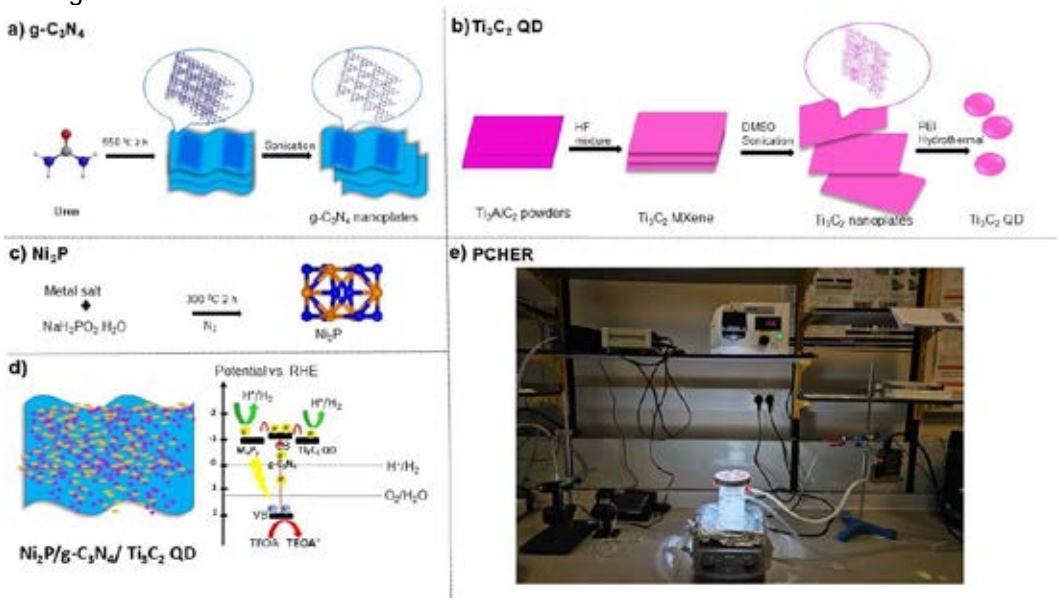

Fig. 1. a) Synthesis of g-C_3N_4, b) Synthesis of Ti_3C_2 QD, c) Synthesis of Ni_2P, d) Proposed mechanism of Ni_2P/g-C_3N_4/Ti_3C_2 QD photocatalysts, e) Design of the PCHER system.

3. RESULTS AND DISCUSSION

The characterization of the synthesized catalysts was performed prior to PCHER to verify the successful synthesis and identify any changes in the structure and morphology of the catalysts. X-ray diffraction (XRD), Fourier Transform Infrared Spectroscopy (FT-IR) and X-Ray Photoelectron Spectroscopy (XPS) analyses of the synthesized catalysts were carried out. The morphological and structural characterizations of the catalysts were performed using Scanning Electron Microscopy (SEM), Transmission Electron Microscopy (TEM), and High-Resolution Transmission Electron Microscopy (HRTEM), providing information about important parameters such as surface properties, homogeneity, and lattice spacing. Energy Dispersive X-ray Spectroscopy (EDS) was used to gather information about the elements constituting the catalyst and to determine whether the syntheses were successfully carried out. Fig. 2 shows the morphological and structural characterization of g-C_3N_4, Ni_2P, Ni_2P/g-C_3N_4, and Ni_2P/g-C_3N_4/Ti_3C_2 QDs. The SEM image of g-C_3N_4 displays the material's nanoplate structure (Fig. 2a). In Fig. 2b, the clustered rock-like structure of Ni_2P is shown. Fig. 2c displays the Ni_2P structures between graphitic nanotubes, illustrating Ni_2P/g-C_3N_4. The SEM image of Ni_2P/g-C_3N_4/Ti_3C_2 QD in Fig. 2d shows no clear MXene QD effect. Figs. 2e and 3f show the EDS spectra of Ni_2P and Ni_2P /g-C_3N_4/Ti_3C_2 QDs, respectively. The successful synthesis of Ni_2P is supported by the EDS results. The EDS spectrum of Ni_2P/g-C_3N_4/Ti_3C_2 QD shows peaks for C and N from graphitic carbon nitride and Ni and P from Ni_2P. To confirm the presence of MXene QDs, HRTEM and FFT images were recorded (Figs. 2g, f, and i). The HRTEM and FFT results show that the lattice spacing corresponding to the Ni_2P (111) crystal plane is 0.221 nm consistent with the literature[13] . Elemental mapping shows the distribution of C, N, P, Ni, and Ti elements in the Ni_2P/g-C_3N_4/Ti_3C_2 QD powder mixture (Fig. 2j).
The band gaps of the nanomaterials were determined using UV-Vis diffuse reflectance spectroscopy (DRS) analysis. The time-resolved photoluminescence spectrum (TRPL) analysis method was used to determine the lifetime of photoexcited charges. The catalyst ratios in the PCHER system were adjusted based on their hydrogen production performance. As part of the photoelectrochemical activity test, the photocurrent-time curve was recorded by switching the light on and off at specific intervals (100 s). Through photocurrent-time curves, information was obtained regarding charge transfer efficiency, photocatalytic activity, charge carrier mobility, and charge separation.

4. CONCLUSIONS

In this study, the structural, morphological, and photoelectrochemical properties of the synthesized $Ni_2P/g\text{-}C_3N_4/Ti_3C_2$ QD nanocomposite were thoroughly investigated. SEM, HRTEM, and EDS analyses confirmed the successful synthesis of the nanocomposite and the homogeneous distribution of its components. XPS analysis verified the surface composition and the chemical bonding states of the elements. The UV-Vis DRS analysis determined the band gaps of the materials, revealing enhanced optical properties for the $Ni_2P/g\text{-}C_3N_4/Ti_3C_2$ QD composite. TRPL analysis demonstrated an extended lifetime of photoexcited charges, indicating efficient charge separation. The catalyst ratios in the PCHER system were optimized to enhance hydrogen production performance. Furthermore, photoelectrochemical activity tests, particularly photocurrent-time measurements, showed that the material exhibits high charge transfer efficiency and excellent photocatalytic activity. These findings suggest that the $Ni_2P/g\text{-}C_3N_4/Ti_3C_2$ QD nanocomposite is a promising photocatalyst for sustainable hydrogen production.

ABSTRACT
Technological and industrial advancements have increased the need for sustainable energy solutions, leading to the widespread use of fuel cells and battery technologies in aviation applications such as unmanned aerial vehicles (UAVs). In this study, battery and fuel cell components of a fixed-wing UAV was modeled in the Matlab/Simulink environment to analyze its voltage response under variable current inputs for the comparison of the simulation results with the measurement from the flight experiment of the mini electric UAV. A 100 W fuel cell was integrated into the system with a constant current output to examine the power and flight distance contributions of both the battery and the fuel cell. Additionally, the study provides a validation of the numerical model of powertrain components of the mini electric UAV. The findings contribute to the development of energy management strategies for hybrid-powered UAVs and provide valuable insights for optimizing flight duration.

Keywords: UAV, battery, fuel cell, sustainable aviation

1. INTRODUCTION

Technological and industrial advancements, driven by the increasing concerns over environmental pollution and the growing demand for sustainable energy solutions, have facilitated the integration of innovative energy technologies across various sectors, including aviation. In particular, the aviation industry has progressively adopted fuel cell and battery systems to enhance energy efficiency and reduce the environmental impact of aerial operations, addressing the urgent need for more eco-friendly alternatives [1].

Currently, Lithium Polymer (Li-Po) batteries are widely used in unmanned aerial vehicles (UAVs). These batteries are well-suited for short-distance flights due to their high energy densities, lightweight structure, and rapid charging capabilities. Additionally, their high discharge rates provide a significant advantage in meeting the sudden power demands of UAVs. However, Li-Po batteries have limited energy capacity, which may not suffice for applications requiring extended flight durations. Furthermore, their tendency to degrade over time and the need for thermal management impose operational limitations on their efficiency. In contrast, hydrogen fuel cells offer significant advantages over Li-Po batteries by providing longer flight durations and higher energy efficiency. Fuel cells generate continuous power through the electrochemical reaction between hydrogen and oxygen, which results in longer range and operational time compared to batteries. With their low carbon emissions and environmentally friendly nature, fuel cells play a crucial role in advancing sustainable aviation solutions. Additionally, hybrid power systems, which combine both battery and fuel cell technologies, offer a more balanced and efficient energy management solution for UAVs. While fuel cells supply continuous and stable power, batteries address sudden power demands, thereby optimizing system performance. This hybrid approach enables longer flights, maximizes energy usage, and increases overall efficiency. Moreover, hybrid systems offer greater flexibility compared to systems relying solely on either batteries or fuel cells, allowing for better adaptability to diverse flight scenarios. As a result, more efficient power usage and an extended system lifespan contribute significantly to the development of sustainable aerial vehicles [2].

This study aims to explore the impact of a hybrid power system incorporating both battery and fuel cell components on UAV performance. The modeling will be conducted in the Matlab/Simulink environment, with simulation results compared to measurements obtained from flight experiments of a mini electric UAV. A 100 W fuel cell will be integrated into the system with a constant current output to analyze the power and flight distance contributions of both the battery and fuel cell. Additionally, the numerical model for the powertrain components of the mini electric UAV will be validated. The findings of this research are expected to contribute to the development of energy management strategies for hybrid-powered UAVs, offering valuable insights for optimizing flight duration.

2. NUMERICAL AND EXPERIMENTAL METHODS

2.1 Mini Electric UAV

In flight dynamics, there are four fundamental forces acting on an unmanned aerial vehicle (UAV): lift, weight, thrust, and drag. Lift is the force that keeps the aircraft airborne, which depends on the flight speed and the characteristics of the wing profile. Weight is the downward force exerted by gravity on the UAV. Thrust is the force generated by the engines that propels the aircraft forward, which varies depending on the motor and propeller configuration. Drag is the resistance

created by the airflow against the motion of the aircraft. These forces change depending on the UAV's design, weight, aerodynamic features, motor power, and flight speed [3].

In hand-launched UAVs, the thrust during takeoff is augmented by human power. In cruising flight, the ideal thrust-to-weight ratio typically ranges from 1:1 to 0.3:1, and it may vary based on the design, mission, and flight conditions [4]. In this study, calculations were made for both scenarios with the throttle at 50% in cruising flight. First, the flight time was calculated for the configuration using only a Li-Po battery. In the second case, the flight time was calculated for the hybrid system, where the integration of a fuel cell and the required body modifications were made to accommodate the increased weight, and a motor and propeller configuration capable of compensating for the additional weight was selected. The flight time formula is given in Equation (1)

$$Flight\ Time\ (hours) = \frac{Battery\ Capacity\ (mAh)}{Current\ Draw\ (A) \times 1000} \quad (1)$$

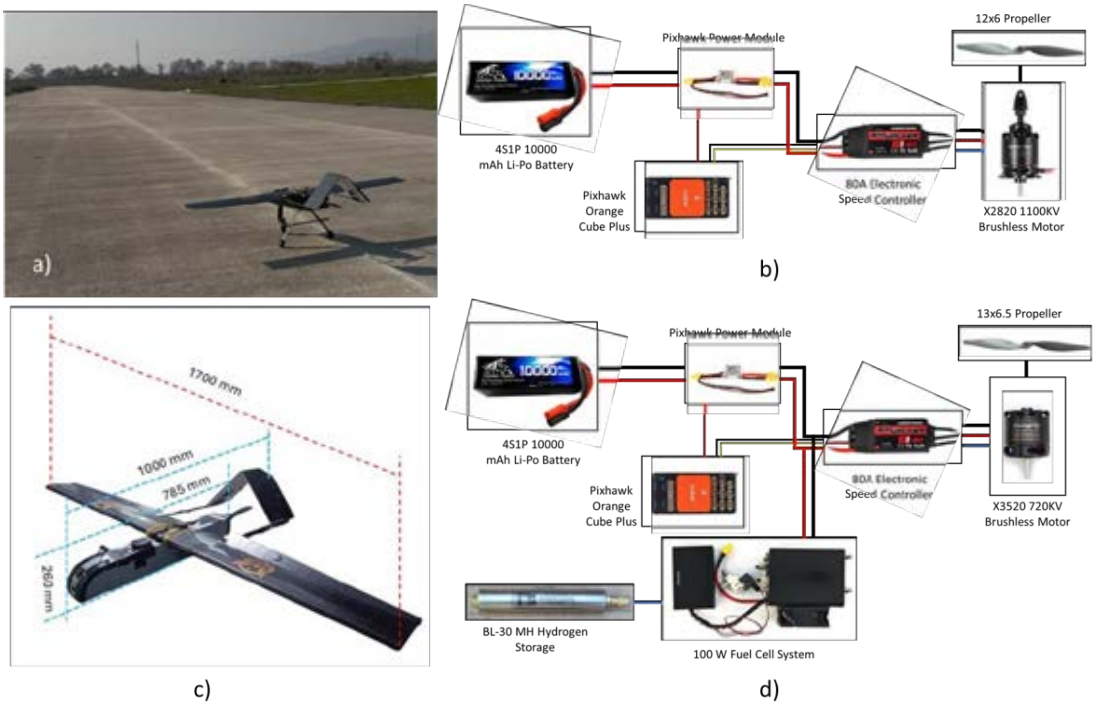

Fig. 1. Mini UAV (a) and its main dimensions (c) for electic (b) and fuel cell hybrid (d) powertrain configurations

2.2. Powertrain Components of the UAV Configurations

The Unmanned Aerial Vehicle (UAV) model examined in both cases operates with a hybrid system using only a Li-Po battery and a hydrogen fuel cell. In the developed model, the UAV parameters listed in Table 1 have been utilized.

Table 1. Parameters of the powertrain system for mini UAV

Parameter	Value	Unit	Parameter	Value	Unit
Total mass for first configuration	2700	g	Nominal power of fuel cell	100	W-
Total mass for second configuration	4000	g	Fuel cell operating voltage range	10-18	V
Wing area	28.65	dm^2	Fuel cell operating current range	0-9.6	A
Density of air	1.22	kg/m^3	Hydrogen consumption of fuel cell	1500	mL/min
Li-Po battery capacity	10000	mAh	Fuel cell weight	630	g
Li-Po battery capacity coefficient	25	C	Number of cell in fuel cell stack	20	-
Brushless motor diameter and length for first configuration	28-20	mm	Fuel cell stack size	94x78x91	mm
			Hydrogen capacity of MH tank	34	sL
Brushless motor diameter and length for second configuration	35-20	mm	MH tank cylinder diameter	28.6	mm
			MH tank mass	438	g
ESC current capacity	80	A	MH tank overall length	198	mm

In battery model, the term of OCV which represents "Open Circuit Voltage", refers to the voltage measured when an electrical circuit is not closed, meaning no load is connected. OCV indicates the maximum voltage potential of a battery or fuel cell and is an important parameter for assessing the health status and charge level of the battery.

The OCV value of a battery can be used to determine its state of charge (State of Charge - SoC) and typically varies based on factors such as the chemical composition of the battery, temperature, and current charge state. SoC describes the remaining energy in the battery as a percentage; it is considered 100% when fully charged and 0% when completely discharged. The SoC at a given time can be calculated using Equation (2) [5].

$$SOC(t) = SOC(0) - \frac{1}{C_{bat}} \cdot \int_o^t P_{bat} \cdot dt \quad (2)$$

In this study, the PEM (Proton Exchange Membrane) fuel cell type has been chosen for the fuel cell hybrid UAV. A 100 W PEM fuel cell model is also modeled in the Matlab/Simulink environment. In this model, current (A) is used as the input, and voltage (V) is observed as the output. The cell voltage (Vcell) is calculated using Equation (3), taking into account various parameters in the system.

When a fuel cell supplies power to a load, several factors contribute to reducing the voltage. These factors include Nernst voltage (E_{Nernst}), activation loss (V_{act}), ohmic loss (V_{ohm}), and concentration loss (V_{conc}). Nernst voltage represents the chemical potential difference within the cell, while activation loss refers to the energy required for the electrochemical reactions to occur. Ohmic loss is the energy loss resulting from resistance within the cell, and concentration loss is associated with the depletion of reactants reaching low concentrations within the cell. This model provides an important foundation for understanding the performance and efficiency of PEM fuel cells [6].

$$V = E_{Nerst} - V_{act} - V_{ohmic} - V_{conc} \quad (3)$$

2.3. Simulation Model

This study models the battery system of a fixed-wing UAV in the MATLAB/Simulink environment to evaluate aircraft performance and flight range. To validate the accuracy of the model, the battery's voltage response under variable current inputs was analyzed and compared with flight test measurements obtained from the mini electric UAV. Additionally, a 100 W fuel cell with a constant current output was integrated into the system to assess the contributions of both the battery and the fuel cell to power generation and flight endurance. The results confirm the validity of the numerical model for the UAV's powertrain components and provide valuable insights into the performance of hybrid power systems. Figure 2 illustrates the Simulink model of the battery.

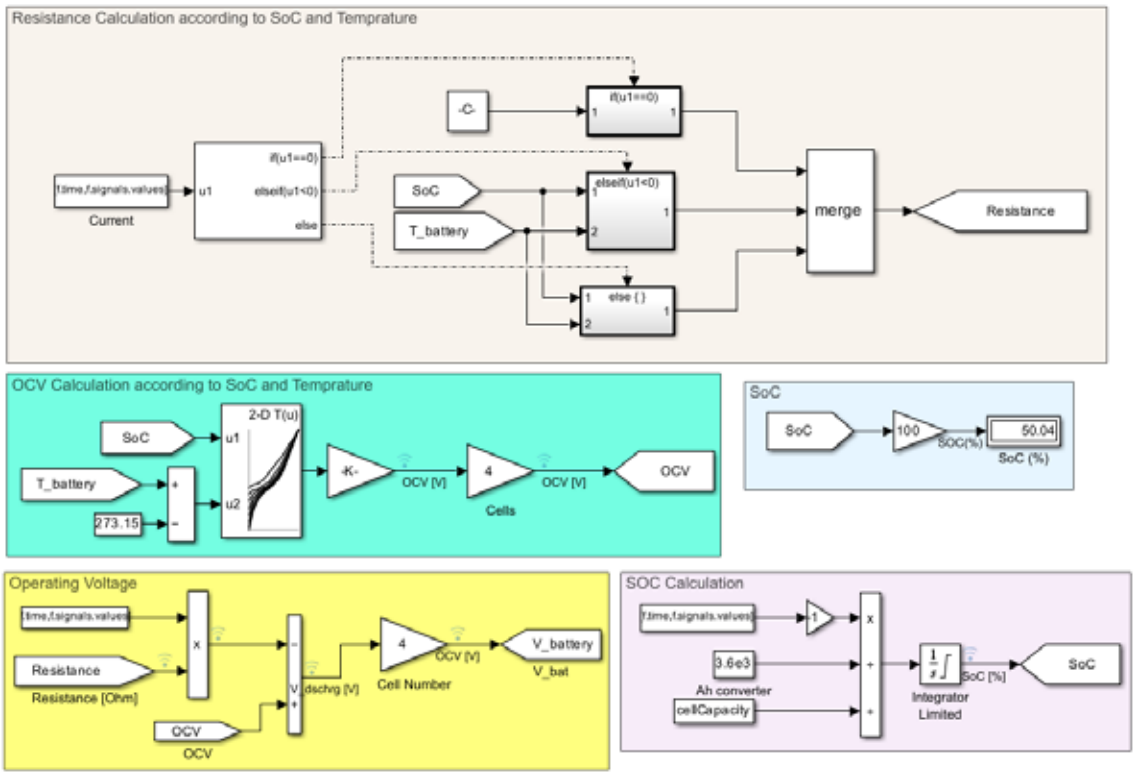

Fig. 2. Matlab/Simulink model of the battery for mini electric UAV

This Simulink model is designed to analyze the dynamic behavior of the battery system in a mini electric UAV and consists of four main components. The first component, Resistance Calculation, determines the battery's internal resistance

based on variables such as State of Charge (SoC) and battery temperature (T_battery). The second component, Open Circuit Voltage (OCV) Calculation, estimates the OCV by considering variations in SoC and temperature. The third component, SoC Calculation, computes the SoC value as a percentage based on the input current and battery capacity. Finally, the Operating Voltage Calculation determines the battery's terminal voltage by incorporating internal resistance and discharge voltage. This model serves as a critical tool for simulating battery responses under various operating conditions, providing deeper insights into its performance.

3.RESULTS AND DISCUSSION

During cruise flight, the required power demand for the UAV was observed, and the time-dependent variation in battery voltage was analyzed using both experimental and simulation data. The flight time was calculated based on the current drawn by the systems throughout the UAV's flight duration.

As shown in Fig. 3a, the decline in battery voltage over time indicates continuous battery discharge, while the similarity between experimental and numerical data confirms the accuracy of the simulation model. In Fig. 3b, the fluctuating and variable battery current demonstrates its sensitivity to load changes, whereas the fuel cell ensures a stable power supply by maintaining a constant current of 9.6 A. In Fig. 3c, the state of charge (SOC) of the battery reveals that the all-electric system depletes significantly faster compared to the fuel cell hybrid system, extending the flight duration by approximately 350 seconds (≈40% of flight time) with fuel cell support.Furthermore, the "End of the Fuel Cell" label marks the point where the fuel cell's energy is depleted, after which the battery discharges at an accelerated rate. In Fig. 3d, the battery power follows a decreasing and fluctuating trend over time, whereas the fuel cell delivers a more stable power output at 115 kW. Overall, the hybrid system offers a more balanced energy management approach, increasing flight time while reducing the load on the battery.

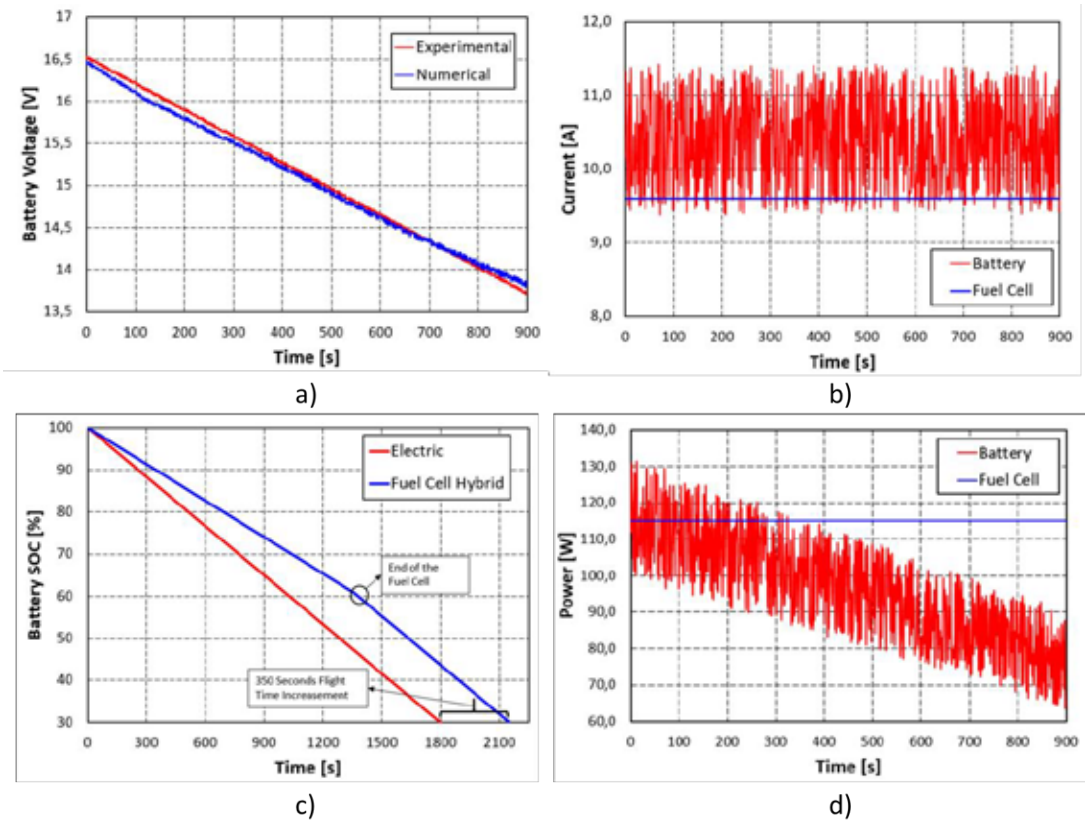

Fig. 3. Validation results for battery output voltage of electric (a) and constant fuel cell operation for hybrid UAV (b)

4. CONCLUSIONS

In this study, the performance of an Unmanned Aerial Vehicle (UAV) powered by a hybrid system, incorporating a Li-Po battery and a hydrogen fuel cell, was analyzed through both experimental and in the Matlab/Simulink environment. The results demonstrate that hybrid powertrains offer significant advantages in terms of energy efficiency, extended flight time, and environmental sustainability. The integration of the fuel cell and battery system enabled effective energy management, optimizing power distribution and enhancing UAV performance. Analyzing UAV performance is crucial for future studies aimed at system optimization and component selection. Different energy management strategies can

influence power distribution, leading to various choices in fuel cell and battery sizing. Hybrid systems, by efficiently balancing the short-term high power demands with the battery and providing long-term efficient energy use through the fuel cell, optimize power management and enhance overall performance. The findings support the feasibility of fuel cell systems for UAV applications. Future studies can focus on further system optimization and real-world testing to advance this technology. The widespread adoption of fuel cell-powered UAVs will contribute to reducing carbon emissions and promoting more sustainable aerial transportation solutions.

ABSTRACT
This study thoroughly compares hydrogen and methanol as marine fuels by implementing an analytical Life Cycle Assessment (LCA) and Return on Investment Analysis (ROI) for Kamsarmax bulk carriers. The feedstock pathways selected for each fuel consist of coal, natural gas and solar PV electricity. The effect of carbon capture technologies is applied to the natural gas pathway for feedstock processing. The life cycle inventory (LCI) model considered feedstock from Australia, processing in the Netherlands, and final bunkering in Rotterdam to simulate real-life trading environments. Software utilisation is a standard tool for most LCA studies. This study focuses on the application of combining two systematic methodologies, the Marine Environment Protection Committee (MEPC-81) well-to-wake (WtW) and the Renewable Energy Directive (RED-II), to assess the greenhouse gas (GHG) intensity of each pathway. The financial assessment is based on the International Maritime Organisation's (IMO) GHG reduction measures, which consider the global fuel intensity (GFI) of each pathway. The results will therefore help to evaluate hydrogen and methanol as plausible alternatives to heavy fuel oil and validate the effectiveness of this methodology through existing studies. The environmental results showed that the fuels with the least carbon equivalent impact, on a WtW and global warming potential (GWP) 100 basis, were "Green" Hydrogen and "Blue" Methanol, with 89.50 gCO2eq./MJ and 39.17 gCO2eq./MJ, respectively. The financial results, taken over a 20-year chartered lifetime of the vessel, showed that a "Blue" Methanol-powered Kamsarmax will generate an 8% return whilst one propelled by "Green" Hydrogen will generate a 23% return, both of which include IMO's regulatory costs. These figures shift to 14% and 11% respectively when IMO measures are included.

Keywords: Maritime Decarbonization, Alternative Marine Fuels, Hydrogen, Methanol, Life Cycle Assessment, MEPC 83

1. INTRODUCTION
Hydrogen and methanol are fuels that are being thoroughly investigated for adoption in the shipping industry [1]. hydrogen accounting for virtually zero green house gas (GHG) footprint [2] and methanol's elimination of nitrous and sulphur oxide emissions [3] form core factors which align with regulatory aims of "International Maritime Organization (IMO) 2050" for achieving net-zero GHG emissions by 2050 [4]. Implementing such fuels, however, is challenging due to the complexity of the industry and its operating environment. Therefore, with the regulatory framework posing stricter operational boundaries to industry stakeholders, emission modelling and monitoring are of the essence.
Recent literature has extensively focused on the environmental implications of various fuel production pathways as given in Table 1. For instance, Nizami [5] evaluated the techno-economic performance of renewable hydrogen production using advanced electrolyser technologies, highlighting the considerable reduction potential in life cycle emissions. Life cycle assessment (LCA) has been integral to quantifying a fuel's GHG efficiency from feedstock to end-use stages. Various studies utilise software tools, such as GREET and OpenLCA, to form their inventory, whilst others apply the ISO 14040 by specific plant data. Śliwińska et al. [6] implemented the ISO 14040 method for methanol production through coal gasification technology and found 117.5 gCO_2eq/MJ of fuel produced. The subject study applied 'system expansion' and 'avoided burdens' approaches. Sutar and Jadhav [7] applied ISO 14040 and formulated an inventory through OpenLCA for methanol production by natural gas. The papers emphasise feedstock conversion processes, a crucial pillar in LCA.

Table 1. Existing LCA studies for selected fuel pathways

Fuel Pathway	GHG Intensity (gCo_2eq/MJ)	Method	Reference	Methanol Institute GHG Intensity (gCO2eq/MJ – EWD II/GREET)
Brown Hydrogen	150.3	FUNNEL-EGY-H2-UCG	Alghool [8]	N/A
Grey Hydrogen	93.5	ReCiPe2016	Cho [9]	N/A
Blue Hydrogen	23.1	FOA	Badger [10]	N/A
Green Hydrogen	22.3	CML 2001	Alghool [8]	N/A
Brown Methanol	117.5	ISO 14040	Śliwińska [6]	300
Grey Methanol	46.2	ISO 14040	Li [11]	97
Blue Methanol	24.8	ISO 14040	Rigamonti [12]	32
Green Methanol	35.4	Ex-ante	Delikonstantis [13]	4.4

Despite this growing body of research, there remains a notable gap concerning comprehensive comparative analyses of hydrogen and methanol fuels using harmonised methodological approaches suitable for maritime applications. This study

addresses this research gap by integrating two established LCA methodologies— Marine Environment Protection Committee (MEPC) 81 [14] Well-to-Wake framework and RED-II [15]—to evaluate and compare the GHG emissions of hydrogen and methanol produced from diverse feedstocks, including coal, natural gas with carbon capture, and solar photovoltaic electricity.

Initially intended for biofuel assessment and European Union (EU) emissions reporting, RED-II is an established method of assessing different pillars of emissions from feedstock sourcing to final bunkering. Similarly, the MEPC method is based on the exact emission boundaries and applies to the maritime industry. Therefore, by combining the two systematic yet mature methodologies, the different emissions contributions can be numerically processed and ultimately form a system boundary to which emissions will be assessed individually, forming the well-to-wake impacts of each fuel pathway. Therefore, the RED II methodology is implemented to model different emissions pillars for the chosen system boundaries. The two methodologies are widely applicable in industry and form part of global environmental objectives through legislation. The return on investment (ROI) considered capital expenses (CAPEX), operational expenses (OPEX), MEPC-83 [16] regulatory effects, and annual charter revenue for a 20-year lifetime of a Kamsarmax bulk carrier utilising Methanol and Hydrogen for equivalent pathways deduced in the environmental assessment.

The novelty of this research lies in its detailed comparative analysis, employing consistent methodological boundaries and realistic geographical scenarios that mimic actual trading and operational environments. The specific objectives are: (1) to quantify and compare the GHG emissions associated with hydrogen and methanol across different production pathways, (2) to validate the applicability and robustness of integrating MEPC and RED II methodologies, 3) Perform a ROI analysis for a Kamsarmax (82,000 DWT) bulk carrier employing hydrogen and methanol and compare to conventional through OPEX, CAPEX, charter revenue and regulatory costs. 4) Quantify penalties/surpluses for the selected pathways based on the IMO's GHG reduction measures. (5) to provide clear recommendations for stakeholders in the maritime sector aiming at decarbonization.

2. METHODOLOGY

This study employs a comparative LCA framework to evaluate the environmental performance of hydrogen and methanol as alternative marine fuels. The assessment adheres to a well-to-wake (WtW) system boundary, integrating emission data derived from the RED II Directive [15] for well-to-tank (WtT) stages and the MEPC-81 [14] guidelines for tank-to-wake (TtW) calculations.

The system boundaries of this assessment consist of four different pathways. Firstly, "Brown" focuses on coal gasification whilst "Grey" focuses on natural gas reforming (SMR), two well-established processes. The former accounted for 27% and the latter for 47% of global hydrogen. "Blue" will implement the exact system boundaries as "Grey" whilst implementing the effect of Carbon Capture and Storage (CCS) technologies. "Green" considers fuel production from Solar PV electricity by PEM electrolysis. Core feedstock is assumed to be sourced in Australia, the seventh largest natural gas producer, and boasts the third largest coal reserves globally. Final vessel bunkering will occur in Rotterdam, Netherlands, the second-largest port for alternative fuel bunkering globally. Hydrogen will be assessed in liquid form to facilitate the endurance demands of the shipping industry. Tank-to-Wake calculations consider fuel combustion in a dual-cycle marine diesel engine.

As MEPC WtT emissions operate under similar boundaries and assumptions to EU methodologies, e_{fecu} (feedstock cultivation), e_p (feedstock processing), e_{td} (transportation) are deduced by the RED II Directive. In contrast, TtW is concluded using the MEPC method. Therefore, ultimate numerical processing is conducted using the MEPC method by taking input values from RED II and TtW MEPC-83.

Life Cycle Inventory Analysis (LCIA) was generated by utilising existing studies. Energy-required ratios, such as kWh/kg (grid electricity per kilogram of fuel produced) or MJ/kg (MJ of Coal/Natural Gas per kilogram of fuel produced), were extrapolated from existing studies, utilising analytical methods based on ISO 14040.

The primary equation for total WtW emissions is calculated as the sum of WtT emissions and TtW emissions, as illustrated by Equation (1):

$$GHG_{WtW} = GHG_{WtT} + GHG_{TtW} \quad (1)$$

In this equation, GHG_{WtW} indicates the total greenhouse gas emissions measured in grams of CO_2 equivalent per megajoule (gCO_2eq/MJ), while GHG_{WtT} refer to the emissions associated with fuel production and onboard combustion processes, TtW, and both are quantified similarly in gCO_2eq/MJ.

Further expanding upon the RED II directive guidelines, the WtT emissions are calculated through the aggregation and subtraction of several emission sources and sinks, shown by Equation (2):

$$GHG_{WtT} = e_{ec} + e_p + e_{td} + e_u - e_{ccr} - e_{ccs} \quad (2)$$

Here, e_{ec} represents feedstock sourcing emissions, encompassing emissions generated from extracting and harvesting fuel feedstock materials, e_p refers to feedstock processing emissions resulting from converting raw materials into usable fuels. Transportation emissions denoted as e_{td}, account for GHG emitted during feedstock, fuel transportation, and distribution stages. The emissions from direct fuel use, e_u, are considered zero in this study due to the assumption that production occurs on industrially designated land, precluding additional land-use emissions. The terms e_{ccs} and e_{ccr} represent emission reductions achieved through CCS and emissions captured for reuse in other industrial processes

(assumed zero in this study). It is important to note that e_{ccr} includes captured emissions not accounted for in the fuel processing stage itself.
For the determination of TtW emissions, calculations adhere to the MEPC-83 guidelines, defined by Equation (3):

$$GHG_{TtW} = \left(M_{CO_2} \times FC\right)/LCV \quad (3)$$

In this relationship, GHG_{TtW} quantifies the emissions released specifically during onboard fuel combustion. Here, M_{CO_2} denotes the mass of carbon dioxide emitted per kilogram of combusted fuel, measured in grams of CO_2 per kilogram (gCO_2eq/kg fuel). Fuel consumption *FC* specifies the amount of fuel combusted during the operational cycle, which is recorded in kilograms. Finally, *LCV* indicates the fuel's lower calorific value, describing the available energy content per unit mass, expressed in megajoules per kilogram.
The financial assessment considers Capital Expenses (CAPEX), Operating Expenses (OPEX), charter rates, and International Maritime Organization (IMO) Green House Gas (GHG) reduction costs. This study simulates a Kamsarmax vessel's 20-year operational lifetime, utilizing WtW intensity results (GFI) from the environmental assessment as inputs. CAPEX baselines are derived from newbuild costs, repair premiums, and steel scrap values. OPEX projections, including a 3% annual inflation, incorporate premiums for advanced machinery and specialised crew training for methanol (7%) and hydrogen (10%) vessels. Annual charter revenues are modelled using a sine wave function to simulate cyclicality and dynamic annual utilisation as shown in Equation (4):

$$Avg_{TCE(t)} = T_0 + r \cdot t + A \cdot sin\left(2\pi \cdot \frac{tmodC}{C} - \frac{\pi}{2}\right) \quad (4)$$

where Avg_{TCE} is the average time charter equivalent for a given year *t*; T_0 represents the base Panamax 5-Time charter level modelled from real data, r is the annual trend increases in the daily rate; *t* is the number of years, A is the amplitude of the earnings cycle, C represents the estimated full cycle length. IMO GHG reduction measures are based on the vessel's annual GFI. Tier-I ($150/$tCO_{eq}$) and Tier-II ($600/tCO_{eq}) targets determine compliance deficits or surpluses. The attained global fuel intensity (GFI) is calculated as given in Equation (5), and the target GFI is calculated as given in Equation (6):

$$GFI_{attained} = \frac{\sum_{j=1}^{J} EI_j \times Energy_j}{Energy_{total}} \cdot \left(1 - f_{voy}\right) \quad (5)$$

$$GFI_t = (1 - Z_T/100) \cdot GFI_{2008} \quad (6)$$

ROI is calculated as the net present value (NPV), incorporating all financial pillars, divided by the initial newbuild investment.

3. RESULTS AND DISCUSSION

The integrated environmental and financial assessment reveals critical distinctions between hydrogen and methanol pathways, underscoring the profound impact of production methods and regulatory frameworks on their viability as alternative marine fuels.
The WtW analysis, which combines RED II and MEPC methodologies, demonstrates a substantial divergence in GHG intensity across the evaluated fuel pathways (Figure 1). For hydrogen, fossil-fuel-based routes exhibit the highest emissions. "Grey" hydrogen, produced via Steam Methane Reforming (SMR) without carbon capture, is the most carbon-intensive hydrogen option, with a WtW intensity of approximately 257 gCO_2eq/MJ. "Brown" hydrogen from coal gasification follows, with an intensity of around 169 gCO_2eq/MJ. The application of Carbon Capture and Storage (CCS) in the "Blue" hydrogen pathway reduces the intensity to approximately 187 gCO_2eq/MJ. The most significant reduction is achieved with "Green" hydrogen, produced via electrolysis powered by solar PV, which registers the lowest GHG footprint among hydrogen options at approximately 90 gCO_2eq/MJ.

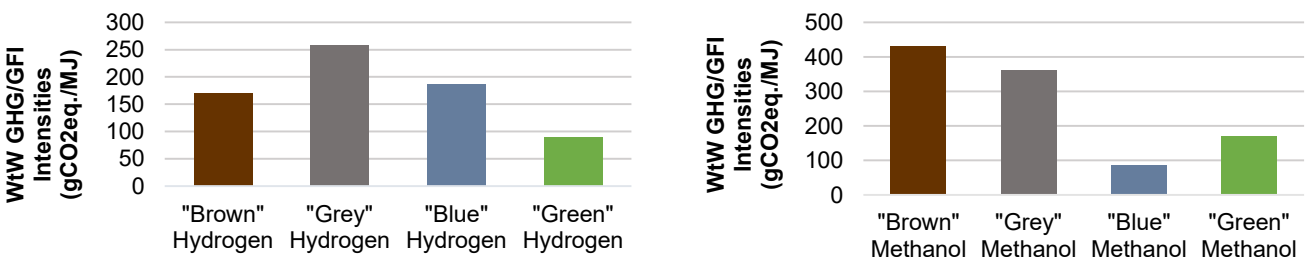

Figure 1. Well-to-Wake GHG Intensities

A similar trend is observed for methanol pathways, though with a wider range of emission intensities. "Brown" methanol from coal gasification is the highest-emitting pathway overall, exceeding 430 gCO_2eq/MJ. "Grey" methanol from SMR

follows at approximately 360 gCO_2eq/MJ. The most striking result is for "Blue" methanol, where the integration of CCS reduces the WtW emissions to approximately 86 gCO_2eq/MJ, making it the lowest-emission pathway evaluated in this study. This superior performance is attributed to the high efficiency of direct carbon capture from the methanol synthesis loop. In contrast, "Green" methanol, while a significant improvement over fossil-based routes, has a WtW intensity of about 170 gCO_2eq/MJ, which is substantially higher than both "Blue" methanol and "Green" hydrogen.

Analysis of the emission sources (Figure 1) clarifies these results. For "Brown" and "Grey" pathways, feedstock sourcing (e_{ec}) and processing (e_p) are the dominant contributors to the WtW footprint. For "Blue" pathways, the negative emission value from CCS (e_{ccs}) partially counteracts the high processing emissions, with a more pronounced effect for methanol than for hydrogen. For "Green" pathways, the lifecycle emissions associated with manufacturing the renewable energy infrastructure (solar panels and electrolysers), captured under the e_{ec} term, become the primary source of GHG impact. Furthermore, the TtW emissions are non-zero for all methanol pathways due to the carbon in the fuel molecule, whereas they are negligible for hydrogen.
The financial analysis, summarized in Table 2, reveals that regulatory costs under the IMO's GHG reduction measures are a decisive factor in determining the of each pathway. The ROI is calculated over a 20-year lifetime for a Kamsarmax vessel, both excluding and including the projected IMO-related financial penalties or surpluses.

Table 2. ROI Balance Table

Pathway	Initial CAPEX	NPV incl. IMO costs	NPV excl. IMO costs	ROI incl. IMO Costs	ROI excl. IMO Costs
Conventional	$39,100,000.00	$70,570,635.45	$5,016,933.72	-180%	13%
"Brown" Methanol	$46,920,000.00	$572,113,921.54	$6,446,106.76	-1219%	14%
"Blue" Methanol	$46,920,000.00	$3,711,768.30	$6,446,106.76	8%	14%
"Grey" Hydrogen	$58,000,000.00	$145,963,448.97	$6,256,636.77	-252%	11%
"Green" Hydrogen	$58,000,000.00	$13,330,281.92	$6,256,636.77	23%	11%

When IMO costs are excluded, the investment returns are modest and primarily dictated by CAPEX and OPEX differentials. "Blue" methanol shows the highest ROI at 14%, followed by conventional fuel (13%) and "Green" hydrogen (11%). However, the inclusion of IMO's GFI-based measures dramatically reshapes the financial landscape (Figure 2). The conventional vessel and high-emission alternatives ("Brown" methanol, "Grey" hydrogen) become financially unviable, posting large negative ROIs.

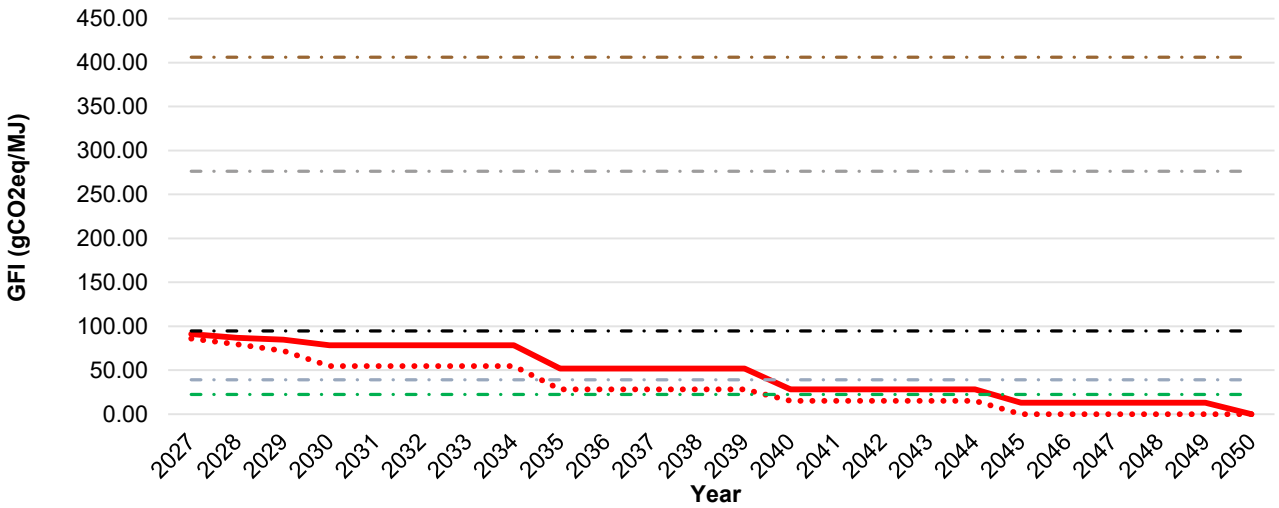

Figure 2. EU IMO GHG reduction intensities (base-strive) for Grey/Green Hydrogen and Brown/Blue Methanol

Crucially, the ranking between the two most promising low-carbon options flips. The ROI for "Blue" methanol decreases from 14% to 8%, indicating that while its WtW emissions are low, it still incurs a net cost under the regulatory scheme. In absolute contrast, the ROI for "Green" hydrogen increases significantly, from 11% to 23%. This indicates that its GFI not only meets but substantially exceeds its regulatory target, generating a financial surplus that enhances its economic attractiveness. This counterintuitive result—where the fuel with the higher WtW emissions ("Green" hydrogen at 90 gCO_2eq/MJ vs. "Blue" methanol at 86 gCO_2eq/MJ) yields a superior post-regulation ROI—highlights the specific

mechanics of the IMO GFI framework. The financial outcome is not solely dependent on the absolute GHG intensity but on the performance relative to a declining annual benchmark ($\boldsymbol{GFI_t}$).
This analysis underscores a critical insight: while CCS can dramatically reduce the WtW emissions of a fuel ("Blue" methanol), its reliance on fossil feedstocks may still place it at a disadvantage within a regulatory framework designed to progressively tighten emission standards. Conversely, a fully renewable pathway ("Green" hydrogen), despite having higher manufacturing-related lifecycle emissions in this assessment, can achieve a more favorable regulatory and financial outcome in the long term.

4. CONCLUSIONS

This study developed an analytical/numerical method of assessing hydrogen and methanol pathways in the shipping industry. By combining MEPC 83 and RED II Directive methodologies, CO_2 equivalent emissions were deduced on a GWP100 basis and compared to benchmark industry figures. LCIs from specific case studies allowed us to develop individual energy consumption ratios and extrapolate to the annual output of the Netherlands. Emissions were modelled through real-life data to simulate trading environments for Hydrogen and Methanol production infrastructure. It can be concluded that “Blue” Methanol emits the lowest WtW emissions, though its SO_x and NO_x footprint poses a considerable trade-off compared to hydrogen utilization. Nonetheless, onboard storage technology for liquid hydrogen is still premature due to the demanding pressure and temperature conditions to achieve desirable endurance.

ABSTRACT
This study presents the design and simulation of a hybrid solar-based energy system aimed at meeting the annual space heating demand of 8,500 households in an off-grid urban area. The proposed system integrates a solar tower, molten salt thermal energy storage, an Organic Rankine Cycle (ORC), a Proton Exchange Membrane (PEM) electrolyzer, and a district heating network. Thermal energy collected from the solar receiver is used for both electricity generation and hydrogen production. The waste heat from the ORC is utilised for district heating, enhancing the overall energy efficiency. Simulation results indicate that the system successfully meets the annual heating demand and produces approximately 722 tons of hydrogen, contributing to long-term energy storage and decarbonization goals.

Keywords: Off-grid cities, Rankine cycle, Hybrid solar-based energy system

1. INTRODUCTION

In an era marked by growing environmental concerns, energy insecurity, and increasing natural disasters, the concept of off-grid cities—urban areas that are self-sufficient and independent from centralised electricity grids has gained considerable importance. These cities are designed to produce, store, and manage their own energy by utilising locally available renewable resources, thus increasing their resilience and reducing reliance on fossil fuels [1].

Off-grid cities play a critical role in enhancing environmental sustainability by minimising carbon emissions through renewable energy integration. Technologies such as solar, wind, biomass, and small-scale hydropower are commonly deployed to meet local electricity and thermal energy demands [2]. In particular, solar-based systems have emerged as promising candidates due to their modularity, scalability, and declining cost.

Beyond environmental concerns, off-grid smart cities also contribute to social and economic sustainability by providing energy access to remote communities, improving quality of life, and enabling energy independence [3]. Moreover, the integration of digital technologies and artificial intelligence into off-grid systems enhances operational efficiency and allows for predictive energy management. This is especially relevant in the context of natural disasters, where smart data-driven systems can improve urban resilience and response strategies.

To meet the complex energy demands of future off-grid urban areas, hybrid energy systems that combine multiple technologies such as renewable electricity generation, thermal energy storage, hydrogen production, and district heating are being explored [4]. In this context, the present study proposes and simulates a hybrid solar thermal energy system that is specifically designed to support off-grid urban applications. The proposed model focuses on the integration of solar tower technology with thermal storage, power generation, and hydrogen production [5].

The detailed structure and operational principles of this integrated energy system are described in the following section.

2. SYSTEM DESCRIPTION

This study aims to develop and simulate an integrated solar-based hybrid energy system designed to meet the annual space heating demand of an off-grid urban area consisting of 8,500 households, while simultaneously producing hydrogen as a long-term energy storage medium. The system is structured to ensure energy reliability through thermal energy storage and to increase overall energy efficiency through waste heat utilisation for district heating applications.

Fig. 1 shows a schematic representation of the proposed hybrid solar-based energy system integrating thermal storage, power generation, hydrogen production, and district heating. The primary energy source of the system is a solar tower (central receiver system), where a field of heliostats concentrates solar radiation onto a central receiver located at the top of the tower. The solar radiation is absorbed by the receiver and transferred to a molten salt fluid, which serves as the thermal energy carrier. The heated molten salt is stored in a hot salt tank during sunny hours.

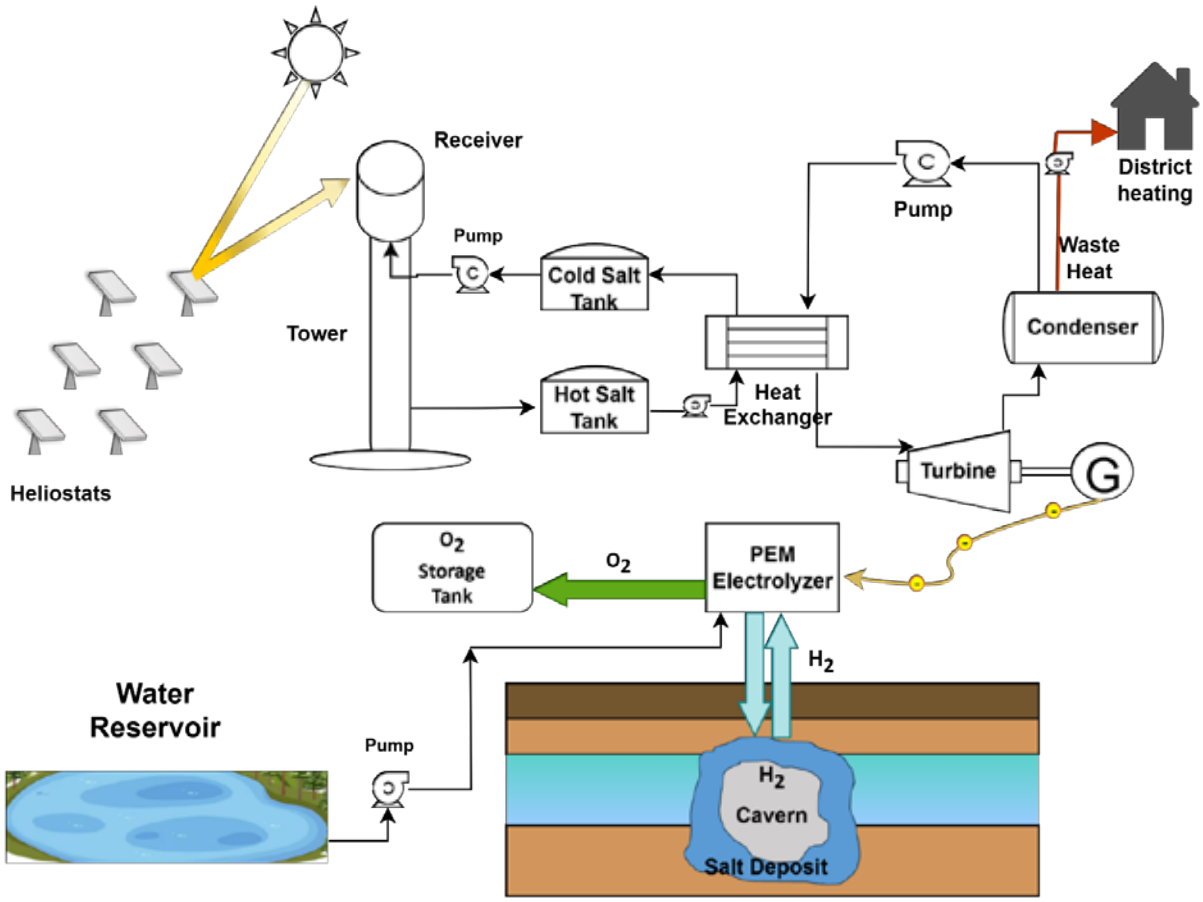

Fig. 1. Schematic representation of the hybrid solar thermal energy system.

When direct solar radiation is not available, such as at night or on cloudy days, the stored thermal energy is transferred from the hot salt tank to a heat exchanger, where it supplies heat to an Organic Rankine Cycle (ORC). The ORC is composed of a heat exchanger (evaporator), an expansion turbine, a condenser, and a feed pump. In the heat exchanger, the working fluid absorbs the heat from molten salt, evaporates, and drives the turbine to produce mechanical power, which is converted into electricity via a generator.

The electricity generated by the ORC is used to power a Proton Exchange Membrane (PEM) electrolyzer, which splits water into hydrogen and oxygen. The produced hydrogen is stored in underground reservoirs or appropriate pressurised tanks, and can later be used as an energy carrier or reconverted into electricity using fuel cells. Meanwhile, the oxygen may be released or used for industrial purposes.

An important feature of the proposed system is the utilisation of waste heat from the ORC condenser. This low-grade thermal energy is directed to a district heating network, providing space heating to residential buildings and thus increasing the overall exergy efficiency of the system.

3. RESULTS AND DISCUSSIONS

Table 1 shows the monthly distribution of heating demand, thermal energy collected from the solar tower, and hydrogen production from surplus energy. Hydrogen was produced between March and November, particularly in summer months when excess energy was available. In winter months, the system mainly relied on stored hydrogen to meet the heating demand of 8,500 households.

The simulation results demonstrate that the system is capable of supplying the required thermal energy throughout the year. Additionally, approximately 722 tons of hydrogen were produced from surplus energy, providing a promising solution for seasonal energy storage and long-term sustainability in future off-grid smart cities.

ABSTRACT

Today, due to reasons such as the depletion of fossil fuels, the release of harmful gases by fossil fuels, and the depletion of non-renewable energy sources, people have turned to renewable energy and conducted research on renewable energy. To meet future energy requirements, hydrogen, which is among the renewable energy sources, is preferred due to its high energy density and clean burning properties. Among hydrogen production technologies, photocatalytic hydrogen evolution (PCHER) has been considered important due to its potential for sustainable and efficient hydrogen production using solar energy, and experiments have been conducted on the PCHER system.
In this study, a new MoP/g-C_3N_4/Ti_3C_2 quantum dot (QD) photocatalyst has been synthesized in order to increase photocatalytic hydrogen production. Metal phosphides, especially compounds such as molybdenum phosphide (MoP), have been obtained by passing metal salts through appropriate phosphorylation processes. In addition, g-C_3N_4 (graphitic carbon nitride) has been synthesized by controlled thermal decomposition of urea precursor. QD were prepared using a hydrothermal method. The developed photocatalyst aims to overcome the fundamental efficiency limitations in the photochemical hydrogen evolution reaction (PCHER) by improving visible light absorption. For this purpose, material design was carried out to ensure efficient separation of charge carriers, optimize surface reaction kinetics and increase catalytic activity. As a result, this new generation hybrid photocatalyst has significant potential for sustainable and efficient hydrogen production. The results showed that the synthesized photocatalyst exhibited superior photocatalytic activity and contributed to increased hydrogen production. This study provides advances in the development of efficient photocatalysts and contributes to the advancement of hydrogen production and supports future renewable energy production.
Keywords: Photocatalytic Hydrogen Production, g-C_3N_4, Quantum Dot, Molybdenum Phosphide

1. INTRODUCTION

In order to meet future energy needs and minimize environmental damage, the development of sustainable energy sources is of great importance. In this direction, photocatalytic water splitting, which is based on obtaining hydrogen from water using sunlight, stands out as a promising method in renewable energy production [1]. The success of photocatalytic hydrogen production directly depends on the properties of the photocatalysts used. g-C_3N_4 is widely used in photocatalytic applications due to its wide band gap, chemical stability and easy accessibility. In addition, although it is a remarkable material with a suitable band gap, chemical durability and low charge carrier separation efficiency, it is not effective enough alone due to its low charge carrier separation efficiency [2,3]. Therefore, it has been used with various hybrid materials in order to increase its performance. In this study, hybrid materials containing Ti_3C_2 QD and metal phosphide were developed to increase the photocatalytic activity of g-C_3N_4 [4]. The high conductivity of Ti_3C_2 QD allows charge carriers to move more efficiently, while quantum dots support photochemical processes thanks to their wide light absorption capabilities. In recent years, transition metal phosphides (TMPs), especially MoP, have emerged as remarkable materials in hydrogen production due to their high catalytic activity and low wear resistance. MoP is considered an effective hydrogen evolution reaction (HER) catalyst with its large surface area, good conductivity and strong proton adsorption ability. In addition, composite structures are formed by combining MoP with different materials to increase its photocatalytic activity [5]. It is thought that these developed hybrid structures can play an important role in the transition to clean energy. In the photocatalytic hydrogen production process, semiconductor photocatalysts absorb sunlight and trigger chemical reactions that will split water molecules [6]. In semiconductors, there is an energy gap between the valence band and the conduction band. When sunlight is absorbed, electrons in the valence band gain energy and move to the conduction band, leaving behind electron holes (h^+). These holes trigger the oxidation of water, while electrons rising to the conduction band complete the photocatalytic process by reducing hydrogen. [7]. In order to ensure effective hydrogen production, the conduction band level of the semiconductor used must be lower than the hydrogen reduction potential and the valence band level must be higher than the oxidation potential of water [8]. Although a band gap of 1.23 eV is considered thermodynamically sufficient in theory, in practical applications, values of 1.8 eV and above are preferred due to factors such as overpotentials and energy band alignment [9]. Photocatalytic hydrogen production is a complex process and studies are ongoing on methods such as photocatalyst surface modifications, improvement of light absorption properties and optimization of charge carrier separation mechanisms to increase efficiency [10].

2. MATERIALS AND METHODS

Synthesis of graphitic carbon nitride (g- C_3N_4):

The synthesis of g-C3N4 was carried out by adopting the method proposed by Y. Li and his team [11]. In this process, a certain amount of urea was subjected to thermal treatment in a tube furnace heated to 550°C with a heating rate of 5°C per minute for 4 hours. Afterwards, the product coming out of the furnace was cooled to room temperature and then ground into powder with the help of a mortar and pestle.

The synthesis of quantum dots (QD):

The synthesis of QD was adapted from the method proposed by Y. Li et al. [11]. This process was based on the method reported in the literature (C. Li et al., 2019). Firstly, 2 g of Ti_3AlC_2 powder was mixed with 240 mL of 40 percent hydrofluoric acid solution and stirred with a magnetic stirrer for 64 h. The resulting suspension was washed with pure water to remove excess HF and residues. Then, the obtained Ti_3C_2 MXene was dried at 50 °C under vacuum for 10 h. In the next step, 0.5 g of Ti_3C_2 MXene was dispersed in dimethyl sulfoxide and stirred for 24 h. This suspension was centrifuged at 4100 rpm for 20 min. After centrifugation, distilled water was added to the dispersion and sonicated in an ultrasonic bath for 3 h. Then, 3.0 mL of polyethylenimine (PEI) was added and the mixture was heated under nitrogen atmosphere for 12 h. Finally, the product was filtered through with membrane filter and purified by dialysis to obtain Ti_3C_2 QD.

The Synthesis of Molybdenum Phosphide (MoP):

The synthesis of MoP was adapted from the method proposed by Y. Li et al. [11]. 100 mg $Na_2MoO_4{\cdot}2H_2O$ and 1 g $NaH_2PO_2{\cdot}H_2O$ are measured using a precision balance. The material is mixed homogeneously in a mortar for 30 minutes. Then, the powdered mixture is placed in a closed alumina crucible. It is heated in a muffle furnace at a speed of 5°C/minute up to 700°C and kept at this temperature for 2 hours. Then, it is left to cool down to room temperature. Then, it is washed with pure water five times and then centrifuged. In the last stage, MoP is dried at 60°C for 12 hours and the MoP synthesis is completed.

2.1. Photocatalytic Performance Tests

The reactor developed for photocatalytic reactions has a quartz glass upper section that can transmit ultraviolet-visible (UV-Vis) light. The reactor was designed to have gas and liquid inlet/outlet connections. In the studies conducted to determine the most suitable level of catalyst amount, 10 mg of catalyst was used initially. Catalyst addition to the reaction medium was provided by an aqueous solution containing 10% tetraethylammonium (TEOA) as electrolyte. The temperature of the reactor was kept constant by continuous water circulation. During the reaction, the catalyst was kept in a homogeneous distribution in the solution with the help of a magnetic stirrer. The gas released as a result of the reaction was directed to a microfluidic pressure sensor with argon (Ar) carrier gas to determine the amount of hydrogen produced. The composition of the produced gas was analyzed using gas chromatography, one of the types of chromatography. The light source was positioned to provide equal distribution over the entire surface of the photocatalyst and the light intensity was adjusted to 100 mW/cm² with the help of a light meter. To prevent intensity fluctuations in the light source over time from affecting the measurement sensitivity, light stabilization was checked before each photocatalytic reaction.

3. RESULTS AND DISCUSSION

Photocatalytic hydrogen production was investigated using a composite photocatalyst composed of g-C_3N_4, Ti_3C_2 QD, and MoP. The synergistic effect of these components was analyzed using various characterization techniques and the successful synthesis of the composite and its improved photocatalytic performance were confirmed. X-ray Diffraction (XRD) technique was used for structural analysis and the characteristic peaks of MoP phase were found to be consistent with the values reported in the literature. MoP was determined to have an orthorhombic crystal structure and this structure has been reported in previous studies to show high activity in hydrogen production catalysis. When the lattice parameters of MoP were examined, it was reported in the literature that it typically has an atomic lattice spacing in the range of 0.3-0.5 nm. X-ray Photoelectron Spectroscopy analyses confirmed that the active sites on the surface of MoP were suitable for hydrogen production when evaluated in terms of surface chemistry, and especially Mo and P elements were determined to be active species in photocatalytic reactions by examining the chemical bonding status on the surface. Diffraction peaks of g-C_3N_4 were observed and new peaks related to Ti_3C_2 QD showed strong interactions between the components, while MoP changed the crystal structure and improved charge transfer Scanning electron microscope images showed the morphology of g-C_3N_4 and the uniform distribution of Ti_3C_2 QD and MoP on the surface, which further enhanced the charge transfer and caused a decrease in electron-hole recombination.The incorporation of quantum dots provided additional active sites for hydrogen production (i). HRTEM and FFT results show that the lattice spacing corresponding to the MoP (101) crystal plane is 0.210 nm, which is consistent with the literature [12-13]. UV-Vis Diffuse Reflectance Spectroscopy (DRS) was used to understand the band structure and optoelectronic properties. DRS analysis showed that the light absorption capacity of MoP/g-C_3N_4/Ti_3C_2 QD composites was broadened compared to pure g-C_3N_4 and absorbed more photons in the visible light region. This can be explained by the broad spectrum light harvesting ability of QD and the high conductivity of MXene. Fourier transform infrared spectroscopy (FTIR) spectra were used to determine the functional groups in the material. The peaks from Ti_3C_2 QD and MoP confirmed the presence of characteristic functional groups of g-C_3N_4, such as C-N and C=N stretching vibrations, and confirmed their successful integration. Photoluminescence (PL) spectroscopy showed lower fluorescence intensity in the composite, suggesting reduced charge recombination. This was supported by electrochemical impedance spectroscopy (EIS), which confirmed lower charge transfer resistance, improved electron mobility, and increased catalytic efficiency. BET surface area analysis revealed that the composite had a higher specific surface area compared to pure g-C_3N_4, and the addition of Ti_3C_2 QD created a more porous structure and provided more active sites for hydrogen production. This increased surface area facilitated mass transfer, further enhancing the photocatalytic efficiency. Photocatalytic hydrogen production experiments showed a significant enhancement in hydrogen production by the g-C_3N_4/Ti_3C_2 QD/MoP composite. Ti_3C_2 QD contributed to rapid electron transfer, quantum dots enhanced charge separation, and MoP acted as an effective water oxidation catalyst, improving the hydrogen production rate. The composite provides improvement in hydrogen production efficiency under visible light and confirms the synergistic effect between the components. The improved photocatalytic performance was attributed to the enhanced charge separation provided by Ti_3C_2 QD and the catalytic activity of MoP. As a result of g-C_3N_4 absorbing photons, electron-hole pairs are formed. Ti_3C_2QD prevents recombination by transferring photogenerated electrons to the reaction sites, while MoP facilitates effective oxidation reactions, improving the overall hydrogen production efficiency. As a result, in photocatalytic hydrogen production tests, MoP/g-C_3N_4/Ti_3C_2QD composites exhibited the highest efficiency. These results indicate that composite materials can increase photocatalytic activity with synergistic effects. In particular, it was determined that MXene accelerates electron conduction and reduces charge carrier recombination, and quantum dots make significant contributions to photochemical processes due to their broad light absorption.

4. CONCLUSIONS

This study demonstrated the effect of synthesized MoP-based composites on photocatalytic hydrogen production. In this study, the structural, morphological and photoelectrochemical properties of the synthesized MoP/g-C_3N_4/Ti_3C_2QD nanocomposite were comprehensively investigated. SEM, HRTEM and EDS analyses confirmed that the nanocomposite was successfully synthesized and its components exhibited a homogeneous distribution. XPS analysis confirmed that the active sites on the surface of MoP were suitable for hydrogen production and proved the existence of MoP in the composite by determining the chemical bond states. UV-Vis DRS analysis examined the band gap of the material and revealed that the MoP/g-C_3N_4/Ti_3C_2QD composite had improved optical properties. In the PCHER system, catalyst ratios were optimized to increase hydrogen production efficiency. Photoelectrochemical performance evaluations, especially photocurrent versus time measurements, revealed that MoP/g-C_3N_4/Ti_3C_2QD nanocomposite exhibited high charge transfer efficiency and good photocatalytic activity. These findings indicate that MoP/g-C_3N_4/Ti_3C_2QD nanocomposite is a strong photocatalyst candidate for sustainable hydrogen production.

ABSTRACT
The increasing demand for renewable energy is driven by the depletion of fossil fuel reserves and the necessity to reduce carbon emissions. In this context, hydrogen emerges as a critical energy carrier in future energy systems due to its high energy density and environmentally friendly characteristics. Among hydrogen production technologies, photocatalytic hydrogen evolution reaction (PCHER) has attracted significant attention. However, this process faces fundamental challenges, including low quantum efficiency, slow charge separation and transfer, recombination losses, and limitations in photocatalyst particle size. In this study, a novel CoP, g-C_3N_4/Ti_3C_2 quantum dot (QD) photocatalyst was synthesized to enhance photocatalytic hydrogen production efficiency. The metal phosphite (CoP) was obtained via the phosphorization of metal salts, while g-C_3N_4 was synthesized through the thermal decomposition of urea, and Ti_3C_2QD were prepared using a hydrothermal method. The designed photocatalyst aims to overcome key efficiency limitations in PCHER by improving visible light absorption. The findings of this study demonstrate a significant advancement in sustainable hydrogen production, offering a promising strategy for future renewable energy applications.
Keywords: Photocatalytic Hydrogen Production, g-C_3N_4, Ti_3C_2 Quantum Dot, Cobalt Phosphite

1. INTRODUCTION

Meeting global energy demands while minimizing environmental impacts necessitates the development of sustainable energy sources. In this context, photocatalytic hydrogen production, which relies on water splitting driven by solar energy, has emerged as a highly promising approach [1]. The efficiency of this process is intrinsically linked to the properties of the photocatalyst materials employed. Graphitic carbon nitride (g-C_3N_4) has been extensively studied in photocatalytic applications due to its suitable band gap, chemical stability, and natural abundance [2]. However, its inherently low charge carrier separation efficiency limits its standalone application [3]. Consequently, various modification strategies have been explored to enhance its photocatalytic performance. This study investigates hybrid composites incorporating Ti_3C_2QD, and cobalt phosphide (CoP) to improve the photocatalytic activity of g-C_3N_4 [4]. Ti_3C_2QD, with its high electrical conductivity and superior electron transfer capability, plays a crucial role in accelerating photocatalytic reactions. Quantum dots, owing to their broad light absorption spectrum, efficiently capture photons and optimize charge carrier dynamics. Additionally, CoP facilitates efficient water oxidation, thereby enhancing the hydrogen evolution process and contributing to the overall photocatalytic efficiency. The synergistic interaction of these materials presents significant potential for improving photocatalytic hydrogen production performance [5]. The development of such hybrid materials offers new opportunities for clean and renewable energy technologies, contributing to a more sustainable future. In photocatalytic hydrogen production, semiconductor photocatalysts absorb light energy to drive water splitting [6]. Semiconductors are characterized by a specific band gap (BG) between the valence band (VB) and conduction band (CB). Upon light absorption, electrons in the VB are excited to the CB, generating electron holes (h^+) in the VB. These charge carriers facilitate water oxidation and reduction reactions, respectively [7]. The photocatalyst also minimizes the accumulation of electrolytic intermediates through regeneration mechanisms. For efficient hydrogen production, the CB edge must be positioned at a more negative potential than the hydrogen reduction potential, while the VB edge must be at a more positive potential than the water oxidation potential, as noted by Dong et al. [8]. Although a theoretical band gap of 1.23 eV is sufficient, practical applications often require band gaps of 1.8 eV or higher due to overpotential and band alignment constraints [9]. Given the complexity of photocatalytic hydrogen production, modifications to photocatalysts are essential [10]. In this regard, strategies such as photocatalyst restructuring, surface modifications, and light absorption enhancement have emerged as key approaches for optimizing performance.

2. MATERIAS AND METHODS

2.1.1 Synthesis of graphitic carbon nitride (g- C_3N_4)

The synthesis of g-C_3N_4 was adapted from the method proposed by Y. Li et al. method [11]. In this process, a specific amount of urea was subjected to thermal treatment in a tube furnace at 550°C for 4 hours, with a of 5°C/min. The resulting product is ground into fine powder.

2.1.2 The synthesis of Quantum Dots (QD)

The synthesis of Ti_3C_2 QD was adapted from the method proposed by Y. Li et al. method [11]. In this prıcess was carried out based on the general procedure outlined in the literature (C. Li et al., 2019). In the initial stage, 2 g of Ti_3AlC_2 powder was treated with 240 mL of 40 percent hydrofluoric acid solution using a magnetic stirrer for 64 hours. The resulting

suspension was washed with pure water to remove excess HF and residues Ti_3C_2 MXene was dried under vacuum at 10 hours. Subsequently, 0.5 g of Ti_3C_2 MXene was stirred of dimethyl sulfoxide (DMSO) for 24 hours. The suspension was centrifuged at 4100 rpm for 20 minutes. After the centrifugation process, 150 mL of deionized water was added to the dispersion, and it was subjected to sonication in an ultrasonic bath for 3 hours. Following this, 3.0 mL of polyethyleneimine (PEI) was added, and the mixture was heated under a nitrogen atmosphere at 12 hours. The product was passed through a membrane filter, and Ti_3C_2 QD were purified by dialysis.

2.1.3 The synthesis of Cobalt phosphide (CoP)

The synthesis of CoP was carried out according to the procedure described by K. Wang et al.[12].Cobalt phosphide. Initially, solution of cobalt(II) nitrate hexahydrate (Co(NO3)2·6H2O) (100 mL, 0.05 M) was combined with sodium hydroxide (NaOH) solution (400 mL, 0.25 M). After 2 hours, the resulting precipitate was gathered, thoroughly washed with distilled water and ethanol, and subsequently dried under vacuum to yield the $Co(OH)_2$ precursor. Then, $Co(OH)_2$ (0.05 g) was mixed with sodium hypophosphite (NaH_2PO_2, 0.25 g) through grinding. The resulting mixture was then subjected to annealing in an argon (Ar) at 300 °C for 1 hour, with a rate of 2 °C min^{-1}. Finally, the obtained black solid was collected, repeatedly washed, and dried to obtain the final CoP product.

2.2. PHOTOCATALYTIC PERFORMANCE TEST

The reactor designed for photocatalytic reactions has an upper section made of quartz glass, which is transparent to ultraviolet-visible (UV-Vis) light. The reactor is equipped with gas inlet/outlet and liquid inlet/outlet ports. Optimization studies to determine the optimum catalyst amount were initially conducted using 10 mg of catalyst. The catalyst was introduced into the reaction medium using a 10% aqueous solution of tetraethylammonium (TEOA) as an electrolyte. The reactor temperature was controlled through continuous water circulation. During the reaction, the catalyst was maintained as a homogeneous suspension using a magnetic stirrer. The gas phase generated as a result of the reaction was carried to a microfluidic pressure sensor using an inert carrier gas (Ar) to measure the amount of hydrogen produced. The characterization of the produced gas was performed using gas chromatography (GC). The light source was positioned to ensure homogeneous illumination of the photocatalyst, and the light intensity was adjusted to 100 mW/cm² using a light meter. To minimize errors that could arise from changes in light intensity over time, the light intensity was checked before each photocatalytic reaction to ensure the stabilization of the light source.

3. RESULTS AND DISCUSSION

This investigation delved into the realm of photocatalytic hydrogen generation, employing a hybrid photocatalyst formulated from graphitic carbon nitride (g-C_3N_4), Ti_3C_2QD, and cobalt phosphide (CoP). The collaborative interplay amongst these constituents was scrutinized via a suite of characterization methodologies, validating the successful fabrication of the composite and its augmented photocatalytic efficacy. X-ray diffraction (XRD) patterns elucidated the crystalline architecture of g-C_3N_4 and the seamless integration of Ti_3C_2QD and CoP. Diffraction peaks attributable to g-C_3N_4 were noted, and novel peaks associated with Ti_3C_2QD signaled robust interactions amongst the components, while CoP refined the crystalline lattice, optimizing charge transfer. Scanning electron microscopy (SEM) imagery showcased the layered morphology of g-C_3N_4 and a uniform dispersion of Ti_3C_2QD and CoP across the surface, contributing to ameliorated charge transfer and diminished electron-hole recombination. The incorporation of quantum dots furnished supplementary active sites for hydrogen evolution, thereby amplifying reaction throughput. High-resolution transmission electron microscopy (HRTEM) and fast Fourier transform (FFT) outputs corroborated that the lattice spacing congruent with the CoP (111) crystal plane was 0.221 nm, aligning with literature benchmarks [13]. UV-Vis diffuse reflectance spectroscopy (DRS) analyses revealed that the composite assimilated a broader light spectrum relative to pristine g-C_3N_4, with Ti_3C_2QD inducing a redshift in the absorption edge, thus enhancing visible light utilization. Fourier transform infrared spectroscopy (FTIR) spectra affirmed the presence of characteristic functional groups of g-C_3N_4, such as C-N and C=N stretching vibrations, alongside peaks emanating from Ti_3C_2QD and CoP, validating their successful amalgamation. Photoluminescence (PL) spectroscopy exhibited a diminished fluorescence intensity in the composite, indicative of curtailed charge recombination. This finding was buttressed by electrochemical impedance spectroscopy (EIS), which confirmed attenuated charge transfer resistance, fostering electron mobility and elevating catalytic performance. BET surface area analyses disclosed that the composite boasted an elevated specific surface area compared to pure g-C_3N_4, and the introduction of Ti_3C_2QD engendered a more porous framework, providing augmented active sites for hydrogen production. This escalated surface area facilitated mass transport, further bolstering photocatalytic efficiency. Photocatalytic hydrogen production trials manifested a pronounced surge in hydrogen yield with the g-C_3N_4/Ti_3C_2QD/CoP composite. Ti_3C_2QD contributed to expedited electron transfer, quantum dots optimized charge segregation, and CoP functioned as an efficient water oxidation catalyst, amplifying the hydrogen production rate. The composite showcased a remarkable elevation in hydrogen production under visible light, validating the synergistic interplay among the constituents. The enhanced photocatalytic performance was ascribed to the refined charge segregation afforded by Ti_3C_2QD and quantum dots, as well as the catalytic prowess of CoP. The postulated mechanism encompasses the creation of electron-hole pairs via light absorption by g-C_3N_4. Ti_3C_2QD thwarts recombination by shuttling photogenerated electrons to the reaction loci, while CoP facilitates efficacious oxidation reactions, augmenting overall hydrogen production efficiency. In summation, the amalgamation of g-C_3N_4, Ti_3C_2QD, and CoP yielded a highly competent photocatalyst for hydrogen generation. Characterization outcomes corroborated the successful integration of these components and their superior photocatalytic performance, driven by refined charge segregation, light absorption, and catalytic activity. The augmented surface area and modified electronic configuration further amplified the photocatalytic performance, underscoring the potential of MXene-based photocatalysts for sustainable hydrogen energy production.

4. CONCLUSIONS

Hydrogen energy serves as a clean and sustainable alternative to fossil fuels, addressing global energy challenges. The increasing demand for renewable energy has driven extensive research into efficient hydrogen production technologies. Among these, photocatalytic water splitting stands out as a promising approach, directly utilizing solar energy to generate hydrogen in an eco-friendly and sustainable manner. In this study, cobalt phosphide (CoP), graphitic carbon nitride (g-C_3N_4), Ti_3C_2 QD, and their hybrid structures were synthesized to enhance hydrogen production efficiency. These materials were chosen for their excellent light absorption, high surface area, and efficient charge separation capabilities, all of which are critical for improving photocatalytic performance. Various characterization techniques, including X-ray diffraction (XRD), scanning electron microscopy (SEM), transmission electron microscopy (TEM), UV-Vis spectroscopy, and photoluminescence (PL) analysis, were employed to assess their properties and effectiveness. The results demonstrated that hybrid nanostructures significantly improved hydrogen production compared to individual materials. The integration of these components broadens the light absorption range, enhances charge carrier transport, and minimizes recombination losses, thereby increasing photocatalytic efficiency. These advancements highlight the potential of hybrid nanomaterials in renewable energy applications. The findings contribute to the development of next-generation photocatalysts for hydrogen production, offering more efficient and cost-effective solutions. Advancing such materials is essential for the widespread adoption of hydrogen technologies, supporting the transition to a cleaner and more sustainable energy future.

ABSTRACT

Internal combustion engines that use a mixture of hydrogen and gasoline are designed to take advantage of the advantages of both fuels. These hybrid systems can reduce emissions compared to conventional gasoline-only engines. The integration of hydrogen can improve the overall efficiency and performance of the combustion process. In this research a comprehensive statistical modeling approach for ecological and energy gaining parameters was performed. Statistical models were trained using 11 input parameters such as fuel mixture level, petrol mass, petrol energy ratio, ethanol mass, ethanol energy ratio, hydrogen mass, hydrogen energy ratio, total input energy, ratio of pure carbon, oxygen, and hydrogen. Output parameters were n, CO, CO_2, lambda, O_2, HC, NOx, p_i, ISFC, and BTE. The best accuracy for the training set was achieved for n, CO_2, lambda, Pi, BTE, and ISFC with MAPE of 0.45%, 1.29%, 0.55%, 0.85%, 2.02%, and 2.48%, respectively. Developed prognostic models were also validated using test dataset and reached valuable accuracy for n, CO_2, lambda, Pi, BTE, and ISFC with MAPE of 1.67%, 0.97%, 2.66%, 2.56%, 2.61%, and 5.39%, respectively. In this study the developed predictive statistical models achieved high accuracy in predicting the ecological and energetic parameters of engine emissions generated by engines powered by a petrol-hydrogen mixture.

Keywords: hydrogen; petrol-hydrogen mixture; statistical modelling; prognostic models; MAPE.

1. INTRODUCTION

The aim of the study is to determine the effect on the energy and environmental performance of a dual fuel engine of varying concentrations of bioethanol in the liquid fuel injected into the intake manifold and the addition of hydrogen gas to the intake air. The study evaluates the changing elemental composition of dual fuel.

2. MATERIALS AND METHODS

2.1. Experimental equipment

The experimental tests were carried out using a spark ignition (SI) Opel 1.8E engine, the main technical data of which are shown in Table 1. The engine was installed on a test bench with the addition of a fuel consumption scale (xxx) with a measuring range of 0–30 kg and an accuracy of 2 g. The composition of the exhaust gases was measured with a CARTEC CET 2200 C exhaust gas analyser, which measures the emission components, their measurement limits and accuracy: CO, 0–9.99% (vol.), 0.01%; CO_2, 0–19.99% (vol.), 0.1%; HC, 0–9999% (vol.), 1 ppm; NO_x, 0–2000 ppm (vol.), 5 ppm; O_2, 0–25% (vol.), 0.01%; air excess ratio λ, 0.5–2.0%, 0.001. A schematic of the engine test is shown in Fig. 1.

Table 1. Main parameters of the tested Opel 1.8E engine.

Parameter	Specification
Engine code	18NE
Displacement V_H	1796 cm³
Engine configuration	Inline, i = 4 cylinders
Cylinder bore D	84.8 mm
Piston stroke S	79.5 mm
Compression ratio ε	8.9:1
Fuel system	Multi-port manifold injection
Engine aspiration	Naturally aspirated engine
Maximum power P_{max}	74 kW (5800 rpm.)
Maximum torque M_{max}	140 Nm (3000 rpm.)

A hydrogen-oxygen mixture produced by electrolysis from water was supplied to the engine intake manifold before the throttle body. The electrolyser was filled with a 4% mixture of distilled water and potassium hydroxide (KOH). The electrolysis produces a mixture of H_2 and O_2 gases which is labelled HHO. The device used an external energy source (12 V), the energy consumed of which was evaluated by an additional measurement of the amperage. At steady-state

operation, the electrolysis device used a current of ~35 A, which means that the electrical power used by the device is 12x35 ≈ 420 W. It is determined that the power required to generate 1 L/min of HHO gas is 190 W, and it is therefore calculated that 420/190 ≈ 2.2 L/min of hydrogen-oxygen gas mixture was generated during the engine test. 2/3 of the volume of gas generated by the electrolysis device was H_2 gas, but due to the low hydrogen density, only 0.06 g H_2 per litre of HHO gas was present [1]. The H_2 gas flow to the engine during the test was calculated to be ~0.0079 kg/h.
During the test, the engine throttle was fixed at 5% and the engine was operated at increased idle speed $n \approx 2000$ rpm. Ignition timing was fixed at 12 CAD bTDC. The engine under test does not have a lambda control system, so the air excess ratio λ varied with different fuels. The engine oil was heated to ~100° C. The test duration was 1 min, during which time the fuel consumption in B_f was measured. The test was repeated 5 times or more if there were significant differences in the measured values.

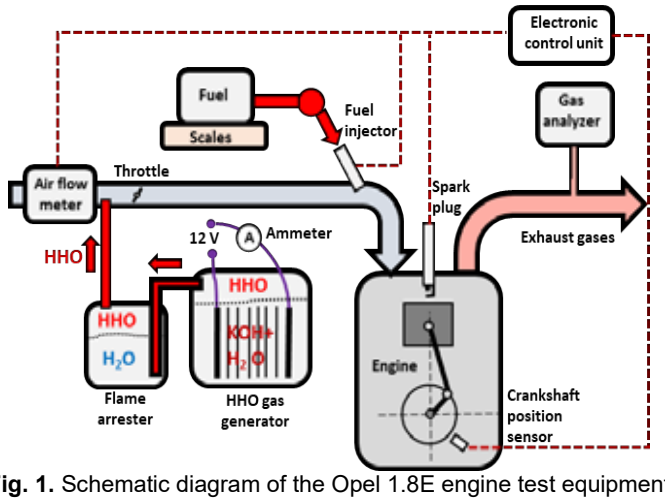

Fig. 1. Schematic diagram of the Opel 1.8E engine test equipment

2.2. Energy characteristics of the engine

The different fuels also varied the energy filling of the cylinders, resulting in different engine speed *n*. The engine was not loaded with additional braking torque and all of the indicative power generated in the cylinders was used to overcome the mechanical resistance-friction of the engine: $P_i = P_F$. Engine friction mean effective pressure, MPa:

$$FMEP = a + b \cdot v_{pist.}, \tag{1}$$

where $a = 0.5;\ b = 0.0155; v_{pist.} = S \cdot n/(30 \cdot 1000)$.
Power of mechanical losses (friction) of the engine, kW:

$$P_F = P_i = \frac{FMEP \cdot V_H \cdot n}{30 \cdot i}. \tag{2}$$

Indicated specific fuel consumption of the engine, g/kWh:

$$ISFC = \frac{(B_{f_{G100}} + B_{f_{E100}} + B_{f_{H_2100}}) \cdot 1000}{P_i}, \tag{3}$$

where: B_{f_G100}, B_{f_E100} *and* $B_{f_H_2100}$ – gasoline, bioethanol and hydrogen fuel consumption, kg/h.
Engine indicate efficiency:

$$\eta_i = \frac{P_i \cdot 3.6}{B_{f_G100} \cdot LHV_{G100} + B_{f_E100} \cdot LHV_{E100} + B_{f_H_2100} \cdot LHV_{H_2100}}, \tag{4}$$

where LHV_{G100}, LHV_{E100} *and* LHV_{H_2100} – gasoline, bioethanol and hydrogen lower heating value, MJ/kg.

2.3. Fuel Properties

The first case study used fuel blend E10, consisting of 10% pure petrol (G100) and 90% pure bioethanol (E100) by volume. The second case used fuel blend E70 consisting of 30% by volume G100 and 70% by volume E100. In the case of dual fuel, E10 or E70 is used to provide additional HHO gas to the intake air, 2/3 of the volume of which is H2. The basic physico-chemical properties of the pure fuels used are given in Table 2.
Increasing the concentration of bioethanol in the fuel increased the oxygen content and reduced the air demand to burn the same amount of fuel. Ethanol, due to its higher latent evaporation temperature, cooled the intake mixture more and increased the density and mass of air in the cylinder. In an engine without lambda control, the above factors contribute significantly to air excess, as the amount of fuel injected depends on the amount of air intake and does not take into account the oxygen concentration in the exhaust gases. With a small variation in fuel injection and a decrease in the *LHV* of the blend as the bioethanol concentration increases, the engine's indicative power decreases and the *ISFC*

increases. The performance of a dual fuel engine is affected by the addition of H_2 when both E10 or E70 fuel is injected into the cylinder and HHO gas is supplied together. Hydrogen increases the combustion speed and combustion quality. The combustion quality is also improved by a higher O_2 content in bioethanol. However, excess oxygen does not increase but even reduces the NOx concentration, due to the greater cooling effect of bioethanol and a significantly leaner mixture. Due to the reduced C/H ratio of the fuel, CO_2 emissions are also significantly reduced. Hydrogen increases the combustion speed and combustion quality. The higher O_2 content in bioethanol also improves combustion quality. However, O_2 does not increase, but even decreases NO_x concentrations, due to the higher cooling effect of bioethanol and the significantly leaner blend. The reduction in fuel C/H ratio also results in a significant reduction in CO_2 emissions.

Table 2. Basic properties of pure fuels.

Parameter		Gasoline G100	Bioethanol E100	Hydrogen $H_2$100
Density at 15°C, kg/m^3		736.0	790	0.09
Lower heating value *LHV*, MJ/kg		43.53	27.0	120.0
Elemental composition, %	C	86.42	52.14	0.0
	H	13.58	13.13	100.0
	O	-	34.73	-
C/H		6.36	3.97	-
Octane number		~95	~109	~130
Adiabatic flame temperature, °C		~2300	~2247	~2207
Laminar flame speed, cm/s		~51	~63	~270
Latent heat of evaporation, kJ/kg		364	840	~120
Stoichiometric air fuel ratio A/F, kg air/1 kg fuel		14.7	9.10	34.5

2.4. Prognostic Model Building

Multivariate linear regression models for predictions of RPM, CO, CO_2, O_2, lambda, HC, NOx, Pi, BTE, and ISFC were build. Models were trained using 11 input parameters such as fuel mixture level, petrol mass, petrol energy ratio, ethanol mass, ethanol energy ratio, hydrogen mass, hydrogen energy ratio, total input energy, ratio of pure carbon, oxygen, and hydrogen. Data set consisted of experimental data when petrol and hydrogen mixture was used. Multivariable regression models were defined as:

$$Y^E = \alpha + \beta X + \varepsilon, \tag{5}$$

where Y^E – engine outcome parameter (dependent variable), E – type of engine outcome parameter, X – prognostic factor (independent variable), ε – random error.

Accuracy between prognostic model and real data was evaluated using mean absolute percentage error (MAPE):

$$MAPE = \frac{1}{N}\sum_{i=1}^{N} \left|\frac{R_i^E - \widehat{Y_i^E}}{R_i^E}\right|, \tag{6}$$

where R_i^E – real engine outcome parameter value for i^{th} experiment, $\widehat{Y_i^E}$ – prognostic engine outcome parameter value for i^{th} experiment, E – engine outcome parameter.

3. RESULTS AND DISCUSSION

Figure 2 compares observed and forecasted (prognosis) counts (n) for four categories: E10, E10 HHO, E70, and E70 HHO. On the x-axis, we have 21 sequential points, each corresponding to specific recorded or projected data. The y-axis shows the numerical values for each category, revealing that E10 and E10 HHO have higher counts (above 2000), while E70 and E70 HHO stay closer to the 1600–1700 range. In each category, the observed and forecasted lines follow generally similar trends, but some differences and crossovers appear. Overall, the prognosis lines tend to track slightly below or above the observed values, depending on the specific data point.

Figure 3 is a correlation matrix showing pairwise relationships among ten variables: n, CO, CO_2, lamda, O_2, HC, NOx, Pi, ISFC, and BTE. In the upper-right triangle, each cell displays a numerical correlation coefficient colored from dark blue (strong positive correlation) to dark red (strong negative correlation). On the diagonal, each variable's distribution is shown by a histogram, revealing the spread of its values. In the lower-left triangle, pairwise scatter plots visualize the trend between two variables, with a smoothed line indicating their general relationship. Overall, we see several strong correlations (e.g., n with CO_2, NOx, or Pi) and strong negative correlations (e.g., lamda with NOx and Pi), suggesting important interdependencies among these variables.

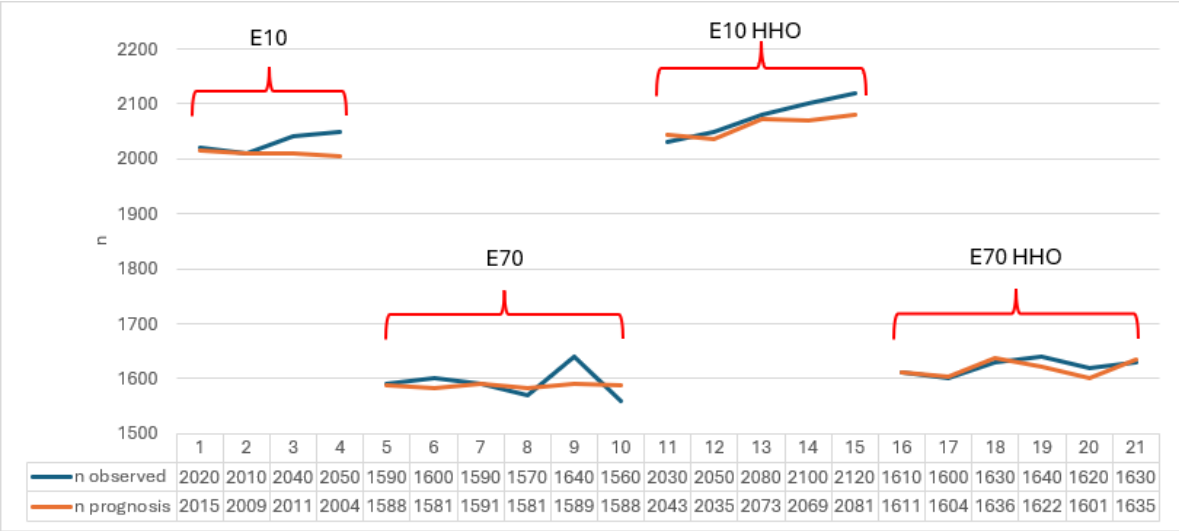

Fig. 2. Comparison of Observed and Forecasted Values for E10, E10 HHO, E70, And E70 HHO

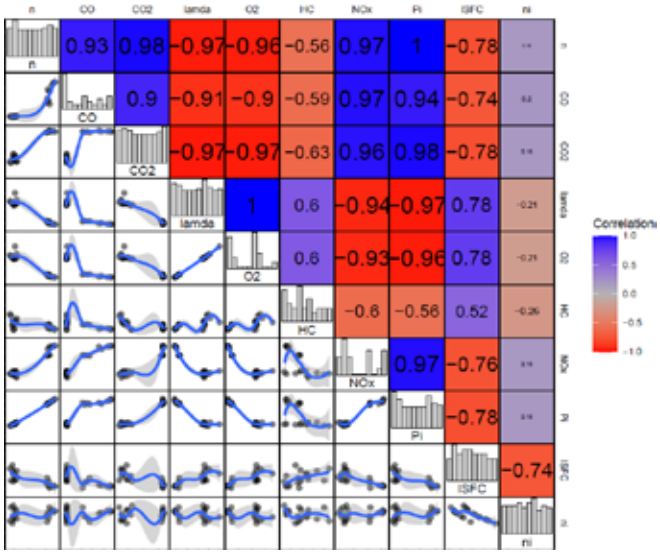

Fig. 3. Correlation Matrix and Pairwise Scatter Plots of Ten Key Variables

4. CONCLUSIONS

1. The high positive correlation between n and CO_2, NOx, Pi indicates that both exhaust gas pollution indicators and engine power increase with increasing engine speed.
2. The negative correlation between lambda and NOx, Pi indicates that a leaner fuel mixture reduces NOx emissions and engine power indicators.
3. Although the correlation between some indicators (e.g. CO and HC) is not very strong, they can be significant under certain engine operating conditions.
4. The overall picture of the correlations indicates that changes in combustion process parameters and exhaust gas composition are closely related.

ACKNOLEDGEMENT

ABSTRACT
Polyvinyl alcohol is a water-soluble, renewable, biodegradable, bio-compatible, environmentally friendly synthetic polymer. Besides that; Solketal was produced with the hybrid material obtained by converting polyvinyl alcohol, which is called the perfect polymer in the literature, into catalytic membrane form with the addition of catalyst. Solketal; developed as a fuel additive to alleviate the negative effects of fossil fuel use, is an environmentally friendly alternative to harmful traditional fuel additives. Solketal was produced from glycerin and acetone in the presence of a functional catalytic membrane as heterogeneous catalysis under environmentally friendly and mild conditions. The catalytic membrane was prepared from polyvinyl alcohol(PVA) as a polymeric matrix and Silicomolybdicacid(SMA), a type of heteropolyacid, as a catalyst. The chemical structure and thermal resistance of the prepared hydrophilic functional catalytic membrane were investigated by FTIR and TGA analyses, respectively. The effects of reaction time, catalyst amount (1,2,3 mmol), acetone/glycerol initial molar ratio (4,5,6) and temperature parameters (40,50,60°C) on solketal yield were investigated in the batch reactions. Maximum solketal yield was obtained as 99,9% at 3 mmol SMA loading, reaction temperature at 60°C, in 1h. Moreover, the reaction parameters catalyst ratio and acetone/glycerol initial molar ratio were investigated statistically by RSM study. **Keywords:** Fuel Additive, Catalytic Membrane, Solketal.

1. INTRODUCTION

Environmental problems related to fossil fuel consumption in the world have become one of the most important problems for people. In particular, many countries, suffer from air pollution caused by toxic gas emissions resulting from the use of fossil fuels in transportations and transport. In recent years, significant increases has been observed in the biodiesel production and use as fuel in order to reduced significant harmful emissions. In fact, it is estimated that biodiesel production has been reach 41.4 billion liters in 2025, an increase of 25% compared to the production exceeding 33 billion liters in 2016 [1]. In biodiesel production, approximately 10% glycerin by weight is obtained as a by-product [2]. The industrial used of glycerin produced as a by-product and its conversion into oxygenated fuel additives has been become a very interesting subject. Oxygen fuel additives were chemical compounds that, when added to the fuel, positively affect the properties of the fuel (kinematic viscosity, density, flash point), increase the octane or cetane number, allowing more efficient combustion, reduce toxic gas emissions, and improve the cold flow properties of the fuel, which has especially important for vehicles in cold climates [3]. Converting glycerin into these compounds through various reactions has an important step both for its evaluation and for cleaner and more efficient combustion in fuels. Solketal, (2,2-dimethyl-1,3-dioxane-4-methanol), synthesized from the reaction of glycerin with acetone help of an acidic catalyst has 5-membered ring cyclic molecule; used for many purposes in the food, polymer pharmaceutical and cosmetic industries its a colorless and odorless [4,5]. Water is released as a byproduct in the synthesis of solketal. Solketal is blended with gasoline and biodiesel as a fuel additive; It improves cold flow properties, increases oxidation stability and flash point, and reduces gum formation and environmental pollution in the fuel mixture [6]. In the synthesis of solketal, traditionally hydrochloric acid (HCl) and sulfuric acid (H2SO4) has widely used as homogeneous catalysts. However, the fact that homogeneous catalysts are difficult to recover from the reaction environment and were weak in terms of reuse has shifted the studies to heterogeneous catalysts. In recent studies, Maurya et al., 2024 synthesized solketal from glycerol and acetone with solid acid SO4-2/ZrO2-Al2O3 catalyst; Under optimized conditions, 99.2% glycerol conversion was achieved at 3% catalyst loading; Acetone/glycerol: 1/10, 70 °C, 180 min [6]. Gujar and Modhera, 2024 synthesized solketal from glycerol and acetone with metal-modified (M=Fe, Co, Ni, Cu, and Zn) M-ZSM-5 catalysts. With the most effective Cu-ZSM-5 catalyst, under optimum conditions (60 °C reaction temperature, acetone /glycerin: 1/4, 0.2 g catalyst amount, 60 min), 99% glycerin conversion was achieved. [7]
Heterogeneous catalysts used as alternatives to homogeneous catalysts was heteropoly acids, zeolites, modified carbon materials, mixed metal oxides [8]. Heteropolyacids, known as green catalysts, were solid acid catalysts that has easily separated, non-corrosive, safe to use, and cause very little waste [9]. Among heteropolyacid catalysts, silicomolybdic acid (SMA) has very good catalytic properties. Silicomolybdic acid has soluble in water, it can be attached to a desired surface or used with a support material; this situation; its has important for recovery and effective use in the reaction system [10,11]. Catalytic membranes prepared by combining membranes and catalysts; it functional materials that performed reaction and sorption processes simultaneously in a single unit [12]. Membranes can be made with various materials, but catalytic membranes are generally polymer structured and can be produced by embedding or coating the catalysts to be used in the reaction in polymeric matrices, or they can be prepared as a result of the polymeric matrix itself being catalytically [13]. Polymeric based catalytic membranes; depending on the physicochemical properties of the polymer; it can be hydrophilic or hydrophobic. The polymeric matrix is used with its absorption-supported feature in

hydrophilic catalytic membranes; it removes the water molecule released as a by-product in the reaction from the environment and encourages product formation by shifting the reaction balance towards the product [14]. Polyvinyl alcohol is a water-soluble, renewable, biodegradable, biodegradable, biocompatible, environmentally friendly synthetic polymer [15, 16]. In addition, it is a good candidate for catalytic membrane production with its good film-forming properties and chemical stability. There are very limited number of solketal syntheses with catalytic membranes in the literature. Hilmioğlu, et al., 2023, synthesized solketal from glycerin and acetone with an acidic catalytic membrane they produced by blending acidic poly (2-acrylamido-2-methyl-1-propanesulfonic acid) PAMPS polymer and PVA. They observed that solketal yield increased as PAMPS content increased, and 95% yield was obtained under optimum conditions (60°C, 3 hours, M:6/1) [17]. This study aims to synthesize fuel additive solketal with acid-functionalized heterogeneous catalytic membrane under environmentally friendly conditions (atmospheric pressure, low temperature, without toxic solvents). With the heterogeneous catalytic membrane used, the recovery of homogeneous silico molybdic acid will be easy and can be used in the reaction again. With this method, homogeneous acidic catalysts can be used in a more active and environmentally friendly way. Thanks to the water sorption support provided by the high hydrophilic PVA polymer, the by-product water will be removed from the reaction medium, and product formation will be supported.

2. MATERIALS AND METHODS

2.1. Materials

PVA (polyvinyl alcohol) (MW~125,000) in solid form, and SMA (silico molibdic acid) solution were acquired from Sigma-Aldrich, while Merck Chemicals provided glycerin (≥ 99%), acetone (≥ 99.0%), and toluene (≥ 99.9%).

2.2. Preparation of Functional Catalytic Membrane

PVA pellets were dissolved in water for 3 hours at 90°C to obtain a 6% PVA solution by weight. Certain amounts of the prepared solution were taken and 1 mmol, 2 mmol, and 3 mmol of SMA acid catalyst were added to the solutions. After stirring the polymer-catalyst mixture for 1 hour, it was poured onto Teflon plates and left to dry at room temperature.

2.3. Batch Reaction System

Acetalization reactions were carried out in the batch reaction system in Figure 1 with the prepared PVA/SMA functional catalytic membrane, 1, 2, 3 mmol catalyst loading 40, 50, 60°C temperatures, and M: 4/1, 5/1, 6/1 acetone/glycerol initial molar ratios in 1 h reactions.

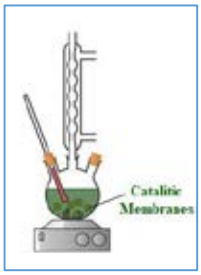

Fig. 1. Batch Reactor System

2.4. Analysis of reaction products

Solketal; was analyzed by gas chromatography (GC-FID). The detector temperature was set to 350 while the DB WAX capillary column was used as the column. Solketal yield was calculated from Equation 1; [18]

$$\textit{Solketal yield (\%)} = \frac{\textit{Mole of produced Solketal}}{\textit{Initial mole of glycerin}} x100$$

3. RESULTS AND DISCUSSION

3.1. Chacterizations of the Catalytic Membrane

3.1.1. FT-IR &TGA Analysis

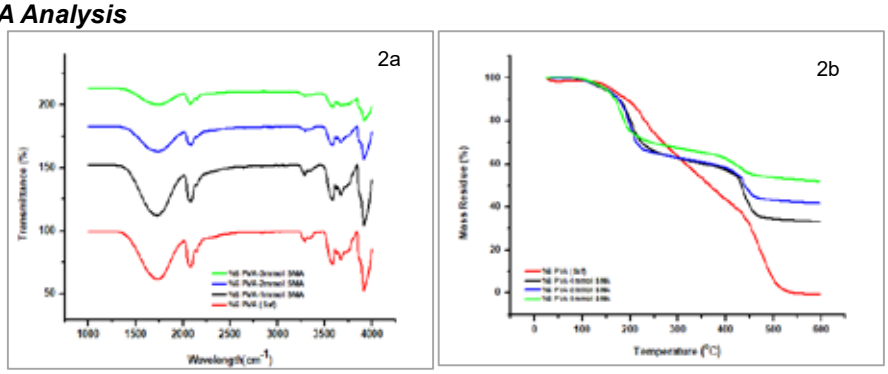

Fig. 2. (a) FT-IR Characterization of Hybrid Catalytic Membranes with SMA Catalysts; (b) TGA Characterization of Hybrid Catalytic Membranes with SMA Catalysts

FT-IR characterizations of the prepared pure PVA and PVA-SMA functional catalytic membranes are given in Fig 2a. According to the FT-IR characterization; the broad peak around 3550–3200 cm-1 can be explained as -OH stretching vibration from intermolecular hydrogen bonds [20]. The 2980 and 2800 cm-1 vibration band represent the C–H group [15, 21]. As for SMA, the peaks of Mo=O, Mo–O–Si, and Mo–O–Mo bonds, which constitute its chemical structure, are seen in the areas of 956 cm-1, 910 cm-1 and 825 cm-1, respectively. These peaks were confirmed by comparison with the literature. The peaks occurring in the band between 1700 cm-1 and 1800 cm-1 were considered cross-linking peaks thanks to the acid-active areas in the SMA catalyst [22].
Thermal degradation curves of the prepared pure PVA-SMA functional catalytic membranes were examined with a Mettler Toledo brand thermal gravimetric analysis (TGA) device between 25 °C and 600 °C. The solvent of all polymeric membranes used in this study is water, and water exists in different states within the PVA blend membranes; solvent water; It forms the polymeric solution in two different ways: firstly, it exists in the form of water molecules held by weak bonds on the outer or inner surface without interacting with the chemical matrix that forms the polymer, and secondly, in the form of water molecules strongly bonded to hydroxyl groups. TGA characterizations of the prepared PVA-SMA functional catalytic membranes are given in Figure 2b.While the primary region between 50-200 °C is the loss of water molecules in the polymer solution forming the membrane, the secondary region between 200-450 °C is related to water loss due to the polymer matrix. The first weight loss in the temperature range of 50-200 °C is due to the removal of water molecules, which are the solvent of the polymers that form polymeric membranes. Secondary weight loss occurred between 200-485 °C due to the loss of organic components. The tertiary weight loss is due to the decomposition of the bonds in the SMA structure between 485-600 °C, and the stable appearance of the graph explains that only metal oxide residues (Si-O-Mo) remain [21].

3.2. Swelling Testing of PVA-SMA Catalytic Membrane

Swelling tests; are performed to determine the affinity of a material to its solvent or to the reactants in the environment to be applied or to the products produced with the input reactants in the reaction to be used. Solketals reaction performed in this study; It is a transesterification reaction that releases water as a byproduct. The simultaneous presence of water and the product produced in the reaction environment reduces the reaction efficiency. Eliminating this situation and shifting the reaction towards the products (Le Chatelier's Principle) is possible by continuously removing water from the reaction medium. For this reason, the catalytic hybrid membrane used must be hydrophilic. Water sorption results of the catalytic hybrid membrane used in the reaction are given in Table 1. Sorption % values were calculated with Equation (2) [20]:

$$Swelling\ (\%) = \frac{W_{wet} - W_{dry}}{W_{dry}} x100 \quad (2)$$

Table 1. Investigation of Water Sorption of Hybrid Catalytic Membranes with SMA Catalyst

Membrane	Swelling (%)
Pure PVA	290.2
PVA-1mmol SMA	235.5
PVA-2mmol SMA	196.6
PVA-3mmol SMA	183.4

As a result of weighings made at 30-minute intervals for 6 hours, the swelling value of the membrane was determined as for PVA-1mmol SMA, PVA-2mmol SMA, PVA-3mmol SMA 235.5, 196.6, 183.4%. The swelling percentage did not change as a result of 24-hour weighing.

4. CONCLUSIONS

In this study, fuel additive solketal was produced under environmentally friendly and mild conditions with the prepared functional catalytic membrane. The produced functional hydrophilic catalytic membrane catalyzed the membrane reaction with SMA loading and simultaneously removed the by-product water from the reaction medium with the hydrophilicity of PVA, thus ensuring that the reaction balance was directed towards the formation of products. In addition, the produced catalytic membrane acted as a green heterogeneous catalyst and was easily recovered from the medium after the reaction. While successful loading of SMA was observed with FT-IR characterization, SMA added to the structure increased the thermal resistance of the catalytic membrane compared to pure PVA with TGA analysis. Moreover, it was observed that the thermal resistance increased even more in direct proportion to the SMA ratio. The affinity of the functional catalytic membrane to the by-product water was determined by swelling tests and interaction parameter calculations. It was observed that the membrane had a high affinity for water with swelling tests, and this ratio decreased as the SMA ratio increased. The interaction parameter of PVA/SMA catalytic membranes is closer to zero compared to pure PVA, and it can be said that SMA added to the structure increases the water affinity in the membrane. In terms of catalytic performance, the acidity of the catalytic membrane was determined by ion exchange capacity calculations. An increase in ion exchange capacity was observed as SMA loading increased. In the batch reactor studies, the maximum solketal yield was obtained as 99.9% at 3 mmol catalyst loading, M:6/1, 60°C and one hours of reaction time. Also RSM study will be conducted within the scope of this experimental study. The effects of catalyst loading and acetone/glycerin

initial molar ratio on solketal yield will be investigated statistically in the central composite design design and at constant temperature in full text.

ABSTRACT
This paper presents the design and techno-economic analysis of an off-grid, wind-powered green hydrogen production system optimized for a Maritime Autonomous Surface Vessel (ASV). Utilizing component modelling, including Proton Exchange Membrane (PEM) electrolysis, and hourly wind resource simulations, the study demonstrates the system's capacity to meet the target vessel's annual demand of approximately 3.9 tonnes H_2. The techno-economic evaluation yielded a Levelized Cost of Hydrogen (LCOH) of approximately £2.77 per kg. This result indicates economic competitiveness and supports the technical feasibility of deploying autonomous, renewable hydrogen solutions to power specialized maritime applications, particularly in remote or off-grid scenarios.

Keywords: Green Hydrogen Production, Maritime Application, Multi-Criteria Decision Making, Techno-economic Analysis, System Design

1. INTRODUCTION

Maritime decarbonization has emerged as a global imperative, driven by commitments from numerous nations to reduce greenhouse gas emissions in alignment with international climate agreements, most notably the Paris Agreement. The International Maritime Organization (IMO) has set ambitious targets to halve greenhouse gas emissions from shipping by 2050, striving towards full decarbonization by the end of the century [1]. The inherent dependence of the shipping industry on fossil fuels, coupled with the increase in global trade, necessitates the exploration of alternative energy carriers to achieve these decarbonization goals.

Green hydrogen stands out as a viable candidate for this transformation, due to its potential to provide a zero-emission fuel alternative when produced using renewable energy sources. Several studies show that large-scale green hydrogen production can effectively decarbonise various energy sectors, including maritime applications [2, 3]. For instance, the co-development of offshore wind and hydrogen production is being explored extensively in regions like the UK [4-6], where green hydrogen can serve not only as fuel for maritime vessels but also to transport renewable energy across long distances [7]. This dual function increases hydrogen's appeal, especially given its ability to integrate with existing energy infrastructures [8].

While the literature predominantly discusses large-scale hydrogen production, there remains a critical literature gap regarding the optimization of small-scale production systems, particularly combining wind turbine technology and electrolyzers tailored for maritime uses. The application of such systems in ports is particularly promising but underexplored. The dynamics of local wind availability and fluctuating hydrogen demand profiles present unique challenges [8].

Despite these advances, existing studies rarely align system design with a real-world vessel's daily operational requirements. This work differs by integrating the hydrogen demand profile of an already manufactured, operational, autonomous surface vessel into the system sizing process. The model employs a dynamic, hourly-resolved simulation to match local wind availability to electrolyser input and utilises a TOPSIS-based multi-criteria decision-making (MCDM) framework for optimal wind turbine selection. Rated power, capacity factor and LCOE are objective criteria for identifying the configuration that best satisfies economic and technical performance targets.

By combining demand-driven system modelling, real vessel requirements, and multi-objective optimisation, this study offers a novel and practical framework for deploying scalable, cost-effective green hydrogen infrastructure at ports. This contributes to the broader goal of maritime decarbonisation through renewable energy integration.

2. MODELLING

2.1. System Overview

Figure 1 shows the general system topology. An onshore Horizontal Axis Wind Turbine (HAT) provides electrical power to a PEM electrolyser, which splits purified water (via Reverse Osmosis (RO) desalination) into hydrogen and oxygen. A hydrogen compressor then raises the pressure to 350 bar for on-site storage, ready to fuel the autonomous vessel.

2.2. Wind Resource Characterization

The Port of Plymouth (50.357°N, –4.1245°E) was selected for its favourable average wind speeds (7.8–8.7 m/s annually). The wind speed distribution for 2023 is further illustrated in Figure 1 in the form of a histogram and fitted Weibull distribution.

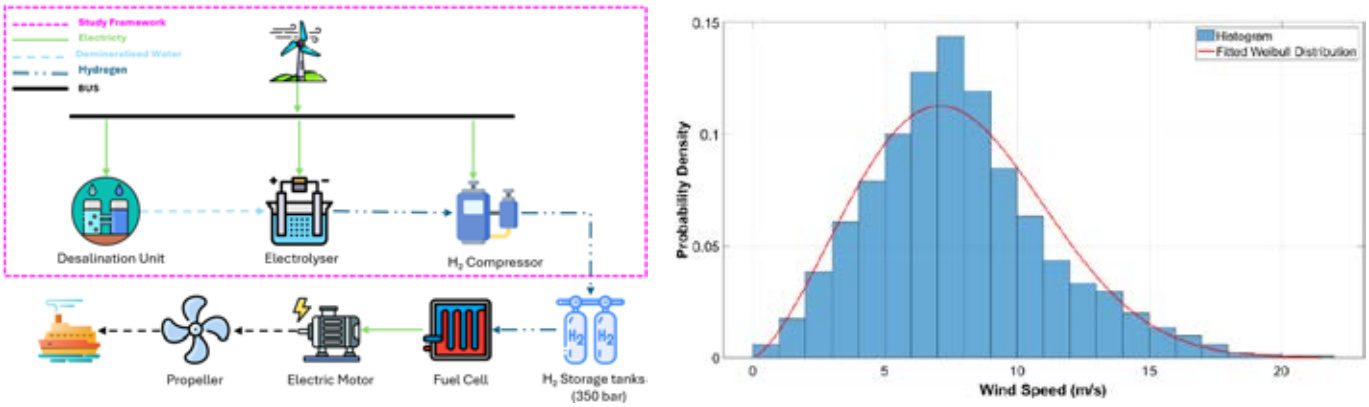

Fig. 1. Schematic of the wind-to-hydrogen production system (left) and Wind Speed Distribution for Plymouth Port (right)

Hourly wind data from the MERRA-2 database was height-adjusted to the turbine's hub (H) using the power-law equation:

$$v(h) = v_{ref}\left(h/h_{ref}\right)^{\alpha} \tag{1}$$

where v_h denotes the estimated wind speed at a specific height h, while v_{ref} indicates the measured reference wind speed at a known height. The power law exponent (α), the wind shear coefficient is a dimensionless value reflecting atmospheric stability and surface roughness. This study uses a wind shear coefficient of 0.16 as a representative value for coastal areas characterised by relatively smooth terrain [9].

2.3. Key Components

The system's key components include a wind turbine, desalination unit, electrolyser, and compressor. Detailed specifications of the key components parameters and their values are given in Table 1.

Table 1. Used parameters and values of the key components for the hydrogen system model

	Parameter	Value Range/Value	Unit	Reference
Wind Turbine	Rotor Diameter Range	20-100	m	[10]
	Hub Height Range	30-120	m	[10]
	Cut-in Wind Speeds	3, 4, 5	m/s	[10]
	Rated Wind Speeds	6-12	m/s	[10]
	Cut-out Wind Speeds	25-30	m/s	[10]
	Max Power Coefficient	0.45	-	[9]
	Mechanical Losses	3	%	[11]
	Electrical Losses	4	%	[10]
	AC-DC Converter Losses	3	%	[10]
	Reference Height (z_{ref})	50	m	[10]
	Power Law Coefficient (α)	0.16	-	[10]
	Reference Capacity	20	kW	[12]
	Reference Purchase Cost	1086	£/kW	[12]
	Scale Index	0.9	-	[12]
	Land Cost	6	% of CAPEX	[12]
	OPEX per kW per year	50	£/kW/year	[12]
Desalination Unit	Recovery Rate	0.5	kg freshwater/ kg seawater	[13]
	Inverter Losses	5	%	[14]
	Specific Energy Consumption	0.0427	kWh/kg H_2	[13]
	CAPEX Rate	1284.8	£/(m³/day)	[15]
	OPEX Percentage	3	% of CAPEX	[16]
PEM Electrolyser	Annual Hydrogen Production Target	3.9	Metric ton/year	[17]
	Initial Degradation Rate	1.0	-	-
	Stack Correction Factor	1.0	-	-
	Stack Lifetime	80000	hours	[18]

	CAPEX Rate	1388	£/kW	[22]
	OPEX Percentage	3	% of CAPEX	[14]

2.4. Sizing Procedure

The following stepwise algorithm ensures the final system can supply the annual hydrogen target (~3.9 tonnes/year) for USV Pioneer:

Step 1: Electrolyser Rating: Determined from:

$$P_{elec}^{rated} = \left(m_{H_2,daily} \times SEC_{elec}\right)/(\eta_{stack} \times CF_{elec} \times 24) \quad (2)$$

where $m_{H_2,daily}$ is the daily H_2 target, SEC_{elec} the specific energy consumption, η_{stack} a conservative stack efficiency accounting for degradation and CF_{elec} the electrolyser capacity factor.

Step 2: Compressor and desalination unit sized proportionally based on electrolyser throughput and known energy consumption profiles.

Step 3: For each candidate wind turbine (varying rotor diameter, hub height, cut-in/rated speeds), the annual energy production (AEP) is computed using:

$$AEP = \sum_{t=1}^{8760} P_{wt,}(v_t) \times \Delta t \quad (3)$$

where v_t is the wind speed at the time step t, and Δt is the step duration from the calculated E_{annual}, the levelized cost of energy (LCOE) then follows:

$$LCOE_i = \sum_{t=0}^{n} \frac{CAPEX_i + OPEX_{i,t}}{(1+r)^t} \Bigg/ \sum_{t=0}^{n} \frac{E_{i,t}}{(1+r)^t} \quad (4)$$

where $CAPEX$ is the initial investment, $OPEX_{i,t}$ the annual operating cost at the year t, $E_{i,t}$ the energy generated in the year t, n the project lifetime, and r the discount rate. A lower LCOE implies greater cost-effectiveness.

Step 4: The TOPSIS method ranks turbines on (i) closeness to required rated power, (ii) LCOE, and (iii) capacity factor. The highest scoring turbine is selected.

2.5. Levelised Cost of Hydrogen

This study's techno-economic analysis evaluates project feasibility by estimating capital expenditure (CAPEX) and operating expenditure (OPEX). CAPEX is determined using methods like the Scale Index approach to account for system size variations. OPEX includes costs such as maintenance, parts replacement, and consumables. The primary evaluation metric is the Levelized Cost of Hydrogen (LCOH), calculated by dividing the discounted sum of total lifetime costs (CAPEX and OPEX) by the discounted total hydrogen production over the same period, as shown in Equation 5:

$$\mathrm{LCOH} = \frac{\sum_{t=0}^{T} \frac{(CAPEX_t + OPEX_t)}{(1+r)^t}}{\sum_{t=0}^{T} \frac{m_{H_2,t}}{(1+r)^t}} \quad (5)$$

LCOH represents the average production cost per unit of hydrogen, enabling comparison between different system configurations and guiding optimal design decisions for green hydrogen production systems.

3. RESULTS AND DISCUSSION

3.1. Optimal Hydrogen Production System Configuration

Since different capacity factors impact the required rated power of the electrolyser, alternative configurations were also assessed. Based on this analysis, a capacity factor of 0.9 was chosen, as it balances efficiency and system reliability while minimising the required rated power**.** Table 2 summarises the final component sizing for the hydrogen production system. This includes the selected electrolyser, compression system, desalination unit, and respective energy requirements.

Table 2. Final Hydrogen Production System Sizing Parameters

Component	Parameter	Value	Unit
Electrolyser	Rated Power	30.9	kW
	SEC @Rated Power	55	kWh/kg H_2
	Stack Lifetime	80,000	Hours
Compressor	Rated Power	**3.9**	kW
	SEC	6.9	kWh/kg H_2
Desalination Unit	Rated Power	0.0242	kW
	Recovery Rate	50	%
	SEC	0.0427	kWh/kg H_2

Applying the above method to wind data from Plymouth identified a moderate-scale turbine (approximately 43 kW rated output, hub height ~50 m, rotor diameter ~30 m) as top-ranked, as depicted in Table 3.

Table 3. Overview of MCDM outcomes for selected turbine candidates

Hub Height (m)	Rotor Diameter (m)	Cut In Speed (m/s)	Rated Speed (m/s)	Rated Power (kW)	Annual Energy (MWh)	Annual Capacity Factor (%)	CAPEX (£)	OPEX (£/y)	LCOE (£/kWh)	Rank
36	**32**	**3**	**6**	**43.25**	**312**	**82.41**	**49255**	**2162**	**0.01719**	**1**

33	26	5	7	45.34	284	71.54	51258	2267	0.01971	6
37	34	3	6	48.82	353	82.59	54570	2441	0.01696	7

3.2. Hydrogen Production Cost and Emissions

Over 8760 hourly wind resource simulations, the system produced **~3.9 tonnes H2_22/year**. The computed **Levelised Cost of Hydrogen (LCOH)** was around **£2.77 per kg**—significantly competitive for an autonomous vessel requiring ~3.9 tonnes per annum. A detailed breakdown of this LCOH, presented in Figure 2, reveals that the primary cost drivers are the capital expenditures (CAPEX) for the wind turbine and electrolyser. Operating expenditures (OPEX), particularly for electrolyser stack replacement and wind turbine maintenance, also form a significant portion of the cost. This LCOH represents the direct production cost; potential requirements for large-scale storage or distribution would incur additional expenses. H_2

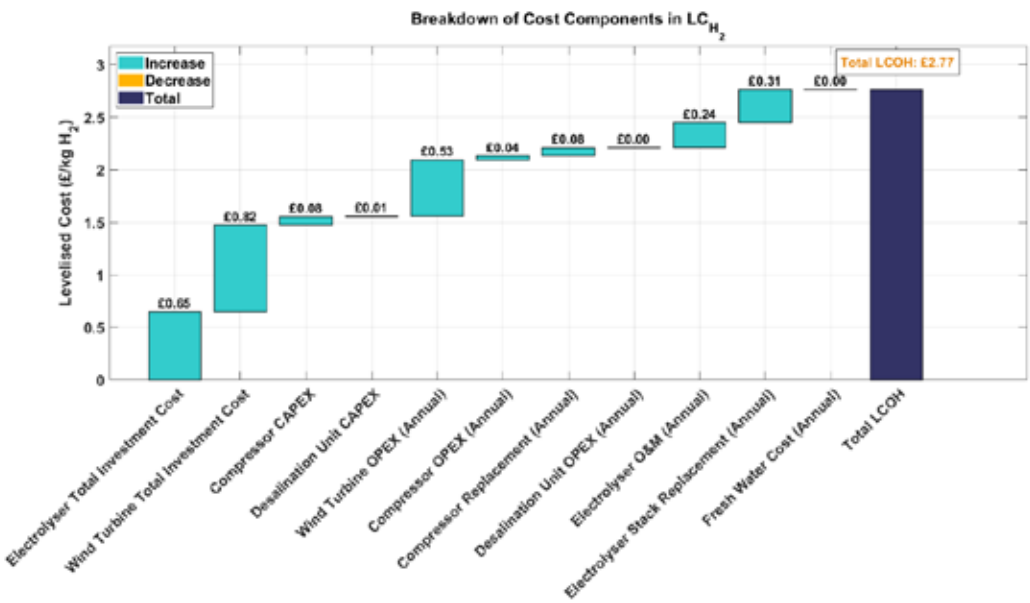

Fig. 2. Detailed LCOH Breakdown for a Wind-Powered Hydrogen Production System

4. CONCLUSIONS

This study successfully designed and evaluated a wind-powered green hydrogen production system tailored for a Maritime Autonomous Surface Vessel (ASV). Simulations confirmed the system's capacity to meet the target vessel's annual demand of approximately 3.9 tonnes H_2. The techno-economic analysis yielded an LCOH of roughly £2.77 per kg, demonstrating competitiveness for this specific off-grid application. The primary cost drivers were identified as the capital expenditures for the wind turbine and electrolyser, with operational costs also contributing significantly. These findings support the feasibility of localized, renewable hydrogen generation for niche maritime applications, providing a baseline for direct production costs.

ABSTRACT
Electricity generation from sustainable and renewable energy sources is one of the priority topics with research potential in our country. With the increase in investments in electricity generation from wind and solar energy, the development of electricity storage systems for use in smart station systems connected to electric vehicle projects, and the increase in investments in smart grid storage systems in many areas, studies in the field of electricity storage have also accelerated. Vanadium redox batteries are one of the leading technologies that can be used in smart electricity grids, providing high efficiency storage of grid electricity and advanced performance (charge-discharge efficiency, cycle life). In this study, it is aimed to produce a new membrane that is alternative to Nafion, durable, cheap and at the same time has a high proton transfer capacity. It is aimed to increase the proton transport mechanism of this membrane by increasing its hydrophilicity and bonding ability and by creating porosity. In this context, polyphenyl sulfone (PPSU), an important engineering polymer, was sulfonated and produced in the form of electrofiber and basic polymer electron membrane tests were performed. According to the test results, both ion exchange capacity and proton conductivity values were obtained as 2.1 meq/g and 1.68 x10^{-2} S/cm, respectively.

Keywords: polyphenyl sulfone, polymer electrolyte membrane, sulfonation, redox battery

1. INTRODUCTION
Today, with the increase in global energy problems and the decrease in the amount of fossil fuel resources and the increase in environmental damage, interest and investments in renewable energy resources are increasing rapidly. Renewable resources are diversified as solar energy, wind energy, geothermal energy resources and bioethanol, biodiesel, biogas, biohydrogen produced from biomass. The easiest of these sources to produce are solar, wind and geothermal energy. Turkey is a country with high potential for sustainable energy resources in many respects. Investments are accelerating especially for wind energy and the amount of investment in solar panels is increasing for solar energy. However, in both cases, the energy generated is non-continuous and uncontrollable. The electricity generated needs to be stored in order to be used in the consumption line. In addition, with the rapid increase in the number of electrically powered vehicles in recent years, the energy requirement at power stations is increasing. In order to obtain this energy from wind and sun, it must be stored and distributed under suitable conditions.

Redox flow batteries (RABs) are high-capacity electricity storage systems with high energy efficiency (>75%), feasible installation cost, high number of cycles (>20,000), long lifetime and low toxicity. Another advantage of RAB systems is that the capacity and power of the battery depend on independent factors. The capacity of the battery depends on the amount of electrolyte stored, the concentration of active species, the voltage and number of individual cells, while the power generated is related to the behavior of the active species and the electrode size. This facilitates the scalability and flexibility of technology. The simplicity of the flow battery and the reversible redox reaction realized by the presence of two soluble redox pairs allows the cycle to be theoretically unlimited. These systems can adapt well to various power applications due to their short response times of milliseconds [1]. Ultimately, this makes them suitable for integration into renewable energy generation systems such as photovoltaic (PV) systems and wind power.

The main objective of this study is to produce high performance and durable VRAB membranes as an alternative to Nafion. Accordingly, in terms of durability and cost, commercial polymeric engineering materials come to the forefront. Polyphenylsulfone (PPSU) is an engineering polymer with high chemical oxidation stability/durability, mechanical strength and relatively low price [2]. Therefore, since it can be produced in high quantities as a film with engineering production techniques, it is low cost and commercializable as an end product. VRAB membranes made with this polymer were found to have low vanadium permeability. However, the intrinsic ion conducting capacity of this polymer is very low.

Polyphenylsulfone is a fully aromatic high-performance engineering polymer known as amorphous thermoplastic materials. Its high chemical and physical properties have led to its use as a proton exchange membrane in PEM fuel cells [3]. Due to its high stability under acidic conditions due to the phenyl groups it contains and its competitive production cost, it has a high potential to be used as a redox battery membrane. Despite this, very limited research has been conducted on this subject. One of the most important features of this polymer is the permanent increase of proton

conductivity by the addition of sulfonic acid groups to the aromatic polymer backbone by chemical processes [4]. These groups also increase the hydrophilicity of the material with high hydrophobicity. The lack of detailed investigations of such a functional and durable polymer in VRAB studies and the lack of modifications that would allow its commercial use was seen as a major deficiency, and the project aimed to produce functional PPSU membranes that could be used in vanadium batteries.

2. MATERIALS AND METHODS

2.1. PPSU sulfonation

For the addition of sulfogroups, a solution containing 20% PPSU was prepared using only NMP (acetone was not added because it causes phase separation). The solution was stirred at 35°C for 24 hours. Then this solution was placed in an ice bath and chlorosulfonic acid was added dropwise (4-5 mL for 4 g PPSU). The ice bath was used to control exothermic reaction. The solution was stirred for 5 minutes and kept in the refrigerator for 1 day.The next day, the solution was poured into ice water at around 0°C with the tip of a spoon in order to form fibers from the solution. At this time, a collapsed fiber-like structure was obtained. These fibers were kept in ice water for 3-5 hours, then washed 6-7 times with distilled water to pH 5 and dried at 80°C overnight to obtain sulfated PPSU (sPPSU).

2.2. PPSU fiber membrane production

Initially, 20 different recipes were tested and the most suitable solution for electrospinning was determined to be a formulation containing 30% PPSU, 20-30% acetone and the rest NMP. This solution was stirred at 35°C for 24 hours. When the appropriate viscosity was achieved, fiber production was achieved in the electrospinning device with 20 kV voltage, 15 cm needle-collector distance and 0.015 mL/h flow rate. The fibers obtained in this way were defined as “PPSU fibers”.

2.3. Membrane characterization

After the membranes were prepared, ion exchange capacity, sulfonation degree, swelling degree, and the empirical porosity were determined according to the degree of sulfonation. The chemical bond structures of the membranes were determined by FTIR analysis. then the mechanical analysis of the prepared membranes were calculated and finally the proton conductivity values were determined. Using Versastat 3-500 electrochemistry workstation and the electrochemical impedance spectroscopy technique (EIS), the proton conductivity of membrane were determined. Platinum wires served as electrodes, and the membranes were positioned between two Teflon plates at 100% humidity. Home-made in-plane system was used for the conductivity test. For the first 24 hours, the membranes were submerged in distilled water. Then, the membranes were put in between the electrodes, which are made in a Teflon block. The membranes' impedance spectra were captured at frequencies between 0.1 Hz and 1 MHz. The conductivity measurements were done using Equation 1. Where σ is the proton conductivity (S/cm), L (cm) and A (cm^2) are the thickness and conductive area of the membrane, respectively. R is the resistance (Ω) of the membrane

$$\sigma = L/R.A \quad (1)$$

3. RESULTS AND DISCUSSION

Figure 1a shows the effect of the degree of sulfonation on the bond structures in the FTIR analysis results. In the unsulfonated and low blended membrane, both SO_3- peaks are weak and the O-H band has a narrow structure. However, as the sulfonated PPSU content increased, the intensity and width of the peak observed in these two regions increased significantly. In the graph, it is observed that the intensity of the -OH peak observed in the 3200-3400 cm^{-1} range also increases in the samples where the amount of sulfonated PPSU increases. This peak belongs to the hydroxyl (-OH) groups in the sPPSU structure and can be caused by three main reasons: Formation of free hydroxyl groups in the polymer structure during or after sulfonation, hydrophilic SO_3H groups attracting water and hydrogen bonding of sulfonic acid groups with water molecules. These observations reveal that the degree of sulfonation can be directly monitored via FTIR and the sulfonic group concentration is clearly reflected in the FTIR spectrum. In conclusion, the structural characterization demonstrated the successful production of sulfonated PPSU.

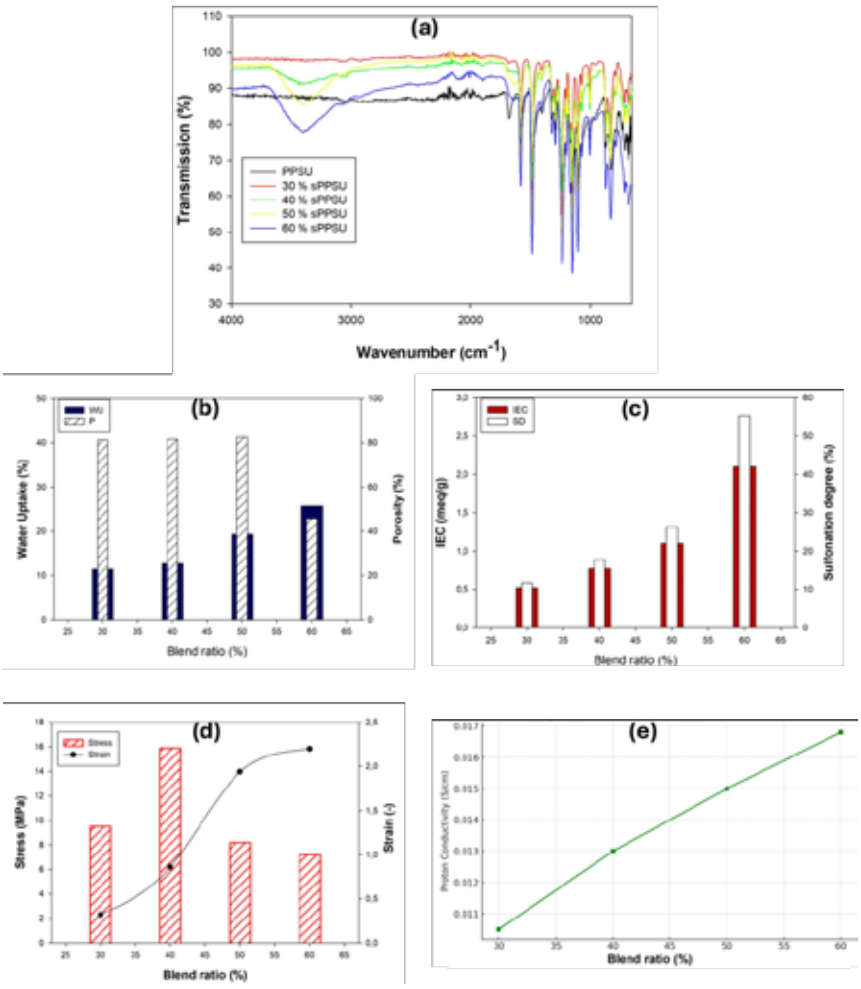

Figure 1. FTIR spectra (a), water uğtake and porosity (b), ion exchange capacity and sulfonation degree (c), mechanical results (d) and proton conductivity results (e) of membranes

Water retention studies were performed in nonporous form, while porosity calculations were performed with electrofiber films. Water retention is especially important for proton transfer. nonporous membranes are used in fuel cells and batteries, where the water retention value of the membrane is critical for proton transfer. In porous membranes, the swelling value is less important. In this study, membranes with increased hydrophilicity in addition to porosity were produced to increase both proton transport and conduction capacities. This is achieved by the degree of sulfonation of the membrane, i.e. the blending ratio of the sulfonated polymer. Figure 1b shows the water retention value and empirical porosity data. Thanks to their hydrophilic nature, sulfonic groups form strong hydrogen bonds with water molecules. These interactions increase the distance between the polymer chains, increasing the water holding capacity of the structure and thus the swelling rate. Since both sample groups contain sulfonated solution, this effect is observed in all samples. However, the main difference that determines the amount of swelling is the amount of PPSU in the formulation; membranes with more PPSU appear to exhibit higher swelling ratio [5].

Especially when used in combination with sulfonated solution, water retention is facilitated by the effect of hydrophilic groups, which increases the formation of micro and macropores. In other words, the coexistence of high PPSU content and sulfonic groups optimizes the phase separation process, resulting in higher porosity values. It is also noteworthy that there is a significant correlation between porosity ratios and swelling behavior. Especially membranes with high water retention capacity can be said to have larger or connected pore structure. This may provide advantages in terms of ion transport and proton conductivity, since high porosity allows ions to be transported more easily across the membrane, while increasing the total permeability [6]. However, this increase in porosity may not always lead to positive results. Excessively porous structures may cause negative effects, especially in terms of mechanical stability and ion selectivity. Therefore, a balance between performance and durability should be struck in membrane design, and the polymer ratio and solvent system should be carefully optimized.

IEC (Ion Exchange Capacity) analyses provide critical data to evaluate the proton conduction potential of membranes

for vanadium redox flow battery applications. IEC value refers to the number of protons that a membrane can exchange per unit mass and is one of the main parameters that determine membrane efficiency, especially in energy storage systems. As can be seen in Figure 1c, with the increase in the percentage of sulfonated polymer, i.e. the blend amount, from 25% to 60%, both the IEC value and the related sulfolization value increased significantly. Figure 1d shows the mechanical properties of the sulfonated blended membranes. The sulfonation fisrtsly increased strength then cause a decrease. The mechanical properties of membranes containing sulfonated PPSU show significant changes depending on the degree of sulfonation. As a result of tensile tests, a significant increase in both tensile strength and elasticity was observed, especially in blend membranes containing 30-40% sulfonated PPSU. The presence of sulfogroups promotes hydrogen bond formation between polymer chains, increasing chain mobility and facilitating water uptake into the structure [7, 8]. Moderate levels of sulfanation allow for the preservation of internal structural bonds with sufficient water retention capacity in the polymer network, resulting in a balanced mechanical performance. However, when the sulfation rate increases to 50% and above, the presence of a large number of hydrophilic groups increases the water uptake excessively, which increases the inter-chain distance and weakens the bond strengths, leading to loosening of the membrane structure and decreased tensile strength.

Figure 1e shows the effect of sulfonation on proton conductivity. Sulfonic groups directly affect not only swelling behavior but also important functional properties such as proton conductivity. Especially in fuel cell technologies, proton conduction is often mediated through sulfonic groups. This conduction mechanism is a process known as the Grotthuss mechanism, in which a proton hops from one water molecule to another. Therefore, as the sulfonic group content in the membrane structure increases, both the swelling rate and proton conductivity increase. Therefore, depending on the application, the optimum sulfonic group content and the amount of PPSU should be determined and a balance of both conductivity and structural strength should be achieved [9]

4. CONCLUSIONS

In this study, electrofiber membranes were produced with sulfonated PPSU and tested for their usability in vanadium redox battery. Accordingly, the swelling value increased as the degree of sulfonation increased, while the porosity first increased and then decreased. It was decided that it was structurally unsuitable because excessive swelling was observed at 60% sulfonation degree. However, sulfonation caused first an increase and then a decrease in mechanical strength. Optimally moderately sulfonated polymer was found to have a strength of 10 MPa and above. IEC value and proton conductivity increased gradually with sulfonation. 2.1 meq/g IEC was obtained at 60% sulfonation and at this point the proton conductivity showed the same value as Nafion. As a result, it was observed that a very cheap polymer exhibited results competitive with Nafion after sulfonation. In the continuation of the study, this membrane will be used in a vanadium redox battery and its charge-discharge performances will be investigated.

ABSTRACT
The rise of industrialization, escalating expenses, and the fast exhaustion of resources, it has become necessary to seek alternatives energy sources and evaluate waste materials. Utilizing energy from waste is considered a viable approach for sustainable energy generation and minimizing environmental concerns. In recent years, microbial fuel cell (MFC), demonstrated to be effective for the treatment of organic and inorganic pollutants in wastewater and for electricity generation, have garnered significant interest. MFC is a system that biochemically oxidizes organic molecules into electrical energy using microorganisms. Proton exchange membranes (PEM) are critical components that influence the performance and cost of MFC. PEMs facilitate electrochemical reactions that transform hydrogen into electrical energy, water, and heat. Furthermore, PEMs have been utilized in applications including biohydrogen-bioelectricity generation, biosensors, and wastewater remediation.This study involved the production of PEM doped with recycled polyvinylidene fluoride (PVDF) and copper (II) nitrate trihydrate (Cu) particles using the technique of electrospinning. The membranes were characterized by swelling, porosity, mechanical, cation exchange capacity (CEC) tests and FTIR analysis to evaluate their performance. In the cation exchange capacity (CEC) test, the increase in CEC values with increasing Cu concentration indicates that Cu-PVDF membranes can be used for MFC.

Keywords: Microbial fuel cell, Proton exchange membranes, PVDF

1. INTRODUCTION

With the developing industry and rapid population growth, the demand for energy is increasing. However, meeting this demand largely based on fossil fuels leads to both depletion of energy resources and serious environmental problems. Excessive consumption of fossil fuels increases competition for energy supply on a global scale, while extraction and utilization processes cause soil, water and air pollution. This has necessitated the development of sustainable and environmentally friendly energy sources [1, 2]. Hydrogen-based systems have significant potential in energy production as an emerging technology. Fuel cells generate electrical energy using the electrochemical conversion of hydrogen, and this process offers great advantages in terms of both energy efficiency and waste management. Hydrogen technology plays an important role in future energy systems by providing an innovative solution for sustainable and carbon-free energy production [3, 4]. The Microbial Fuel Cell (MFC) generates electricity using microorganisms that break down organic matter found in wastewater. Anaerobic microorganisms in the motherboard break down organic matter into protons, electrons and carbon dioxide. The electrons produced are transported via the external circuit to the cathode, where they react with oxygen to form water. Protons migrate through the proton exchange membrane to the cathode chamber. For the MFC to work efficiently, one proton for each electron must be transferred from the anode to the cathode through the membrane. This process enables the metabolic activities of microorganisms to extract energy from organic compounds and convert them into electricity [4].

Membranes play a critical role in MFC internal resistance, as high internal resistance leads to decreased proton transfer, resulting in reduced performance. In order to achieve better performance and lower production costs, membranes with good ionic selectivity, high proton conduction capacity, low fouling, chemical and biological stability need to be developed. Such membranes will improve the efficiency and longevity of MFC, thus providing economic benefits in large-scale applications [5]. Since membrane costs account for a large proportion of the total cost of MFCs, optimization of this factor becomes an important factor affecting the wide-scale use of MFCs. Nanofibers can be used to enhance proton transfer in MFCs as functionalized materials that can selectively transport specific ions or molecules, such as proton-selective membranes. Nanofiber membranes can reduce the internal resistance of MFCs by acting as microfiltration, especially as proton exchange membranes. Nanofibers produced by electrospinning provide flexibility in material selection and advantages in production capacity, thus becoming a popular choice in various applications. Proton exchange membranes commonly used in MFCs provide high conductivity and low internal resistance, but existing membranes such as Nafion can affect performance due to limitations such as oxygen permeability, bioaccumulation, and water loss at high temperature [2]. To solve these problems, membrane modifications are emerging as an effective method to improve the performance of MFCs.

PVDF is a thermoplastic with advantages such as low density, chemical stability and corrosion resistance. PVDF, which is more economical than Nafion membrane, can increase its water retention capacity and environmental durability with modifications. In this way, overall cost-effectiveness can be increased by improving both electricity generation and wastewater treatment efficiency in MFC systems. In a study by Fan et al. [2], PVDF-modified Nafion membranes were shown to increase the water holding capacity of MFCs and thus improve electricity generation and wastewater treatment

efficiency. In addition, acetone-modified PVDF was reported to further improve the stability of the output power of the MFC. With these modifications, the stable output voltage of the MFC increased above 0.21 V and the Chemical Oxygen Demand (COD) removal rate of molasses wastewater reached about 66.7%, which were 96.3% and 75.1% higher than those of MFCs using ordinary Nafion membrane, respectively.
Copper (Cu) modification plays an important role in enhancing the performance of Microbial Fuel Cells (MFC) systems by improving membrane properties. Cu-doped membranes offer increased ion exchange capacity (IEC), improved mechanical strength and enhanced antibacterial properties. The antimicrobial effect of copper improves the long-term stability and efficiency of the membrane by reducing biofouling, while contributing to higher power densities by increasing ion conductivity. In addition, it is reported in the literature that PVDF membranes modified with copper-based materials such as Cu-MOF increase the membrane's adaptability to temperature and humidity changes by improving its water retention capacity, thus providing a more stable and efficient electrochemical environment in MFC systems [6]. These modifications increase the energy generation capacity of MFC systems and allow them to provide a more efficient performance in wastewater treatment processes.
In this study, PEM doped with recycled polyvinylidene fluoride (PVDF) and copper (II) nitratetrihydrate (Cu) particles were fabricated using electrospinning. Characterization tests were conducted to investigate the effects of PVDF and modified PVDF on the power generation performance and water treatment effect of MFCs. The membranes were characterized by swelling, porosity, mechanical, cation exchange capacity (CEC) tests and FTIR analysis to evaluate their performance.

2. MATERIALS AND METHODS

2.1. Membrane Synthesize

A solution comprising 20% (w/w) recycled PVDF and 2.5% (w/w) PVP were dissolved in DMF and acetone. Various concentrations of 1%, 2%, and 3% (w/w) copper (II) nitrate trihydrate (Cu) were dissolved in DMF, added into the PVDF solution and stirred until get homogeneous. Approximately 10 mL of this solution was taken into a syringe, and membranes coded PVDF, PVDF-Cu1, PVDF-Cu2, and PVDF-Cu3 were produced using the electrospinning technique. The electrospinning conditions were established at 19 kV, a flow rate of 0.01 ml/min, and a plate spacing of 18 cm.

2.2. Characterization Tests

The membranes were characterized using FTIR, swelling analysis, empirical pore size measurement, mechanical strength evaluation, and cation exchange tests. The bonding structures of the membranes correspond to those observed in FTIR. Swelling is determined by the weight of the membranes, empirical pore size as described by the equation in 1 [7].

$$Pore\ size\ (\%) = \left(\frac{\frac{Ma-Mb}{\rho a}}{\frac{Ma-Mb}{\rho a} + \frac{Mb}{\rho p}} \right) x100 \quad (1)$$

Ma: Mass after to wetting, Mb: Mass before to wetting, *p*a: Density of water, *p*b: Density of polymer

Cation exchange capacity (CEC) of membranes was evaluated after immersion in NaCl solution overnight at room temperature, followed by titration with 0.1M NaOH and calculation by the equation in 2 [8].

$$CEC = (M_{NaOH} x V_{NaOH}) x W \quad (2)$$

M_{NaOH} and V_{NaOH} are the molarity and volume of NaOH and W is the weight of the membrane.

3. RESULTS AND DISCUSSION

Fig. 1 shows the SEM image of the PVDF (a) pure membrane and the microscope images of the PVDF (b), 2 wt% (c) Cu-doped fiber membranes. The fiber structure diameters are homogeneous, and no accumulation or pilling is observed, indicating that the membranes were successfully formed.

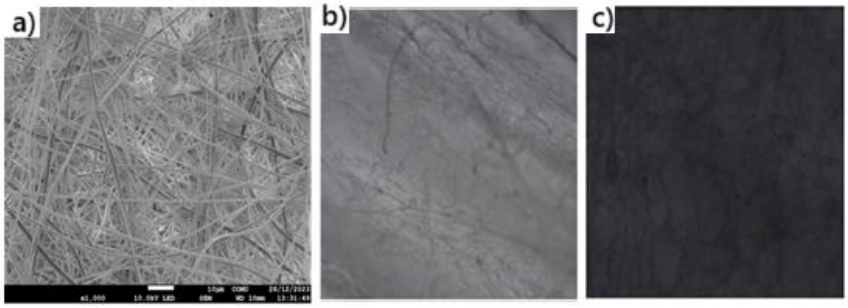

Figure 1. SEM image of PVDF (a) and microscope images of PVDF (b)PVDF-Cu2 (c).

ATR-FTIR spectra are shown in Fig. 2. The reason for the absence of different peaks depending on the doping ratio is the alpha (α) and beta (β) phases formed due to electrospinning. The spectrum around 870 cm^{-1} can be attributed to the alpha (α) phase, while the spectra around 1170 cm^{-1} and 1400 cm^{-1} can be attributed to the beta (β) phase. The spectrum at 1660 cm^{-1} can be attributed to the C=O bond, while the spectra around 1170 cm^{-1} and 1400 cm^{-1} can be attributed to the C-F bond [9-12].

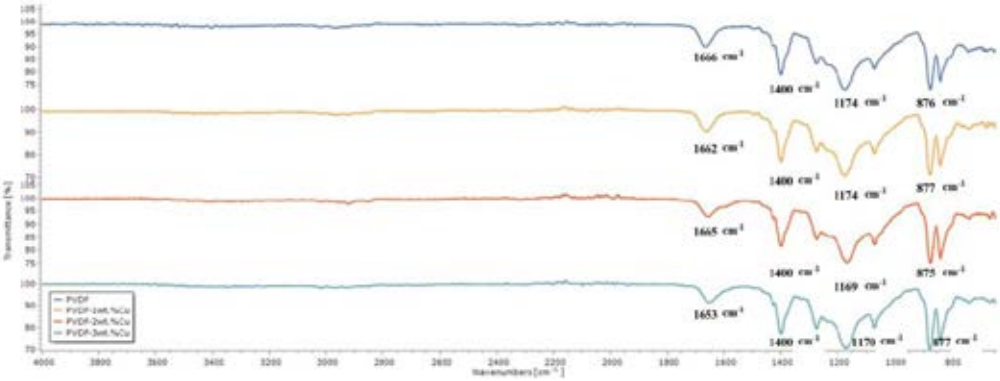

Fig. 2. ATR-FTIR spectra of PVDF and PVDF-Cu

A reduction in porosity and water retention was noted with the incorporation of Cu particles into PVDF (Fig. 3a). This occurs because copper particles tend to aggregate due to their elevated surface area and diminutive size. Coalescing particles can occupy voids and pores, resulting in reduced porosity. Similar to the literature, Cu addition decreased porosity [13-14].

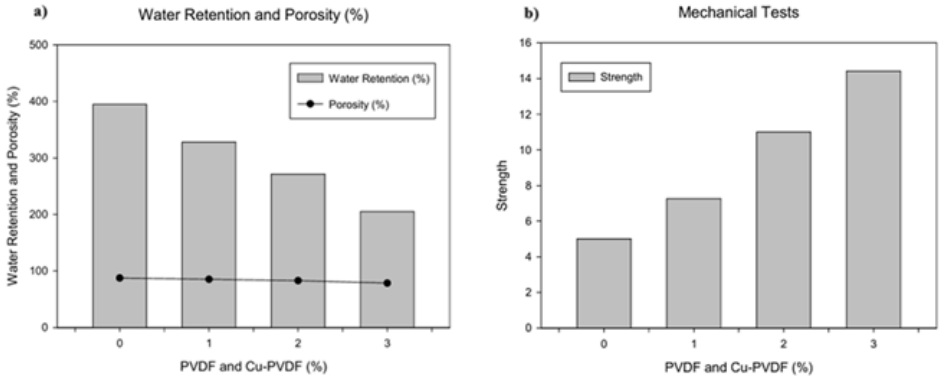

Fig. 3. Results of water retention and porosity (a) and mechanical strength (b).

The mechanical strength of pure PVDF membrane is 5 N/mm² (Fig. 3b). The tensile strength of PVDF-Cu membranes ranges from 7.26 to 14.42 N/mm². It was shown that an increase in Cu concentration improves the mechanical strength of the membranes. The maximum durability is to membranes coded as PVDF-Cu3. Merugu et al. [13] demonstrated enhanced mechanical strength with the incorporation of carbon nanofibres and copper oxide nanoparticles into electrospun PVDF-based membranes.

The cation exchange values give information about the proton carrying capacity of the membranes. The CEC value of the membranes with Cu added significantly increased (Table 1). The highest value is 2.56 mmol/g in PVDF-Cu3 membranes. A study shown that increased copper concentration in cation exchange membranes composed of polyvinyl chloride (PVC) and multi-walled carbon nanotubes enhanced ion exchange [15].

Table 1. Cation exchange values of membranes.

Membrane	Cation Exchange Values (mmol/g)
PVDF	1.96
PVDF-Cu1	2.13
PVDF-Cu2	2.32
PVDF-Cu3	2.56

4. CONCLUSIONS

In this study, Cu-doped PVDF membranes were successfully fabricated by electrospinning method to be used as PEM for use in MFC. The fiber structure of the membranes was successfully imaged with the help of a microscope. With the increase in Cu concentration, the water retention and porosity values of the membranes decreased due to the properties of Cu. However, it was found that the mechanical strength of the membranes increased with the increase in Cu concentration. Also, CEC increased with increase in Cu concentration. This shows that Cu-PVDF membranes are suitable for MFC use. In the next stage, a microbial fuel cell (MFC) system using wastewater will be established to evaluate the performance of the Cu-doped PVDF membranes within the MFC, and the membranes will be tested accordingly.

ABSTRACT
This investigation presents a comprehensive computational thermodynamic analysis of a combined carbothermal reduction and water splitting cycle utilizing a ZnO/Zn redox system. Initially, a thermodynamic equilibrium analysis was conducted to gain insights into the temperature requirements for effective cycle operation, as well as the equilibrium compositions related to the involved redox reactions. Following this, a computational efficiency analysis was performed to quantify various process parameters, including the energy penalties associated with the reduction chamber, heating of the ZnO, and gas separation. Ultimately, the study estimates the total solar energy required for the cycle and explores the corresponding solar-to-fuel energy conversion efficiency, particularly in relation to variations in the C/ZnO molar ratio. This work advances our understanding of the potential efficacy of this innovative cycle for sustainable energy production.

Keywords: ZnO, Carbothermal Reduction, Water Splitting, Hydrogen, Syngas

1. INTRODUCTION
Concentrated solar power presents a promising approach to enhance fuel production through its ability to support chemical reactions. One notable application is in a redox cycle involving metal oxides, which facilitates thermochemical water splitting to generate hydrogen (H_2)[1]. H_2 can be directly utilized as a clean fuel source. Moreover, it can be combined with carbon monoxide (CO)—which can be produced through CO_2 splitting or the oxidation of carbon—to produce solar syngas[2], further expanding the potential for sustainable energy solutions.

The ZnO/Zn-based redox cycle has been extensively explored among the various metal oxides studied. Between 1990 and 2005, research focused on ZnO decomposition using solar thermal energy[3], the role of O_2 in Zn crystallization[4], ZnO reduction kinetics[5], economic factors of the ZnO water-splitting cycle[6], and the development of a solar chemical reactor for ZnO dissociation[7]. Since 2005, research on the ZnO/Zn thermochemical cycle has diversified. Studies included the hydrolysis of Zn in an aerosol reactor[8], analyzing ZnO decomposition in a fluid wall reactor[9], and exploring reaction kinetics for H_2 and syngas production through thermogravimetric experiments[10]. To achieve higher Zn production at 2000 K, a solar concentration ratio of 2500 is necessary[11]. A solar reactor, initially with a 10 kW capacity, was scaled up to 100 kW and tested for nearly 100 hours, resulting in the thermal decomposition of 28 kilograms of ZnO[12].

One of the key challenges associated with the ZnO/Zn cycle is the high temperature required for thermal reduction. This elevated thermal reduction temperature complicates the operational aspects of the process. To address this issue, this study explores the carbothermal reduction of ZnO to produce Zn. By employing carbothermal reduction, we can not only lower the temperature needed for the reduction of ZnO but also generate CO through the oxidation of carbon. This innovative approach combines carbothermal reduction with water splitting, yielding a valuable mixture of H_2 and CO, commonly referred to as syngas. Syngas serves as an essential precursor for the production of liquid transportation fuels. This paper aims to perform a thorough thermodynamic evaluation of the ZnO/Zn-driven carbothermal reduction and water splitting cycle, with a focus on generating solar syngas. The results of this computational thermodynamic study will provide a solid foundation for future experimental investigations.

2. THERMODYNAMIC ANALYSIS
Utilizing the HSC Chemistry Software, we conducted a comprehensive thermodynamic analysis, consisting of two pivotal sections: (a) equilibrium analysis and (b) efficiency analysis. The equilibrium analysis was essential for determining the carbothermal reduction and the water splitting temperatures pertinent to the ZnO/Zn redox cycle. Furthermore, this analysis provided valuable insights into how the C/ZnO molar ratio influences the reduction of ZnO to Zn, along with the oxidation of carbon to CO. The findings from the equilibrium analysis subsequently informed our efficiency analysis. We developed a thermodynamic model (illustrated in Fig. 1) that incorporates reduction and oxidation chambers, a separator, and multiple heat exchangers and heaters. This model served as the foundation for deriving the equations listed below, enabling a thorough efficiency analysis of the ZnO/Zn driven carbothermal and water splitting cycle.

<u>Heater-1:</u>

$$\dot{Q}_{heater-1} = \dot{n}_{C(s)} \Delta H|_{aC(s)@T_0 \rightarrow aC(s)@T_{red}} \quad (1)$$

Reduction Chamber:

$$\dot{Q}_{ZnO-red} = \dot{n}_{ZnO(s)}\Delta H|_{ZnO(s)+Ar(g)+aC(s)@T_{red} \rightarrow aZn(g)+(1-a)ZnO(s)+aCO(g)+Ar(g)@T_{red}} \quad (2)$$

Heat Exchanger-2 and Heater-2:

$$\dot{Q}_{Ar-heat} = \varepsilon_{gg}\left[\dot{Q}_{(Ar+\,aCO)-cool}\right] + \dot{Q}_{heater-2} \quad (3)$$

$$\dot{Q}_{Ar-heat} = \dot{n}_{Ar}\Delta H|_{Ar(g)@T_0 \rightarrow Ar(g)@T_{red}} \quad (4)$$

$$\dot{Q}_{(Ar+\,aCO)-cool} = \dot{n}_{Ar}\Delta H|_{Ar(g)@T_{red} \rightarrow Ar(g)@T_0} + \dot{n}_{CO}\Delta H|_{aCO(g)@T_{red} \rightarrow aCO(g)@T_0} \quad (5)$$

Separator-1:

$$\dot{Q}_{sep-1} = \dot{n}_{ZnO}\left[\frac{T_{sep-1}}{\eta_{sep-1}}(\Delta S_{mix,R_2} - \Delta S_{mix,R_1})\right] \quad (6)$$

$$\Delta S_{mix,R_1} = -R\{n_{Ar}\ln(1 - y_{CO,R_1}) + n_{CO,R_1} ln y_{CO,R_1}\} \quad (7)$$

$$\Delta S_{mix,R_2} = -R\{n_{Ar}\ln(1 - y_{CO,R_2}) + n_{CO,R_2} ln y_{CO,R_2}\} \quad (8)$$

Heat Exchanger-1 and Sensible Heat for ZnO Heating:

$$\dot{Q}_{ZnO-sens} = \dot{Q}_{ZnO-heat} - \varepsilon_{ss}[\dot{Q}_{(aZn+(1-a)ZnO)-cool}] \quad (9)$$

$$\dot{Q}_{ZnO-heat} = \dot{n}_{ZnO}\Delta H|_{ZnO(s)@T_{oxd} \rightarrow ZnO(s)@T_{red}} \quad (10)$$

$$\dot{Q}_{(aZn+(1-a)ZnO)-cool} = \dot{n}_{Zn}\Delta H|_{aZn(g)@T_{red} \rightarrow aZn(s)@T_{oxd}} + \dot{n}_{ZnO}\Delta H|_{(1-a)ZnO(s)@T_{red} \rightarrow (1-a)ZnO(s)@T_{oxd}} \quad (11)$$

Oxidation Chamber:

$$\dot{Q}_{ZnO-oxd} = -\dot{n}_{ZnO}\Delta H|_{aZn(s)+(1-a)ZnO(s)+aH_2O(g) \rightarrow ZnO(s)+aH_2(g)@T_{oxd}} \quad (12)$$

Heat Exchanger-3 and Heater-3:

$$\dot{Q}_{H_2O-heat} = \varepsilon_{gg}\left[\dot{Q}_{H_2-cool}\right] + \dot{Q}_{heater-3} \quad (13)$$

$$\dot{Q}_{H_2O-heat} = \dot{n}_{H_2O}\Delta H|_{aH_2O(l)@T_0 \rightarrow aH_2O(g)@T_{red}} \quad (14)$$

$$\dot{Q}_{H_2-cool} = \dot{n}_{H_2}\Delta H|_{aH_2(g)@T_{oxd} \rightarrow aH_2(g)@T_0} \quad (15)$$

Conductive-Convective Surface Losses:

$$\dot{Q}_{surf} = 0.2 \times \dot{Q}_{ZnO-red} \quad (16)$$

Thermochemical Energy Requirement:

$$\dot{Q}_{TC} = \dot{Q}_{heater-1} + \dot{Q}_{ZnO-red} + \dot{Q}_{heater-2} + \dot{Q}_{sep-1} + \dot{Q}_{ZnO-sens} + \dot{Q}_{heater-3} + \dot{Q}_{surf} \quad (17)$$

Solar Energy Absorption Efficiency:

$$\eta_{abs} = 1 - \left(\frac{\sigma T_{red}^4}{IC}\right) \quad (18)$$

Total Solar Energy Requirement:

$$\dot{Q}_{solar} = \frac{\dot{Q}_{TC}}{\eta_{abs}} \quad (19)$$

Re-radiation Losses:

$$\dot{Q}_{re-rad} = \eta_{abs} \times \dot{Q}_{solar} \quad (20)$$

Solar-to-Fuel Energy Conversion Efficiency:

$$\eta_{solar-to-fuel} = \frac{[\dot{n}_{CO} \times HV_{CO}] + [\dot{n}_{H_2} \times HV_{H_2}] - [\dot{n}_C \times HV_C]}{\dot{Q}_{solar}} \quad (21)$$

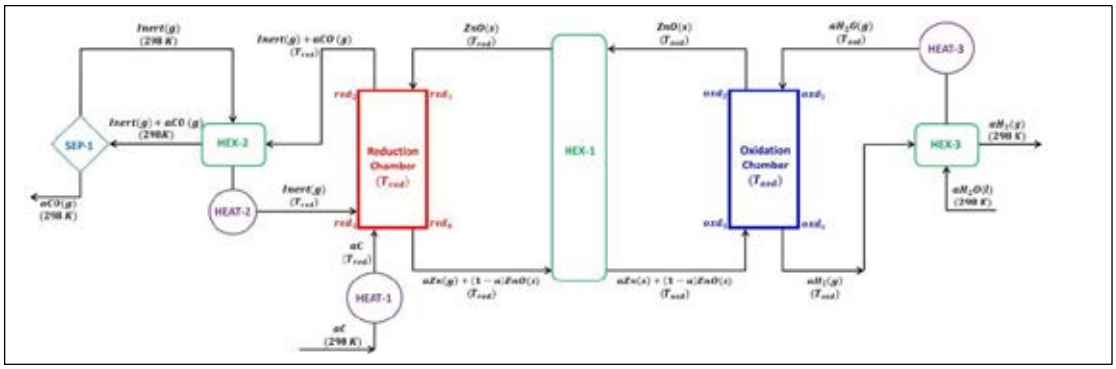

Fig. 1. Process Flow Diagram (ZnO/Zn-Carbothermal Reduction-Water Splitting Cycle).

3. RESULTS AND DISCUSSION

The impact of increasing the C/ZnO molar ratio from 0.2 to 1.0 on the equilibrium compositions related to the carbothermal reduction of ZnO is illustrated in Fig. 2. As demonstrated, a higher C/ZnO molar ratio significantly enhances the reduction of ZnO to Zn, as well as the generation of CO compared to carbon. This positive correlation highlights the importance of optimizing the C/ZnO ratio for improved efficiency in the reduction process.

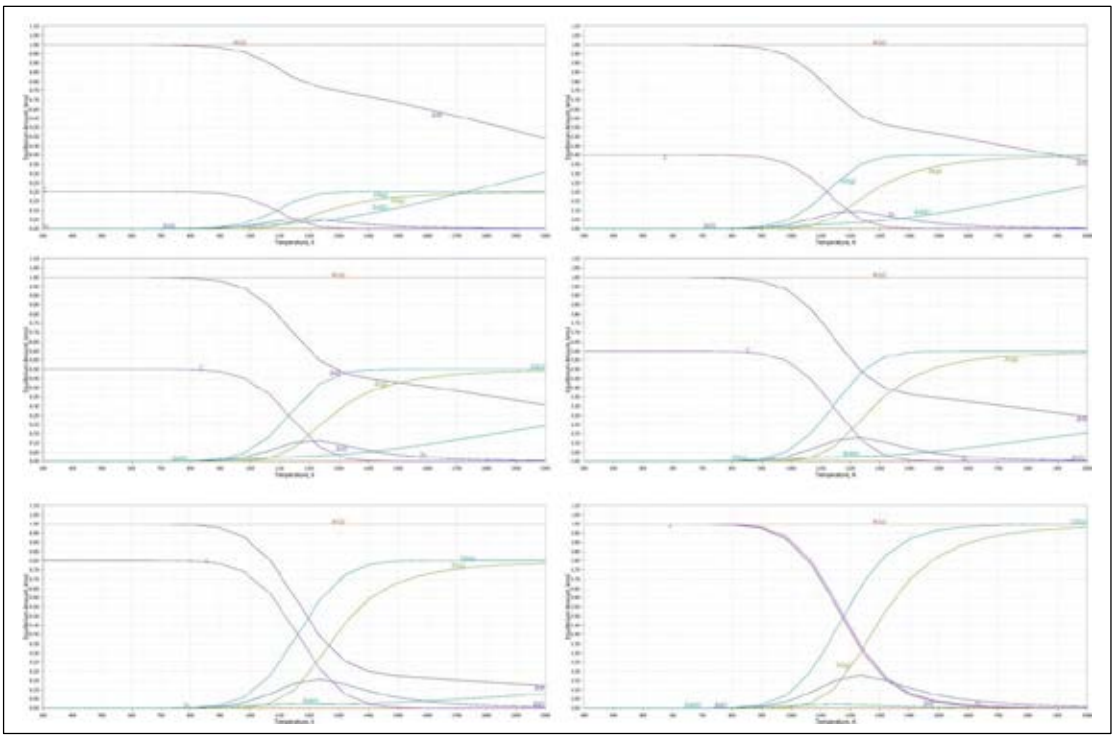

Fig. 2. Equilibrium Compositions associated with the carbothermal reduction of ZnO.

The thermodynamic efficiency analysis performed at gas-to-gas and solid-to-solid heat recuperation equal to 0.1 and 0.0 using our developed model and equations (described in the previous section) revealed insightful trends regarding energy requirements. Specifically, it was found that the energy needed to elevate the temperature of carbon (C) from 298 K to the reduction temperature of 1250 K increased significantly, from 3.48 kW to 17.39 kW, as the C/ZnO molar ratio rose from 0.2 to 1.0. This adjustment in the ratio also resulted in a notable energy penalty associated with the carbothermal reduction of ZnO, which increased by 282.88 kW.

Additionally, while heat exchanger-2 effectively recuperated energy from the cooling of the Ar + CO gas mixture for preheating inert Ar to 1250 K, it became evident that further heat energy from heater-2 was necessary. Encouragingly, this requirement was reduced by 2.41 kW as the C/ZnO molar ratio increased from 0.2 to 1.0, showcasing the potential for improved efficiency with optimized ratios.

The increase in CO production was notably influenced by the rising C/ZnO molar ratio, which escalated from 0.2 to 1.0. This adjustment necessitated an additional 13.87 kW of energy to operate separator-1. Meanwhile, the sensible heat required for preheating ZnO remained consistent at 38.13 kW, as the temperature difference between the water splitting reaction (500 K) and the carbothermal reduction reaction (1250 K) stayed the same. With an increased availability of Zn for the water splitting process, there was a corresponding rise in H_2 production, which contributed to a significant increase in exothermic heat release. For example, as the C/ZnO ratio improved from 0.2 to 1.0, the energy generated by the oxidation chamber rose by an impressive 80%. Additionally, the heightened demand for H_2O supply resulted in a fivefold increase in the heat energy requirements from heater-3.

The total thermochemical energy required for the ZnO/Zn driven carbothermal reduction and water splitting cycle increased significantly, rising from 162.64 kW to 567.74 kW. This increase in thermochemical energy demand has implications for the total solar energy needed, which in turn affects the solar-to-fuel energy conversion efficiency. For instance, with a C/ZnO ratio of 0.2, the total solar energy requirement was 170.51 kW, but this escalated to 595.21 kW when the C/ZnO ratio increased to 1.0. Interestingly, while the solar-to-fuel energy conversion efficiency was lower at 20.62% for a C/ZnO ratio of 0.2, it improved to 29.54% as the ratio rose to 1.0. This suggests a complex interplay between energy requirements and conversion efficiency that merits further exploration.

4. CONCLUSIONS

Increasing the C/ZnO ratio improved ZnO reduction to Zn and CO production from carbon. The energy needed to heat carbon from 298 K to 1250 K increased from 3.48 kW to 17.39 kW as the C/ZnO ratio rose from 0.2 to 1.0, resulting in an energy penalty of 282.88 kW. While heat exchanger-2 preheated inert argon effectively, it required less energy from heater-2, decreasing by 2.41 kW with a higher C/ZnO ratio. CO production raised the energy demand for separator-1 by 13.87 kW, and preheating ZnO energy remained constant at 38.13 kW. With more Zn, hydrogen production and exothermic heat increased, boosting energy from the oxidation chamber by 80%. Energy from heater-3 increased fivefold due to H2O supply needs. Overall, thermochemical energy for the ZnO/Zn process surged from 162.64 kW to 567.74 kW, raising solar energy needs from 170.51 kW to 595.21 kW, while solar-to-fuel energy conversion efficiency improved from 20.62% to 29.54%.

ABSTRACT
The hybrid $MnSO_4$/MnO water splitting (WS) cycle that produces H_2 from the sun is carefully examined thermodynamically in this work. It seeks to calculate solar-to-fuel energy conversion efficiency by considering variations in inert sweep gas flow rates and reduction temperatures, gas separation methods, and heat recovery techniques. Teaching solar thermochemical fuel production to University of Tennessee at Chattanooga undergraduate students is another aspect of the research. Assuming total thermal reduction of MnSO4 to MnO, SO_2, and O_2, as well as re-oxidation via WS, a thermodynamic model was created. It was discovered that a 7.4% decrease in efficiency resulted from raising the inert sweep gas flow rate from 10 to 100 mol/s, which increased the solar energy requirements by 403.5 kW.

1. INTRODUCTION
The dependence on fossil fuels presents serious issues as the world's energy needs increase. In order to guarantee a sustainable energy future, efforts must be made to develop renewable energy sources. As a clean energy carrier from renewable sources, H_2 is crucial for sustainability because it only emits water vapor when used and helps lower greenhouse gas emissions, especially in industries like the transportation sector. It is a viable energy carrier since H2 can be coupled with CO to form syngas for liquid fuels and chemicals.

Because of the high heat needs and safety issues, direct water thermolysis is not a practicable method for producing H_2. As a result, studies have turned to water-splitting (WS) techniques, especially solar thermochemical WS with metal oxides (MOs). This technique can use a variety of volatile and non-volatile MOs and works at temperatures between 1700 and 2000 K, which is lower than direct thermolysis, which occurs at temperatures above 2700 K [1–10].

Alternative methods that operate between 1073 and 1473 K, closer to the temperatures utilized in methane reforming, like the sulfur-iodine and hybrid sulfur cycles [11–12], provide valuable benefits. On the other hand, sulfur trioxide (SO_3) breakdown is complicated and frequently results in sulfation poisoning, which reduces catalytic activity. Although cost is a barrier, researchers are looking into noble metal catalysts supported on metal oxides to improve SO_3 breakdown [13-15].

One possible remedy is a hybrid metal oxide-metal sulfate (MO-MS) WS cycle, in which metal sulfate (MSO4) is broken down by solar-driven thermal reduction into MO, SO_2, and O_2. The second stage creates H_2 by reoxidizing MO with SO_2 and water. To produce a trustworthy estimate of the solar-to-fuel energy conversion efficiency for the MnSO4/MnO WS cycle, our team assessed the thermodynamics of the cycle (Fig. 1), taking into account energy losses from gas separation and heat transmission.

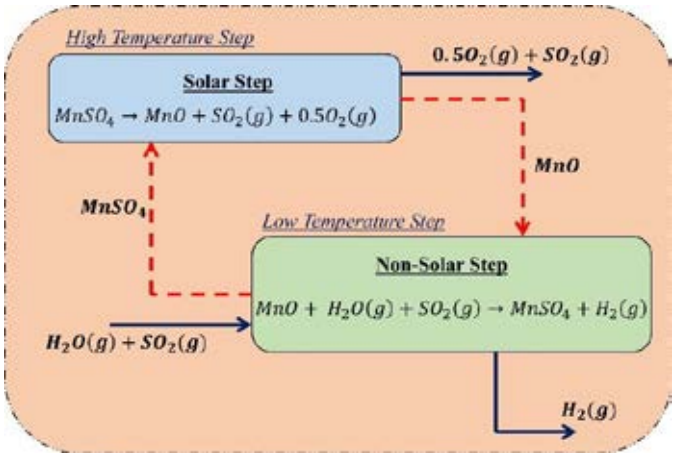

Fig. 1. $MnSO_4$/MnO WS cycle.

2. THERMODYNAMIC MODEL AND EQUATIONS

As illustrated in Fig. 2, this study employed a thermodynamic process model for efficiency analysis. The model makes the following assumptions: perfect gas behavior under equilibrium conditions, complete conversion for reactions, and constant temperatures for the reduction and oxidation reactors. It has two separators for inert/O_2/SO_2 and inert/O_2 gas combinations, with a 99.9% separation rate, and integrates an H_2/O_2 fuel cell with a maximum efficiency of 100%. All calculations were standardized to 1 mol/s, and a 20% thermal energy loss from the reduction reactor was considered.

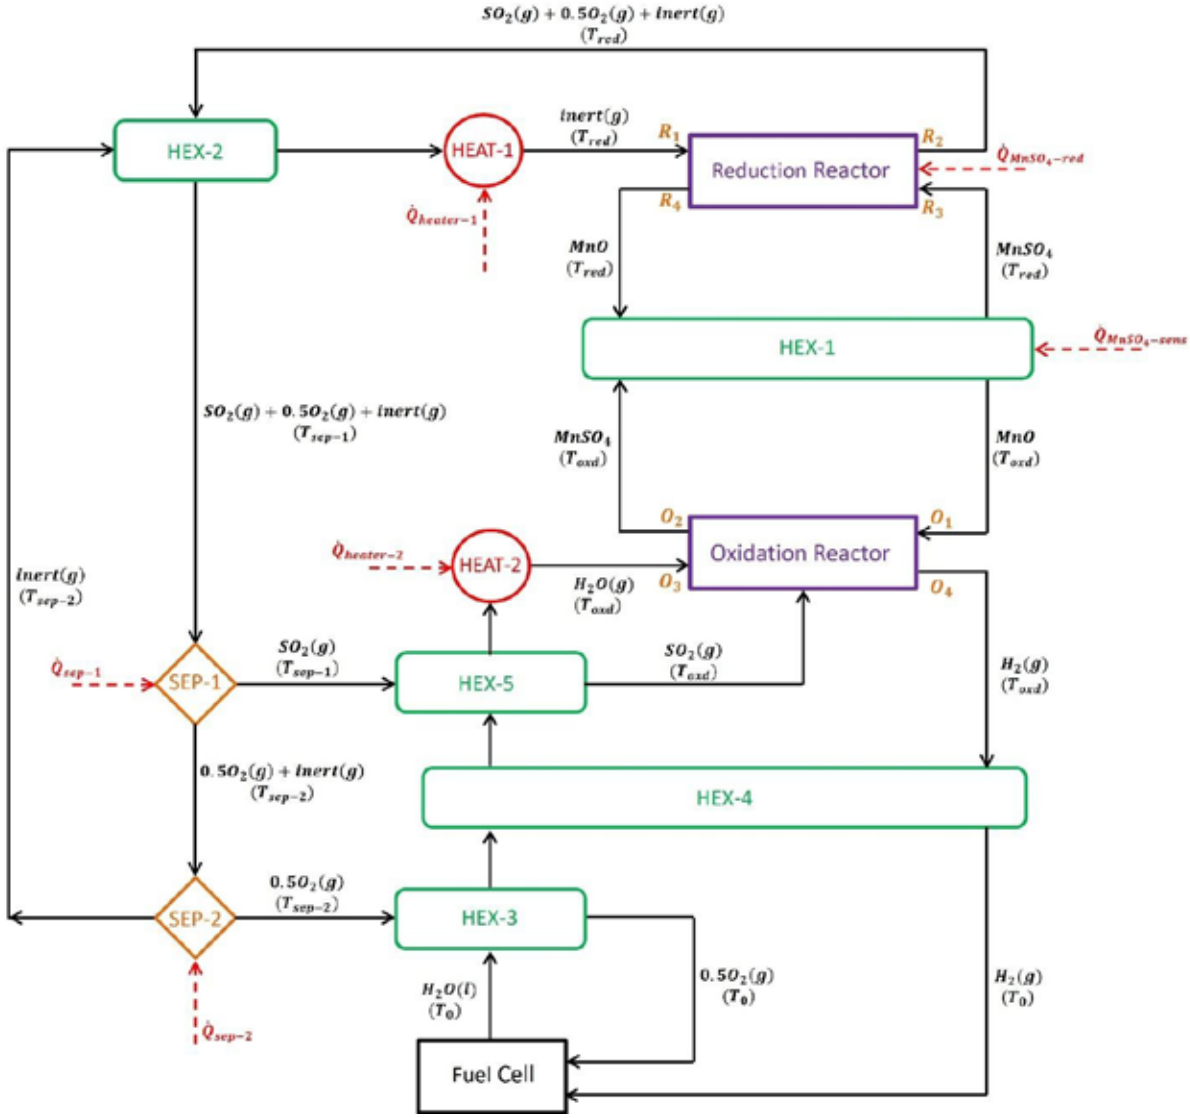

Fig. 2. Process Flow Thermodynamic Model: $MnSO_4$/MnO WS cycle.

Here is a collection of key formulas created and applied to the $MnSO_4$/MnO WS cycle efficiency analysis.

The reduction reactor's heat penalty:

$$\dot{Q}_{MnSO_4-red} = \dot{n}_{MnSO_4}\Delta H|_{MnSO_4 \rightarrow MnO+SO_2(g)+O_2(g)} \quad (1)$$

Exothermic heat produced throughout the oxidation process:

$$\dot{Q}_{MnSO_4-oxd} = -\dot{n}_{MnSO_4}\Delta H|_{MnO+SO_2(g)+H_2O(g) \rightarrow MnSO_4+H_2(g)} \quad (2)$$

Sensible heat required to heat $MnSO_4$:

$$\dot{Q}_{MnSO_4-sens} = \dot{n}_{MnSO_4}\Delta H|_{MnSO_4@T_{oxd} \rightarrow MnSO_4@T_{red}} \quad (3)$$

The energy needed for separators 1 and 2 to function:

$$\dot{Q}_{sep-1} = \dot{n}_{MnSO_4}\left[\frac{T_{sep-1}}{\eta_{sep-1}}(\Delta S_{mix,R_2} - \Delta S_{mix,R_1})\right] \quad (4)$$
$$\Delta S_{mix,R_1} = -R\{n_{mix}\ln(1 - y_{SO_2,R_1}) + n_{SO_2,R_1} ln y_{SO_2,R_1}\} \quad (5)$$
$$\Delta S_{mix,R_2} = -R\{n_{mix}\ln(1 - y_{SO_2,R_2}) + n_{SO_2,R_2} ln y_{SO_2,R_2}\} \quad (6)$$

$$\dot{Q}_{sep-2} = \dot{n}_{MnSO_4}\left[\frac{T_{sep-1}}{\eta_{sep-1}}(\Delta S_{mix,R_2} - \Delta S_{mix,R_1})\right] \quad (7)$$
$$\Delta S_{mix,R_1} = -R\{n_{inert}\ln(1 - y_{O_2,R_1}) + n_{O_2,R_1} ln y_{O_2,R_1}\} \quad (8)$$
$$\Delta S_{mix,R_2} = -R\{n_{inert}\ln(1 - y_{O_2,R_2}) + n_{O_2,R_2} ln y_{O_2,R_2}\} \quad (9)$$

The following is an estimate of the additional heat energy needed from heaters 1 and 2:
$$\dot{Q}_{inert-heat} = \varepsilon_{gg}\left[\dot{Q}_{(inert+\,O_2+SO_2)-cool}\right] + \dot{Q}_{heater-1} \quad (10)$$
$$\dot{Q}_{H_2O-heat} = \varepsilon_{gg}\left[\dot{Q}_{O_2(g)-cool} + \dot{Q}_{H_2(g)-cool} + \dot{Q}_{SO_2(g)-cool}\right] + \dot{Q}_{heater-2} \quad (11)$$

Conductive/convective heat losses from the solar reactor were calculated as:
$$\dot{Q}_{surf} = 0.2 \times \dot{Q}_{MnSO_4-red} \quad (12)$$

The total amount of thermochemical energy required to drive the cycle was calculated as follows:
$$\dot{Q}_{TC} = \dot{Q}_{MnSO_4-red} + \dot{Q}_{MnSO_4-sens} + \dot{Q}_{heater-1} + \dot{Q}_{heater-2} + \dot{Q}_{sep-1} + \dot{Q}_{sep-2} + \dot{Q}_{surf} \quad (13)$$

The solar-to-fuel energy conversion efficiency was estimated as per the following equation.
$$\eta_{solar-to-fuel} = \frac{\dot{n}_{H_2} \times HHV_{H_2}}{\dot{Q}_{solar}} \quad (14)$$

Where,
$$\dot{Q}_{solar} = \frac{\dot{Q}_{TC}}{\eta_{absorption}} \quad (15)$$

3. RESULTS AND DISCUSSION

The study analyzed the impact of Ar flow rates on the temperature required for 100% dissociation of $MnSO_4$. Complete dissociation was achieved at different temperatures depending on the Ar flow rates. Although the temperature decreased from 1488 K to 1361 K when increasing Ar flow rates up to 100 mol/s, the thermal energy needed to drive the reduction reaction increased by 3.5 kW. Equilibrium analysis indicated that the MnO re-oxidation into $MnSO_4$ via WS reaction is feasible at temperatures ≤ 500 K. Though a solid-to-solid heat exchanger was in place, all calculations assumed no heat recovery and the sensible heat required to hear the MnSO4 from oxidation to reduction temperature was higher at Ar = 10 mol/s (150.8 kW) as compared to Ar = 100 mol/s (130.4 kW). The separation of SO_2 from the $Ar/O_2/SO_2$ gas mixture was achieved using an ion transport membrane at high temperatures. The energy required for the operation of separator-1 and separator-2 was recorded to be increased by 39.5 kW and 36.2 kW with a rise in the Ar flow rate from 10 mol/s to 100 mol/s. As the Ar exiting separator-2 was at a lower temperature than the reduction reactor, HEX-2 and an auxiliary heater-1 were installed for preheating. The auxiliary heat needed to increase the temperature of Ar was supplied by heater-1, and it was recorded to be increased by a factor of 9.9 as the Ar flow rate surged by 90 mol/s. On the other hand, the energy supplied by the auxiliary heater-2 remained steady at 24.8 kW.

The total thermochemical energy required for the $MnSO_4$/MnO WS cycle was calculated, with recorded values ranging from 961.3 kW at 10 mol/s to 1368.1 kW at 100 mol/s. To calculate the solar energy required for the cycle, absorption efficiency was also considered. The absorption efficiency rose from 90.7% to 93.5% as flow rates increased from 10 to 100 mol/s. The total solar energy required surged above 1059.4 by 403.5 kW due to the rise in Ar flow rate from 10 to 100 mol/s, respectively. Solar-to-fuel energy conversion efficiency was the highest (26.7%) when the Ar flow rate was equal to 10 mol/s, and it decreased to 19.4% because of the rise in the Ar flow rate up to 100 mol/s.

4. CONCLUSIONS

Thermodynamic efficiency modeling investigated the $MnSO_4$/MnO solar-driven hybrid thermochemical WS cycle. The reduction temperature decreased by 127 K when the Ar flow rate was increased from 10 to 100 mol/s, with the lowest reduction temperature equal to 1361 K for 100 mol/s. Around 500 K, MnO re-oxidation made it possible to produce H_2 via WS. While other parameters either stayed the same or decreased, the higher Ar flow resulted in a decrease in the sensible heat needed by 20.4 kW to increase the temperature of $MnSO_4$ from oxidation to the reduction temperature. Gas separation entropy was significantly impacted by the shifting mole fractions of SO_2 and O_2, which raised the energy requirements for gas heating. Even with gas-to-gas heat exchangers installed, more energy was needed to preheat the Ar. Even though the temperature dropped, the total solar thermal energy demands increased from 1059.4 kW to 1462.9

kW. At 1488 K, the highest solar-to-fuel energy conversion efficiency was recorded (26.7%) for 10 mol/s.

ABSTRACT
The increasing demand for clean and sustainable energy sources is driving research into alternatives due to the environmental issues associated with fossil fuels. Hydrogen energy stands out among these alternatives because of its high energy density, low environmental impact, and renewable characteristics. This study focuses on the synthesis, characterization, and application of metal-organic frameworks (MOFs) that hold the potential to enhance hydrogen energy efficiency. For this purpose, MOF-235 was synthesized to facilitate hydrogen production. Subsequently, MOF-235 was modified with graphene oxide to improve hydrogen production. Characterization of the MOFs was successfully conducted using BET, FT-IR, TGA, and SEM techniques. Additionally, the catalytic activity of the hydrolysis reaction of sodium borohydride in the presence of the efficient MOF-235 and MOF-235@GO catalysts was investigated. Both MOF-235 and MOF-235@GO were found to serve as effective catalysts in hydrogen production. This study presents promising advancements for hydrogen energy efficiency and supports ongoing research in this area.

1. INTRODUCTION

The world is currently facing a climate crisis, predominantly manifested as global warming, which is driven by the increasing levels of greenhouse gases, particularly carbon dioxide (CO_2), in the atmosphere, leading to a rise in the Earth's temperature. Addressing this urgent challenge requires the reduction of non-carbon-neutral CO_2 emissions from various transportation methods and industrial sectors. This has prompted a potential transition from hydrocarbon-based fuels to a hydrogen economy as a means to tackle this global issue. As a result, extensive efforts have been undertaken over the past few decades to develop sustainable hydrogen production processes through a variety of methods.have been made over the past few decades to develop sustainable hydrogen production processes through various routes [1,2].

Metal-organic frameworks (MOFs) are a class of crystalline materials formed by the coordination of organic linkers with metal ions or clusters. They have gained significant attention in recent years due to their exceptional porosity and adaptable structures [3]. MOFs' structures can be engineered to meet specific needs by varying the metal ions and organic linkers used in their formation. This customization allows for fine-tuning of properties such as pore size and functionality. The combination of organic and inorganic components provides unique properties that can result in enhanced performance in various applications. MOFs exhibit high levels of crystallinity, which is essential for reproducibility in both synthesis and application, thus ensuring consistent performance. MOFs typically have a large surface area and significant pore volume, making them suitable for applications that require efficient gas adsorption and storage [4]. Because of these unique characteristics, MOF structures are perfect for a wide range of uses, including as gas storage, biomedicine, magnetics, sensing, separation procedures, and heterogeneous catalysis [5-8]. Due to their structural versatility, MOFs can host acidic and basic Lewis sites, enhancing their effectiveness as catalysts in hydrogen production [9-10]. Composites made of graphene oxide (GO) and metal-organic frameworks (MOFs) have attracted a lot of interest lately.

MOF-235, also known as $[Fe_3O(1,4\text{-}BDC)_3(DMF)_3]FeCl_{43}$, is a notable metal-organic framework characterized by its distinct orange powder appearance and octahedral crystal formation. MOF-235 is composed of trivalent iron atoms that are coordinated with ditopic ligands—specifically, 1,4-benzenedicarboxylic acid (BDC). This coordination creates a complex structure where the iron ions serve as nodes in a three-dimensional lattice. The structure of MOF-235 consists of repeated metal complex units, leading to a robust three-dimensional framework. This architecture is instrumental in defining the material's porosity and stability [9]. By strategically selecting different metal ions and organic ligands, the pore size and overall framework topology of MOF-235 can be customized. This tailoring capability allows for specific functional properties that cater to various applications [10].

In this study, MOF-235 was first synthesised and then modified using GO. The synthesised MOFs were characterised and structurally validated using different characterisation tests. Then, hydrogen production performances were investigated and interpreted.

2. MATERIALS AND METHODS

2.1. MOF-235 Synthesis
The terephthalic acid was dissolved in 60 mL of DMF, and the mixture was stirred for 10 minutes until a clear solution was obtained. Following this, $FeCl_3 \cdot 6H_2O$ was added to the solution, and the mixture was stirred for an additional 5 minutes to allow for the integration of the metal precursor into the solution. The reactant mixture (30 mL) and an additional 30 mL of ethanol were combined. This combined mixture was then transferred to a Teflon-lined autoclave. The autoclave was placed in a preheated oven at 80 °C for 24 hours. After the reaction period, the resulting orange powder of MOF-235 was collected using centrifugation, which separates the solid product from the liquid phase. The product was then washed with a DMF/ethanol mixture at least three times to remove any unreacted materials, excess solvent, or by-products that may interfere with the purity of the final product. The obtained MOF-235 was dried overnight at 150 °C.

2.2. Modification of MOF-235 with Graphene Oxide
The process began by dissolving the certain amount of terephthalic acid in 30 mL of DMF. The solution was stirred for 10 minutes until a clear solution was formed, ensuring that the terephthalic acid was fully dissolved to promote effective reaction conditions. Following the initial stirring, certain amount of $FeCl_3 \cdot 6H_2O$ was added to the solution, and the mixture was continually stirred for an additional 10 minutes. The graphene oxide was added to the solution, with concentrations varying between 1% and 5%. This inclusion aims to improve the structural and functional attributes of the synthesized MOF. The final solution (30 mL reaction solution plus 30 mL of ethanol) was transferred into a Teflon-coated stainless steel autoclave. The autoclave was heated at 80 °C for 24 hours. Upon completion of the heating period, the reaction vessel was allowed to cool to room temperature. The crystals were then dried at 150 °C for 15 hours to eliminate any residual solvents. After drying, the crystals were washed several times with a DMF-ethanol mixture to remove any unreacted materials or impurities, ensuring the final product's purity.

2.3. Characterization of MOF-235 and MOF-235@GO
The obtained MOF-235 and MOF-235@GO was characterized by using BET, FTIR, TGA and SEM analysis. The thermal stability of the MOF-235 is determined by using thermal gravimetric analyzer. The MOF sample heated from 25 °C to 600 °C at a rate of 10 °C/min under a nitrogen flow. A Carl Zeiss/Gemini 300 and a Bruker/XFlash 6-100 were used for SEM. A Leica/ACE600 apparatus was used to gold-coat the samples. Using a PerkinElmer Spectrum Two FT-IR spectrometer, the chemical functional groups of the MOFs were identified. Analysis was done with a resolution of 4 cm^{-1} and a scanning range of 400–4000 cm^{-1}. A Micromeritics TriStar II 3020 analyzer with nitrogen adsorption was used for the BET measurements. Before analysis, samples were degassed for 12 hours at 200 °C to eliminate any moisture or adsorbed gases. The structural, thermal, morphological, compositional, and surface properties of the MOF catalysts are all thoroughly understood thanks to these analytical methods.

2.4. Hydrogen Production from Sodium Borohydride Hydrolysis
To carry out the dehydrogenation experiments of sodium borohydride, an alkaline solution was initially prepared. This was accomplished by adjusting the pH of the medium to a range of 12-13 using sodium hydroxide (NaOH), which is the metal hydroxide linked to sodium borohydride. The solution was stirred until the sodium hydroxide completely dissolved in pure water. Subsequently, the required amount of sodium borohydride was weighed and added to prepared solution. Following this, a MOF235 and MOF-235@GO catalysts were included in the alkaline mixture, and the reactor lid was securely closed. The reaction commenced immediately after adding the catalyst to the solution. The hydrogen produced during the experiment was measured by monitoring the change in liquid level in a burette at specified intervals, employing the reverse burette method.

3. RESULTS AND DISCUSSION

3.1. SEM Analysis

SEM analysis results of the synthesised MOFs are given in Fig. 1. SEM analysis shows that MOF-235 has regular and well-defined crystal structure. Crystals are usually observed in octahedral or cubic morphology with smooth surfaces and prominent edges. This structure reflects the strong three-dimensional network structure formed by regular coordination bonds between iron ions and terephthalic acid ligands. The high resolution in SEM images allows a detailed study of the porous structure of MOF-235 and any defects in this structure [11].

3.2. BET Analysis
The surface areas of the synthesised MOF-235 and MOF-235@GO were measured and found to have surface areas of 870 and 1024 m^2/g, respectively.

3.3. Hydrogen Production
To investigate the influence of reaction time, the hydrogen generation yield was assessed over time. Fig. 2 illustrates the impact of reaction duration. The reaction was conducted using 0.25 M (25 mL) sodium hydroxide and a 0.1 g MOF

catalyst at a temperature of 50°C.

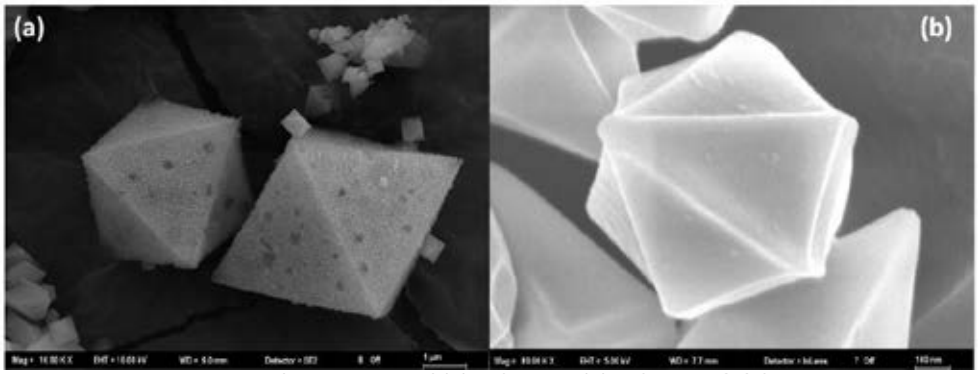

Fig. 1. SEM images of (a) MOF-235 (b) MOF-235@GO

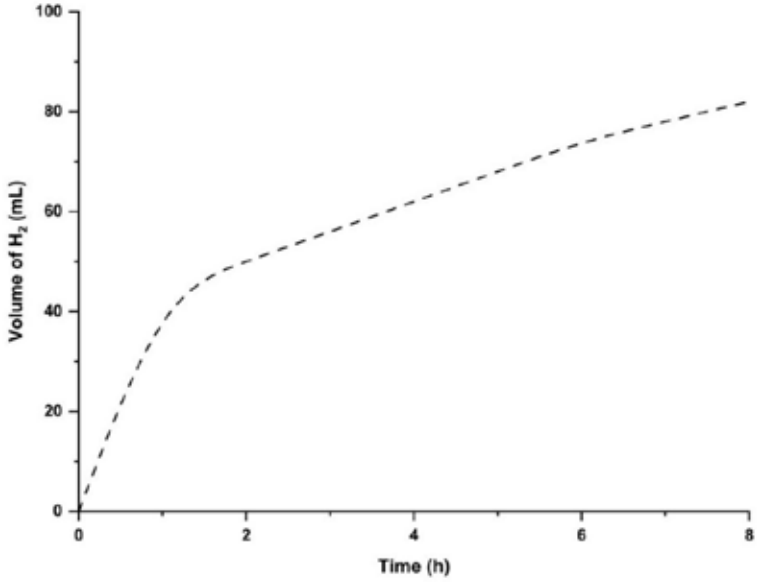

Fig. 2. Hydrogen production

Hydrogen production rate has increased over time. Hydrogen production increased rapidly for about the first 2 hours and then increased more slowly. This may be related to the fact that the MOF used as a catalyst acts as a catalyst at the beginning and stores the hydrogen produced as time progresses. At the end of 8 hours, 82 mL of hydrogen was produced.

4. CONCLUSIONS

In this study, sodium boron hydride was utilized as a source of boron and hydrogen for hydrogen production, and a heterogeneous catalyst was synthesized for the dehydrogenation experiments. The synthesized catalysts, MOF-235 and MOF-235@GO, have not been previously explored in the literature for hydrogen production from sodium boron hydride. Various analyses, including BET for surface area measurement, FTIR for chemical bond structure, TGA for thermal stability, and SEM for structural analysis, were conducted on the catalysts. The results from these analyses confirmed the successful synthesis of the metal-organic frameworks (MOFs). To evaluate the catalytic activity of the synthesized catalysts, hydrogen production from sodium borohydride was investigated, yielding a total of 82 mL of hydrogen after an 8-hour reaction period. The findings indicate that MOF-235 and MOF-235@GO exhibit potential as effective catalysts for hydrogen production from sodium borohydride.

ABSTRACT
Due to the use of fossil fuels, the world is dealing with a series of catastrophes. In order to avoid potential future hazards, the intensive studies and efforts are ongoing to replace them with renewable and non-carbon-based energy sources. Currently, one of the most promising ways to eliminate carbon emissions caused by fossil fuels is to use hydrogen. In order to increase the level of decarbonization, which means getting the optimum benefit from the element, it needs to be produced through green production with renewable energy support. The clean energy fuel produced in this way, called green hydrogen, will play a crucial role in the fight against global carbon emissions. Under these considerations, the main aim of this paper is to apply some exergetic sustainability parameters to a 1MW electrolyzer installed in a green hydrogen production station. For the selected electrolyzer, the values of 0.647 as exergetic efficiency, 0.0415 as waste exergy ratio and 0.65 as exergetic sustainability factor were estimated.

Keywords: Decarbonization, Exergy, Green Hydrogen, Hydrogen Station, Sustainability.

1. INTRODUCTION

Because of the carbon emissions, promoting the adoption of green technologies to replace carbon in the industry is one of the primary goals. At this point, hydrogen is among the favourites in terms of sustainability. Considering its many attractions, the element hydrogen makes sense for production and usage. Oxygen can be mixed with it. Water is the reaction's product, and there are no emissions. Of all the fuels, it has the largest gravimetric energy density [1]. Its electrochemical and chemical activity is adequate [1] . This element is among the greatest candidates for decarbonization because of these benefits [1].

Compared to the previous years, global hydrogen demand increased by 2% to 54 Mt [2]. 60% of the demand was for ammonia production, 30% for methanol and 10% for Direct reduced iron process [2]. Most of the hydrogen used in these processes is produced by natural gas reforming and gasification and is called gray hydrogen. These methods have their own carbon emissions that disrupt the intended full clean life cycle of hydrogen production [2]. This implies that the life cycle of hydrogen production also needs to be decarbonized for maximum impact. The production process could be cleaner when electricity or high temperature comes from renewable sources. This is where electrolyzer technology that can produce green hydrogen comes in [2]. For hydrogen to be considered green, no GHG gases or pollutants must be released into the atmosphere during its production. Renewable energy sources such as wind, solar, hydro, wave, tidal, thermal, geothermal, ocean thermal, biomass and another clean energy sources and energy recovery systems are the pathways of the production of the green hydrogen [3]. Through these systems, we can generate electrical, thermal, biochemical and photonic energies [3]. There are currently 4 types of electrolyzer that produce green hydrogen in this clean way [4]. Alkaline and proton exchange membrane electrolyzers are currently used commercially [4]. Solid oxide and anion exchange membrane-based electrolyzers have high potential but low commercial maturity [4]. In this study, the proton exchange membrane (PEM), whose commercialization is more mature, is considered for the system.

In the literature, there are many studies on the evaluation of such green systems in terms of exergetic sustainability. In a study [5], the importance of energetic and exergetic assessment of the sustainability of renewable energy systems such as green hydrogen stations are emphasised. In another study [6], a hibrit system of hydrogen production from renewable energy and storage of the produced hydrogen was evaluated from energy, exergy, economic and environmental perspectives.

Due to the high cost, the role of electrolyzer in hydrogen production is currently limited. Nevertheless, as technology advances, the time for green hydrogen will eventually come. Therefore, it is important to investigate the exergetic indicators that give some important clues about the sustainability of a green station, which is also the aim of this study.

2. ANALYSIS

Considering a system similar to the one shown in Fig. 1, some exergetic parameters to be calculated for the electrolyzer part will have an important place for further analyses of the system. The inputs and outputs in a typical PEM electrolyzer are shown in Fig. 2. The definitions for the calculations are shown in Table 1.

Fig. 1. General View of a Green Hydrogen Station

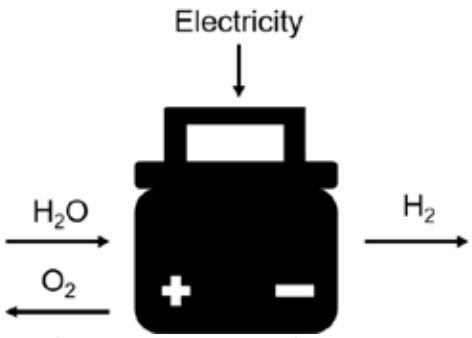

Fig. 2. Schematic Illustration of a PEM Electrolyzer

Table 1. Exergetic sustainability definitions for the electrolyzer

Parameters	Definitions	Range	Ref.
Exergetic efficiency	$\frac{\textit{Total exergy of desired output}}{\textit{Total exergy input}}$	Ranging from 0 to 1	[7]
Waste exergy ratio	$\frac{\textit{Total waste exergy output}}{\textit{Total exergy input}}$	Ranging from 0 to 1	[7]
Exergy destruction factor	$\frac{\textit{Exergy destruction}}{\textit{Total exergy input}}$	Ranging from 0 to 1	[7]
Unusable exergy ratio	$\frac{\textit{Unusable waste exergy}}{\textit{Total exergy input}}$	Ranging from 0 to 1	[7]
Reusable exergy ratio	$\frac{\textit{Reusable waste exergy}}{\textit{Total exergy input}}$	Ranging from 0 to 1	[7]
Environmental destruction coefficient	$\frac{1}{\textit{Exergetic efficiency}}$	Ranging from 1 to +∞	[7]
Environmental destruction index	$(\textit{Exergy destruction factor} + \textit{Unusable waste exergy ratio}) \times \textit{Environmental destruction coefficient}$	Ranging from 0 to +∞	[7]
Environmental benign index	$\frac{1}{\textit{Environmental destruction index}}$	Ranging from 0 to +∞	[7]
Exergetic stability factor	$\frac{\textit{Total exergy of desired output}}{(\textit{Total exergy of desired output} + \textit{Unusable waste exergy} + \textit{Exergy destruction})}$	Ranging from 0 to 1	[7]
Exergetic sustainability index	$\textit{Environmental benign index} \times \textit{Exergetic stability factor}$	Ranging from 0 to +∞	[7]
Sustainability index	$\frac{1}{1 - \textit{Exergetic efficiency of system}}$	Ranging from 1 to +∞	[6]
Improvement potential ratio	$\frac{(1 - \textit{Exergetic efficiency}) \times (\textit{Total exergy input} - \textit{Total exergy output})}{\textit{Total exergy input}}$	Ranging from 0 to 1	[8]

The data required for the calculation of exergy-based sustainability characteristics for the electrolyzer are obtained from [4, 9, 10]. Chemical exergy values are taken from [11]. The following assumptions were also made.

- The PEM electrolyzer functions under steady-state conditions.
- The water used as reactant is laminar, incompressible and steady.
- The water used is in liquid form.
- All gases are considered ideal gases.
- Kinetic and potential exergies are ignored.
- Based on the PEM operating conditions at the source, the cell temperature is assumed to be 353 K [10].
- The cell pressure is defined as 30 bar [10].
- The death state temperature is 298.15 K, while the dead state pressure is 1 atm [7].
- The physical exergy of the hydrogen in the output is assumed to be reusable.
- The physical and chemical exergies of oxygen in the output are assumed to be unusable.
- Depending on the electrolysis technique, it has been stated in the literature that the amount of electrical energy required to produce 1 kg of hydrogen (H_2) varies between 50 and 55 kWh [9]. In this study, it is assumed that 50 kWh of electrical energy is required to produce 1 kg of hydrogen.

3. RESULTS AND DISCUSSION

According to the calculations, the exergetic sustainable parameters in Table 2 were obtained by putting the data of the selected electrolyzer into the specified definitions.

Table 2. Some exergetic sustainability parameters of selected electrolyzer

Parameters	Results	Reference values [6–8]
Exergetic efficiency	0,647	Close to 1
Waste exergy ratio	0,0415	Close to 0
Exergy destruction factor	0,3115	Close to 0
Unusable waste exergy ratio	0,018	Close to 0
Reusable waste exergy ratio	0,0235	Close to 0
Environmental destruction coefficient	1,545	Close to 1
Environmental destruction index	0,509	Close to 0
Environmental benign index	1,964	>>1
Exergetic stability factor	0,65	Close to 1
Exergetic sustainability index	1,2766	>>1
Sustainability index	2,832	>>1
Improvement potential ratio	0,124	Close to 0

The identification and calculation of exergetic sustainability parameters can be the cornerstones for vital analysis prior to the establishment of such systems. By obtaining indicators for the electrolyzer part of the station, the exergy efficiency of the electrolyzer can be found, losses can be discovered and improvement possibilities for better production can be accessed. Furthermore, the station's impact on decarbonization and contribution to the environment can be measured.

4. CONCLUSIONS

Green hydrogen production with clean methods is of great importance for the decarbonization of hydrogen production, which will be a solution to global decarbonization. For this purpose, it is essential to determine and analyze the exergetic sustainability criteria of green hydrogen production stations. These findings can be used in feasibility analyses to provide information on the barriers that may be encountered during and after the establishment of the station and contribute to the sustainability of the green hydrogen economy. Considering the values obtained, the exergetic efficiency of the electrolyzer is close to the values in the literature [12, 13]. As with the value found as waste exergy ratio, it is desired to be close to 0. The exergetic stability factor was also measured as 0.65, which is an acceptable value. Improvement potential is a relative concept. If the system is already working properly, a low value can be considered positive. However, if the system is not currently performing as expected, a high value is a good sign of upgradability. A low value in the calculations indicates that the system is working efficiently.

ABSTRACT
This study explores a solar-powered hydrogen production and storage system developed and simulated in MATLAB/Simulink. The system integrates photovoltaic panels (PV), anion exchange membrane water electrolyzers (AEMWE) utilizing polybenzimidazole (PBI) membranes, and metal hydride (MH) tanks. AEMWE presents a cost-effective alternative to traditional water electrolysis methods, and MH tanks provide safe, low-pressure hydrogen storage, addressing one of the main challenges in hydrogen commercialization: safe and efficient storage. Based on Izmir's average irradiation and ambient temperature in July, the simulation estimates a total hydrogen production of 0.35 kg. To illustrate the significant impact of operating temperature and thermal management on storage efficiency, the thermal behavior of MH tanks is assessed under varying convection coefficients (10–1500 $W/m^2 \cdot K$). The effects on tank temperature and hydrogen weight fraction are evaluated, with pressure and temperature limits applied to ensure a realistic depiction of system operation. Results indicate that higher convection coefficients (500 and 1500 $W/m^2 \cdot K$) facilitate efficient storage within acceptable limits, while lower values (10 and 100 $W/m^2 \cdot K$) result in up to 0.28 kg and 0.04 kg of unstored hydrogen, respectively, highlighting the crucial significance of thermal management in system performance.

Keywords: Metal Hydride, Electrolyzer, AEMWE, Thermal Effect, PV-Integrated Electrolyzer

1. INTRODUCTION
Climate change adversely affects the environment, economy, and public health, necessitating a transition to renewable energy sources (RES) like solar, wind, and hydrogen energy, which serve as cleaner alternatives to fossil fuels. Solar energy, produced by PV panels, has an edge due to its abundance and easy accessibility and is particularly promising in various regions. Hydrogen energy, on the other hand, stands out as it is not only a promising fuel but also a versatile energy carrier, offering exceptional energy storage capability with a high heating value (HHV) of approximately 142 MJ/kg. Sustainable hydrogen production through water electrolysis has been established for over two centuries, with alkaline water electrolysis (AWE) and proton exchange membrane water electrolysis (PEMWE) being the most common two methods. While AWE is a well-established technology, its design involves gaps that reduce efficiency and raise safety risks under pressure differences. With a zero-gap design, proton exchange membrane (PEM) electrolyzers improve proton transfer and high-pressure operation but require expensive noble metals for their electrodes, increasing costs. Anion exchange membrane water electrolysis (AEMWE) presents a promising alternative by combining the zero-gap structure of PEM with cheaper electrode materials, like nickel-based electrodes, and operating in near-neutral or alkaline conditions. Among various membranes used for anion exchange membrane (AEM) electrolyzers, polybenzimidazole (PBI) is favored for its mechanical strength and thermal stability, potentially enhancing the viability of green hydrogen technologies.

Challenges remain in hydrogen transport and storage, typically handled as gas or liquid. Gaseous storage needs high pressures (up to 700 bar), which raises safety and energy concerns, while liquid storage requires cryogenic temperatures around -253°C, complicating infrastructure and operational costs. Solid-state storage using metal hydride tanks is an alternative, allowing hydrogen to be stored in solid form through reversible chemical absorption with transition metals. This method supports lower pressures (10-30 bar) and moderate temperatures, enhancing safety and simplifying operations. The temperature of the metal hydride tank bed can be effectively adjusted by changing the flow rate of hydrogen gas fed into the tank, thus improving operational safety and enabling efficient thermal management. In this context, this study investigates how variations in convection coefficients, influenced by thermal management systems, affect the temperature of metal hydride tanks and the amount of hydrogen stored.

2. MODELING
The system consists of a PV panel powering a PBI-based AEM electrolyzer, enhanced by a maximum power point tracking (MPPT) unit for improved efficiency. Hydrogen is managed through a PID-controlled system that regulates pressure and flow to metal hydride (MH) storage tanks—filling switches to the next tank when one reaches its maximum temperature, resuming only after it cools to a safe level, ensuring efficient and safe hydrogen storage. A schematic of the system is shown in Fig. 1.

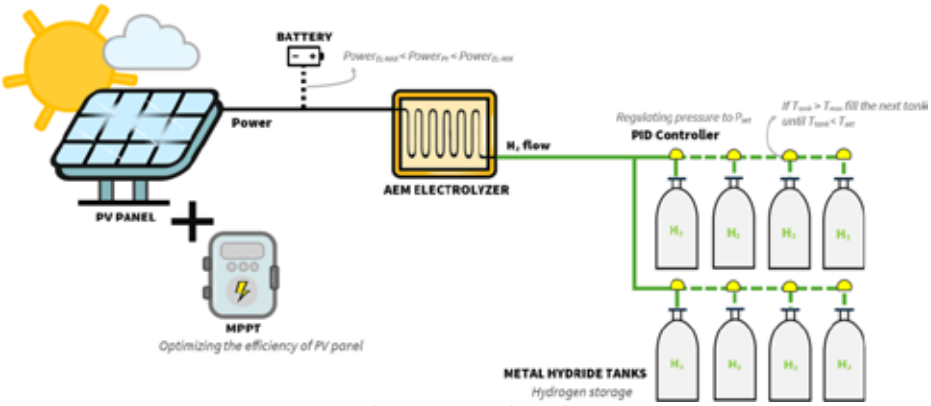

Fig. 1. Schematics of the System

An AEMWE involves complex transport and electrochemical processes. A 0D model is developed to relate cell voltage and current, focusing on deviations from ideal voltage as described in Eq. 1 [1]. This model is implemented in Simulink using a MATLAB Function block for integration with system simulation

$$V_{cell} = V_{Rev} + \eta_{act,a} + \eta_{act,c} + \eta_{ohm} + \eta_{KOH} + \eta_{Bub} \quad (1)$$

Here, V_{cell} represents the cell voltage and calculated as the sum of the reversible voltage (V_{Rev}), the anodic ($\eta_{act,a}$) and cathodic activation overpotential ($\eta_{act,c}$), the ohmic losses (η_{ohm}), the electrolyte (KOH) resistance losses (η_{KOH}), and the bubble resistance losses (η_{Bub}). PBI was employed as the membrane in the AEMWE model, where the ohmic overpotential was calculated using membrane resistance determined by Eq. 2.

$$R_{mem} = \frac{t_{AEM}}{\sigma_{AEM}} \quad (2)$$

Here, t_{AEM} is the membrane thickness (50 µm), σ_{AEM} is the OH^- conductivity, and R_{mem} is the area-specific resistance, taken as 84.4 Ω·cm² for the selected PBI membrane [2]. The resulting hydrogen mass flow rate is used to compute the hydrogen volumetric mass flow input for the metal hydride model, as shown in Eq. 3 [3].

$$\epsilon \frac{\partial \rho_g}{\partial t} = \dot{m}_{in}''' - \dot{m}''' \quad (3)$$

This equation describes the rate of change of hydrogen gas density (ρ_g) within the porous medium of the metal hydride bed. The porosity of the metal hydride bed is described by ϵ, $\dot{m}_{in}'''$ represents the volumetric mass flow rate of hydrogen entering the tank, and $\dot{m}'''$ represents the volumetric mass flow rate of hydrogen absorbed by the metal hydride.

Fig. 2 shows the overall proposed system, including the PV-electrolyzer system (Fig. 2a) and metal hydride storage units (Fig. 2b) modeled in Simulink.

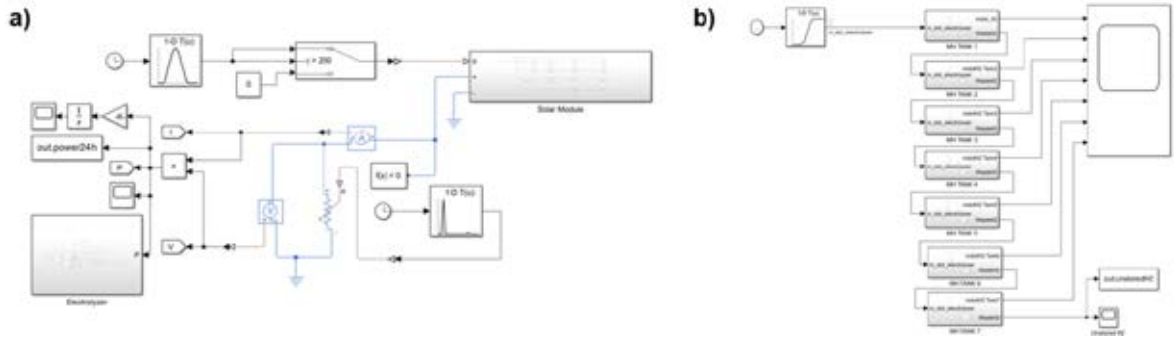

Fig. 2 (a) PV-electrolyzer **(b)** MH tank system blocks in Matlab-Simulink

3. RESULTS AND DISCUSSION

Simulations were performed considering Izmir's average irradiation and ambient temperature in July [4]. The analysis utilized 12 TrinaSolar Duomax_TSM_DEG5_60C_280W photovoltaic modules, achieving a maximum output of 2796 W at midday. Power generation begins around 5th hour peaks near midday, and ends around 15th hour. In parallel, the hydrogen mass flow rate, as shown in Fig. 3b, reached a maximum of 0.0466 kg/s at around 10th hour. The electrolyzer efficiency, depicted in Fig. 3c, was operated under conditions that allowed a minimum efficiency of 55%. Throughout the operational period, it successfully maintained an average efficiency of 60.45% (LHV). System efficiency remained consistently above this threshold, so battery integration was not required for the selected configuration. As shown in Fig. 3d, cumulative hydrogen production increased steadily, totaling 0.3527 kg by the end of the day.

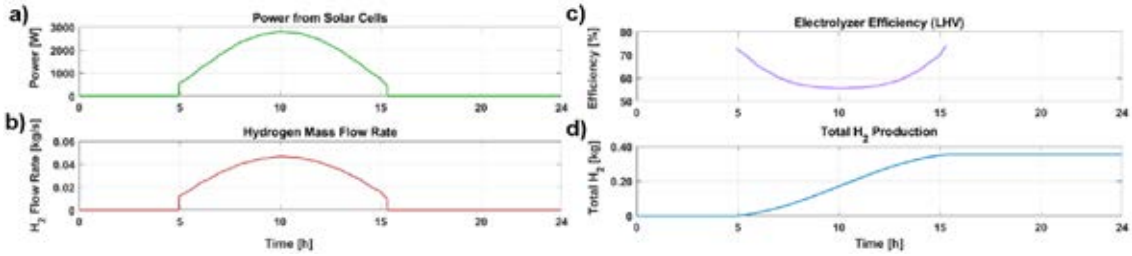

Fig. 3 (a) Power from solar cells (W) **(b)** Hydrogen mass flow rate (kg/s) **(c)** Electrolyzer LHV efficiency **(d)** Total H_2 production (kg)

Based on the total mass of hydrogen produced, the required number of MH tanks was calculated to be 6.56; therefore, 7 tanks were employed in the analyses. A PID controller managed the hydrogen flow rate and maintained pressure within a safe range, set conservatively at 25 bar, below the maximum of 30 bar specified by the MyH_2 300 tank manufacturer. The maximum operational temperature for the tanks was 60°C, pausing hydrogen filling until temperatures dropped to 40°C. The filling can co-occur in two or more tanks when temperatures are below 40°C, but the pressure is near the 25 bar threshold. Analyses were conducted using convection coefficient (*h*) values of 10, 100, 500, and 1000 W/m^2·K. Fig. 4 demonstrates the tanks' filling process when the *h* is set to 100 W/m^2·K.

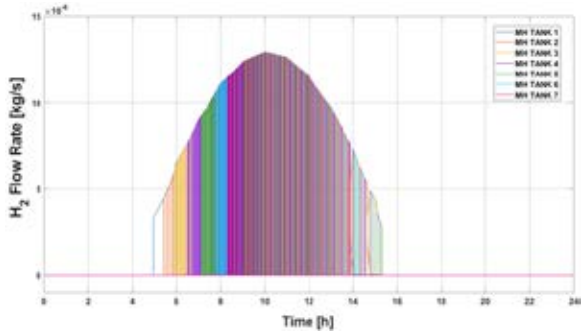

Fig. 4 Hydrogen flow rate distribution into each MH tank over time when the convection coefficient (*h*) is set to 100 W/m^2·K.

Fig. 5 highlights how different convection coefficients influence the tank temperature behavior as the ambient temperature varies.

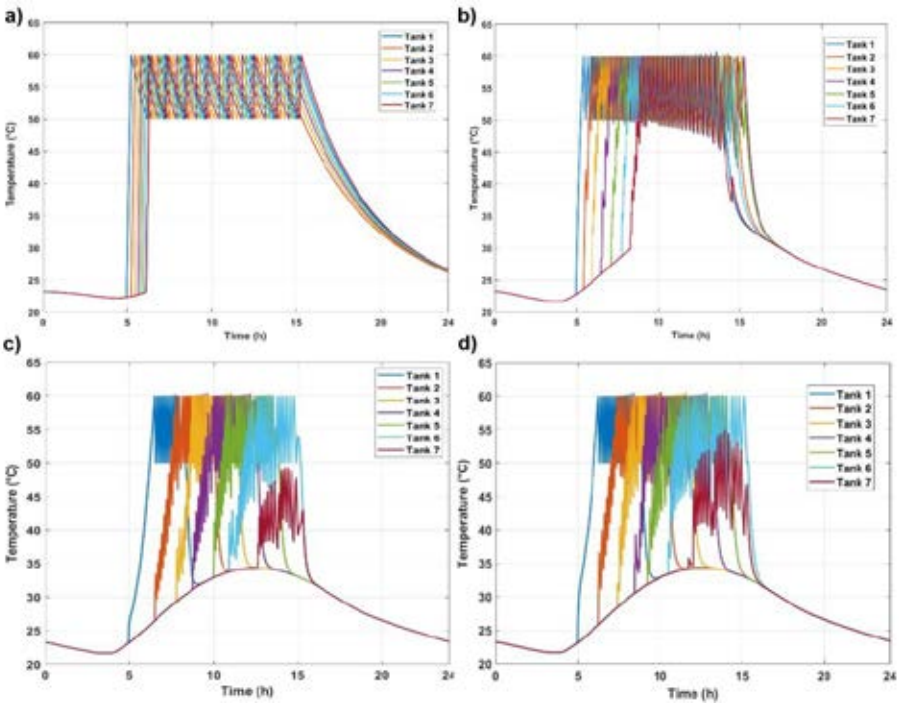

Fig. 5 Temperature profiles of metal hydride tank bed with a convection coefficient (W/m^2·K) of **(a)** *h* = 10 **(b)** *h* = 100 **(c)** *h* = 500 **(d)** *h* = 1500

As shown in Fig. 5, when the *h* is 10 and 100 W/m²·K, the slow temperature decrease prevents sufficient cooling, which in turn limits the filling process in the tanks. Consequently, most tanks cannot reach the maximum achievable weight

fraction (*wf*) of 1.3087. Finally, Fig. 6 shows the impact of convection coefficients on the hydrogen weight fraction stored in the MH tanks.

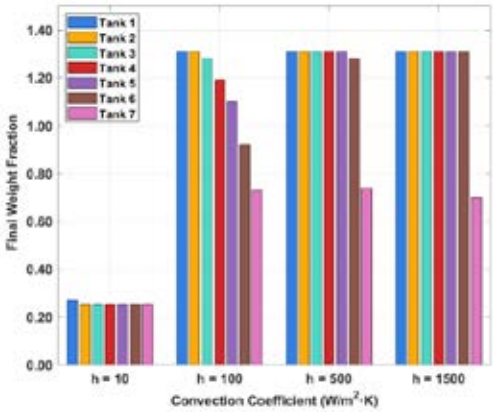

Fig. 6 Final weight fraction in metal hydride tanks at the 24th hour for different convection coefficients

As shown in Fig. 6, the maximum *wf* for one tank is approximately 0.27 by the end of the day when *h* is 10 W/m^{2}K. In contrast, the tanks reach complete filling when *h* is increased to 500 or 1500 W/m^2·K. This directly affects the amount of hydrogen that can be stored versus the amount that remains unutilized. Fig. 7 illustrates this impact by comparing the cases with *h* = 10 and *h* = 100 W/m^2·K.

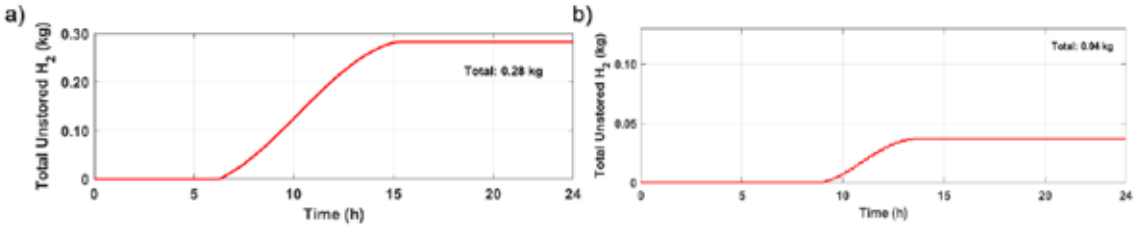

Fig. 7 Unstored H_2 mass flow rate (kg/s) and total unstored H_2 (kg) with a convection coefficient (W/m^2·K) of **(a)** *h* = 10 **(b)** *h* = 100

Fig. 7a illustrates the amount of hydrogen that remains unstored when *h* = 10 W/m^2·K, while Fig. 7b presents the case for *h* = 100 W/m^2·K. In these scenarios, 0.28 kg and 0.04 kg of hydrogen remain unstored, corresponding to 80% and 11.43% of the total 0.35 kg produced, respectively. The entire amount of hydrogen is successfully stored at higher convection coefficient values.

4. CONCLUSIONS

Simulation results indicate that under typical July conditions in Izmir, using 12 photovoltaic modules and 8 AEMWE cells, approximately 0.3527 kg of hydrogen can be produced throughout the day. Different convection coefficients were tested to highlight the importance of thermal management strategies. Metal hydride tanks achieved complete filling at 500 and 1500 W/m²·K while remaining within safe limits. In contrast, lower coefficients of 10 and 100 W/m²·K resulted in insufficient cooling, leaving 0.28 kg and 0.04 kg of hydrogen unstored, respectively. This demonstrates that effective thermal management enhances storage efficiency and overall system performance, with the convection coefficient playing a crucial role in managing operational temperature limits.

ABSTRACT

Recently, the high penetration of solar photovoltaic (PV) panels has emerged as a prominent solution for hydrogen production. With the easy availability of solar energy and the high efficiency of solar energy conversion systems, these systems have been adopted to maximize solar energy use to supply local loads, such as electrolyzers. The power generated by the PV module fluctuates depending on both solar radiation and ambient temperature. This variability in solar PV energy must be minimized to ensure a steady flow of energy to the electrolyzer. To reliably power the electrolyzer and provide constant power to direct current (DC) loads, it is crucial to maintain the output voltage of the PV converter within the desired range. The primary challenge addressed in this work is managing the fluctuations in energy generated by PV panels to produce hydrogen efficiently. To achieve this, the Perturb and Observe (P&O) algorithm, a type of maximum power point tracking (MPPT) algorithm, was implemented in the model to make optimal use of the energy provided by PV panels. Consequently, a DC-DC buck converter is designed to lower the voltage to the appropriate level and supply the electrolyzer both safely and efficiently. Simulation studies were conducted in the MATLAB/Simulink environment. Our findings indicate that the design operates with high efficiency and yields satisfactory results concerning sustainability. This study confirms that the designed system operates stably under varying solar irradiance values and can contribute to advancements in related fields for future work.
Keywords: Photovoltaics (PVs), Power Electronic Converters, Hydrogen Energy, Maximum Power Point Tracking (MPPT), Electrolyzer.

1. INTRODUCTION

Nowadays, renewable energy sources such as solar, wind, hydro, geothermal, and hydropower are becoming increasingly important due to the growing energy crisis, environmental pollution, and global warming [1]. Thanks to the easy accessibility of solar energy, which is abundant among these renewable energy sources, and highly efficient solar energy conversion systems, PV panels have become a preferred energy source in many areas, such as green hydrogen production. However, the energy produced by PV modules varies depending on environmental factors such as ambient temperature and solar radiation. This variability can complicate the smooth and continuous supply of electrolysers for green hydrogen production. Therefore, it is important to ensure a stable, constant, and highly efficient transfer of the generated energy to the electrolyser. To solve this problem, the study focuses on designing a system that optimizes the energy flow by stabilizing the variable state of solar energy.

Hydrogen is seen as the most promising energy carrier of the future due to its zero emissions and high energy density. Electrolysis is essentially the process of splitting water into hydrogen and oxygen, its elements. Solid oxide electrolysis (SOE), proton exchange membrane (PEM), and alkaline electrolysis are the most widely used methods for hydrogen production, and integration with renewable energy sources can produce green hydrogen [2]. However, the variable nature of PV systems poses challenges such as integration and energy management. Since electrolyzers operate stably at certain power levels, irregular energy input can lead to system performance degradation and equipment failure. Therefore, it is crucial to employ an effective power management strategy for the safe and efficient operation of the system [3]. For this reason, a DC-DC buck converter is included in our study to adjust the voltage and current values generated by the PV system to the required level for the electrolyzer.

Among the electrolyzers prominent in the literature, PEM electrolyzers possess advantages such as high purity gas production, low power consumption, and efficiency compared to other electrolyzers [4]. M. E. Amri et al. developed a model for battery charging with PV energy and green hydrogen production using the electrolyzer. The system modeled in Simulink showed good performance under varying solar irradiation [5]. N. J. W. Chieh et al. studied the efficiency of green hydrogen production by integrating PV panels and electrolyzers in a simulation environment. The simulation results confirmed that the proposed model operates at high efficiency [6].

In this study, a model is proposed to produce green hydrogen efficiently and safely by managing the variable energy output produced by the PV system with the aid of an electrolyzer. With the proposed model, the variable output of the PV system is stabilized, and the electrolyzer that produces green hydrogen receives the current and voltage values at which it will operate at an optimum level. As for the remaining sections of the study, a general summary of the proposed

model for green hydrogen production is presented in Section II. The findings obtained in the study are presented in Section III, while the conclusions drawn from this research are summarized in Section IV.

2. GENERAL OVERVIEW SOLAR PV GREEN HYDROGEN PRODUCTION MODEL

Solar panels are renewable resources that convert sunlight into electricity. The voltage produced by solar panels and the current values transferred to the load vary depending on weather conditions. Additionally, the installation order of the panels and dust significantly affect the operation of the solar panel. The green hydrogen production model, aided by the proposed PV-based electrolyzer, consists of the PV system, electrolyzer, DC-DC Buck converter, MPPT P&O Algorithm, and hydrogen storage tube, as shown in Figure 1.

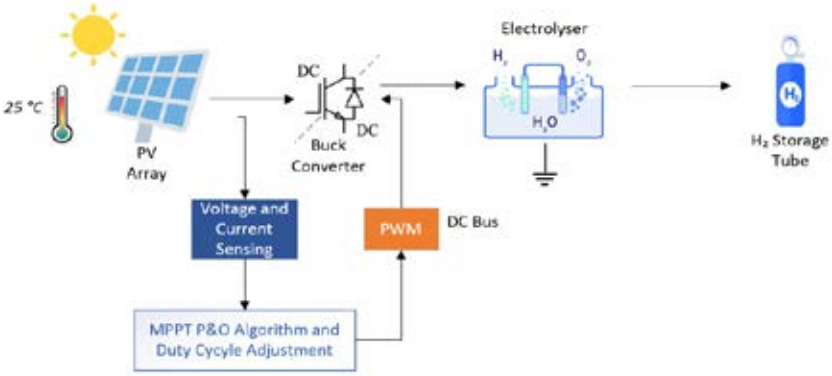

Fig. 1. Overview of proposed solar PV green hydrogen production model.

As shown in Figure 1, the energy from the solar panel is directly routed to the electrolyzer through a DC-DC buck converter managed by the P&O algorithm. The buck converter is integrated into the system to ensure a stable and safe energy supply to the electrolyzer. The Perturb & Observe (P&O) approach is chosen as the MPPT algorithm to reduce the fluctuations caused by the variable output of the PV system and to improve energy efficiency. In the simulation, ramp, trapezoidal, and staircase irradiance profiles, shown in Figure 2, are selected as PV system irradiance inputs to analyze system performance under varying real environmental conditions. The ramp irradiance profile examines the system behavior at periodically varying irradiance levels throughout the day, while the trapezoidal irradiance profile assesses the irradiance levels during the late and early hours. The staircase irradiance profile is used to analyze the system behavior during sudden changes, such as cloud cover.

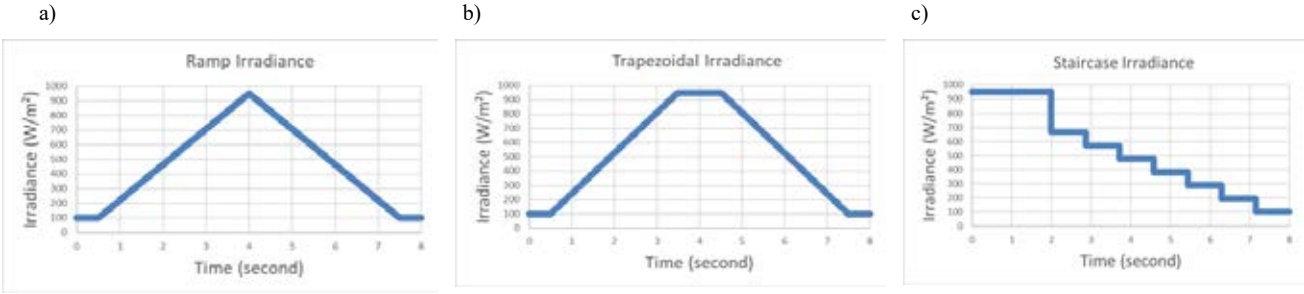

Fig. 2. a) Ramp irradiance profile, b) Trapezoidal irradiance profile, c) Staircase irradiance profile.

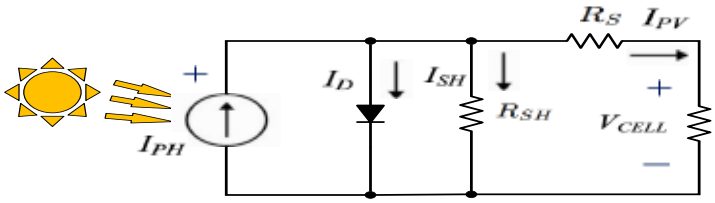

Fig. 3. Conventional PV panel equivalent circuit.

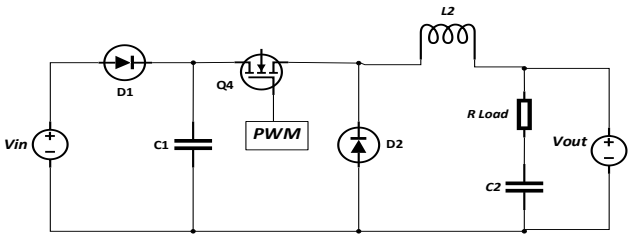

Fig. 4.DC-DC Buck Converter Circuit

The electrical equivalent circuit diagram of a conventional PV panel is shown in Figure 3. When PV cells absorb sunlight, the photons excite electrons, producing a photocurrent (*Iph*). This current depends on solar irradiance (G) and panel temperature (T). In the equivalent circuit of a conventional PV panel, Ipv is represented as (2).

$$-Iph+Id+Ish+Ipv=0, \quad (1)$$

$$Ipv=Iph-Id-Ish, \quad (2)$$

$$Vt= \frac{nk(Tstc)}{q}, \quad (3)$$

$$Vt= Iph-Id(e^{\frac{Vcell+IpvRs}{nVt}} - 1) - \frac{Vcell+IpvRs}{Rsh} \quad (4)$$

$$Iph=Isc +ki(T-Tstc) \frac{G}{Gstc} \quad (5)$$

Here, Id is the saturation current of the diode, Rs is the series resistance, and Rsh is the shunt resistance. n is the ideality factor of the diode, which affects the electrical behavior of the cell. Environmental factors cause the thermal cell voltage, known as Vt, to occur. q is the charge of the primary charge carrier, the electron, while k is the Boltzmann constant. Furthermore, Isc is the short-circuit current, Tstc is the reference temperature determined under standard test conditions, and Gstc is the solar irradiation level under the same conditions [7]. In this project, a buck converter, also called a step-down converter, is used to regulate the output voltage supplied to the electrolyzer. It operates in two states depending on the switch position: when open, energy is stored in the inductor; when closed, the stored energy is transferred to the capacitor and through the diode to the load, i.e., the electrolyzer. The capacitor meets instantaneous power demands, preventing current and voltage fluctuations in the circuits and ensuring stable operation. This cycle repeats continuously according to the duty cycle of the MOSFET, and the output voltage is lower compared to the input voltage. The following formulas can be used to calculate the inductor, duty cycle, and capacitor values in the DC-DC buck converter model schematically shown in Figure 4.

$$D = \frac{Vo}{Vin} \quad (6)$$

$$L= \frac{Vo(1-D)}{\Delta IL\ fs} \quad (7)$$

$$C= \frac{Vo(1-D)}{8\Delta Vofs^2L} \quad (8)$$

To maximize the benefits of the photovoltaic system, the MPPT P&O algorithm was employed in our study. When discussing the operational logic of the P&O algorithm, it first calculates the power output produced by the PV system using sensor data, while simultaneously introducing voltage distortion values into the algorithm to determine the direction for maximum power point tracking. These values are then compared with previous measurements, allowing adjustments in the system's output power based on the voltage distortion. This process enables the algorithm to oscillate around the maximum power point (MPP) and operates on the principle of continuously monitoring the MPP. The P&O algorithm was integrated into our proposed model, ensuring the PV system operates at peak efficiency. The electrolyzer received the appropriate energy input through a DC-DC buck converter controlled by the algorithm. Compared to other hydrogen electrolyzers, PEM electrolyzers are favored for their ease of maintenance, wide operating temperature range, and higher energy efficiency. The electric current flowing through the PEM electrolyzer is converted into a calculation for hydrogen production in accordance with Faraday's law. According to Faraday's law, the molar production rate of hydrogen gas is expressed by the following equation:

$$nH_2(t) = \frac{I(t)\eta\text{faraday}}{2\text{F}} \quad (9)$$

Here, I(t) represents the instantaneous electric current (A) of the system, η is the Faraday efficiency of the Faraday electrolyzer (taken as 95% in this project), and F is the Faraday constant (96485C/mol).

$$VH_2(t) = \frac{I(t)\eta\text{faradayVm}}{2\text{F}} \quad (10)$$

The amount of hydrogen produced is converted to volume according to the ideal gas law and is calculated using formula (10). The total amount of hydrogen produced is determined by integrating the instantaneous flow rate with respect to time.

3. RESULTS AND DISCUSSION

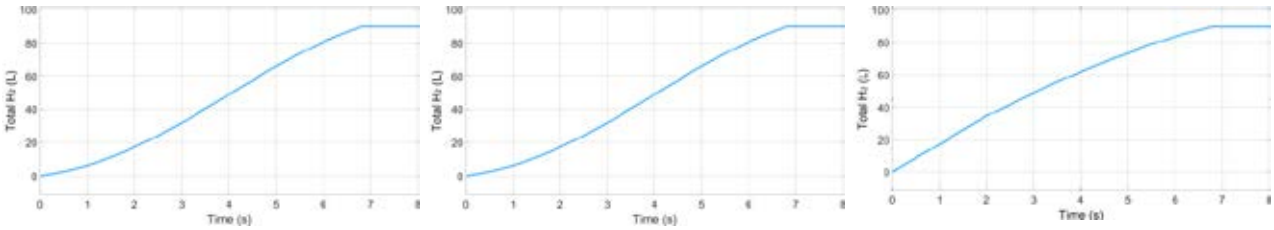

Fig. 5. a) Total hydrogen production in ramp irradiance profile, b) Total hydrogen production in trapezoidal irradiance profile, c) Total hydrogen production in staircase irradiance profile.

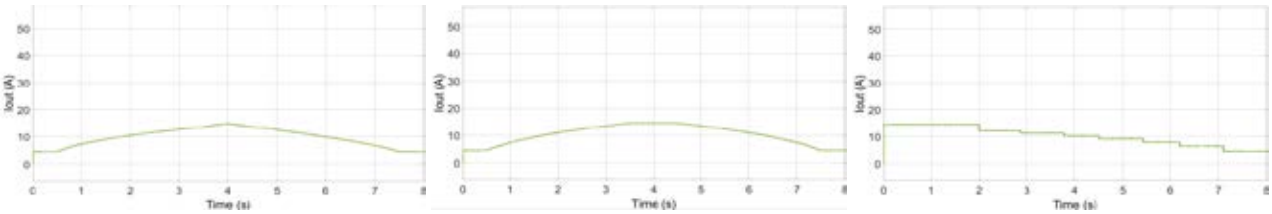

Fig. 6. Current curves for different irradiance profiles.

According to the simulation results conducted under various irradiance profiles, as can be seen in Figure 5, hydrogen production curves differ based on the temporal changes in irradiance. In the ramp irradiance scenario, where irradiance increases gradually, the hydrogen production curve initially shows a slow increase before accelerating over time, ultimately reaching the tube's capacity. In the Staircase profile, due to sudden changes in irradiance at specific steps, hydrogen production rises in parallel to these steps, leading to sharp transitions in the production curve. In the trapezoidal irradiance scenario, irradiance increases to a certain level, remains constant for a period, and then decreases again; thus, hydrogen production initially accelerates, displays a linear increase during the constant irradiance phase, and is constrained by the tube capacity as the irradiance decreases in the final segment. These results highlight the dynamic effect of solar irradiance on hydrogen production and demonstrate that the irradiance profile directly influences the production characteristics. Furthermore, the current curves for different conditions are shown in Figure 6.

4. CONCLUSION

This study introduces a system for producing green hydrogen using a PEM electrolyzer powered by variable energy from photovoltaic panels. The paper thoroughly discusses the MPPT P&O maximum power tracking algorithm and the buck converter circuit. A simulation environment was established to assess solar panel efficiency across different irradiance profiles—staircase, ramp, and trapezoidal—representing real-world conditions. With MPPT, the hydrogen production system successfully generated hydrogen in the PEM electrolyzer, even under changing irradiance levels, by optimizing power from solar panels rated at approximately 790 W. Consequently, the system effectively and safely completed the hydrogen production process, maximizing the use of solar energy despite variability in solar irradiance. This study aims to contribute to the advancement of hydrogen production systems reliant on renewable energy and to enhance performance by incorporating more advanced MPPT algorithms in future work. Notably, this system is intended to serve as a foundation for an experimental dashboard in our upcoming research.

ABSTRACT
In this study, 3 different electrolytes were used as 1 M sodium chloride (NaCl), calcium chloride ($CaCl_2$) and magnesium chloride ($MgCl_2$) salts. The hydrogen production performance of these solutions was investigated using the chlor-alkali method. While the electrodes were made of carbon rods consisting of a mixture of carbon and graphite obtained from waste batteries, the main body of the reactor was manufactured from Delrin polymer material using CNC technology. Nafion 117 membrane was used to separate the anode and cathode compartments. The study was carried out at 20 ° C temperature and 5 V cell voltage. According to the experimental results, in the electrolysis process carried out using NaCl solution, 10 mL of hydrogen was produced in 5.30 minutes, 20 mL in 9.40 minutes and 30 mL in 13.20 minutes, and the average current during was measured 0.30 A. Similarly, in the experiments conducted with $CaCl_2$ solution, the same amount of hydrogen production was completed in 6.58 min, 13.54 min and 21.42 min, respectively, and the average current was measured 0.16 A. In contrast, in the experiments conducted with $MgCl_2$ solution, the hydrogen production times of 10 mL, 20 mL and 30 mL were recorded as 45.32 min, 92.04 min and 134.10 min, respectively, and the current was only 0.02 A. As a result, $MgCl_2$ solution was found to have much lower current but required more time compared to the other two solutions.

1. INTRODUCTION

Hydrogen presents significant potential for clean energy production and is recognized as a crucial element in the shift towards sustainable energy systems, owing to its eco-friendly attributes. As an energy carrier, hydrogen can play a key role in reducing carbon emissions across various sectors, such as transportation, industry, heating, and power generation, offering sustainable alternatives. Its significance goes beyond just mitigating greenhouse gas emissions; it also enables the seamless integration of renewable energy sources and offers viable energy storage solutions. Therefore, hydrogen is a fundamental element in building a more sustainable and robust energy infrastructure. Since chlor-alkali processes consume large amounts of energy, it is obvious that processes supported by renewable energy sources will be more advantageous for hydrogen production. A significant number of studies have been undertaken to research hydrogen production via the chlor-alkali process. These studies focus on the production of a hydroxide with hydrogen and chlorine gases, which are the natural results of the chlor-alkali process. Research has been conducted on hydrogen production efficiency, usually based on reactor design, variety of electrolytes used, and temperature and cell voltage.

In one of these studies, a mini chlor-alkali reactor was constructed to compare the hydrogen production performances of aqueous solutions of NaCl, KCl and $CaCl_2$ salts. The hydrogen production rates of these salts were experimentally investigated by changing the cell voltage, operating temperature and electrolyte flow rate. In this study, since steel electrode was used, very active chlorine gas was produced in trace amounts while an effective hydrogen gas evolution was observed. It was found that KCl salt was slightly faster than NaCl salt in terms of hydrogen production rate, while $CaCl_2$ salt was far behind them [1].

The electrode surface area used in the chlor-alkali process and the distance between the electrodes and the undesirable gas accumulation on the electrodes also have significant effects on the current density, which directly affects hydrogen production. In another study conducted to investigate these effects, the effects of electrolyte temperature and flow rate on the current density were also examined in addition to these variables. It was observed that increasing the electrode surface area and operating temperature increased the current density, while increasing the distance between the electrodes significantly reduced the current density by reducing the electric field. It was noted that increasing the electrolyte flow rate increased the current density very slightly. Apart from these, it was observed that air bubbles on the electrodes caused the current density to decrease very slightly over time [2-3].

In another paper, the hydrogen generation efficiency of the aqueous solution of $ZnCl_2$ salt, which is very various from the salts commonly utilized in the chlor-alkali method, was researched. The anode and cathode sections of the reactor divided by Nafion 212 membrane were injected with $ZnCl_2$ water-based solution and clean water, respectively. The hydrogen generation ratio was 0.89 mL/min under 20°C working temperature, 0.3 g/s mass flow ratio and 5 V operating voltage. Under the working temperature of 45°C, mass flow ratio of 0.3 g/s and cell voltage of 10 V, the hydrogen generation ratio was 5 mL/min [4].

The effect of treatment with HCl, H_2SO_4, and HNO_3 on the physicochemical properties of the Nafion 117 membrane has been investigated. Water uptake capacity, crystallinity, proton conductivity, and water dynamics were evaluated for both

treated and untreated membranes [5]. The effect of acid pretreatment on the conductivity of Nafion 117 was comprehensively studied using HNO_3, HCl, H_2SO_4, and H_3PO_4 at different concentrations [6-7].
In this study, a durable N177 membrane was used to separate the pure water and brine compartments of the chlor-alkali reactor. The chlor-alkali process supported by renewable energy systems appears to be an important application for hydrogen production despite some difficulties. Therefore, the energy efficiency of the chlor-alkali system and sustainable hydrogen production are important goals. The impact of certain system components involved in achieving this will be investigated in terms of their effect on hydrogen production performance.

2. SYSTEM DESCRIPTION

The schematic diagram of the chlor-alkali reactor constructed for the experimental study and the auxiliary equipment around the reactor is shown in Fig. 1. The nafion membrane 117 was used to separate the compartments of the rector. Electrolyte feed tanks were used to feed the reactor compartments, and another tanks were used to collect the waste electrolyte from the reactor. The volume of the produced gases was measured according to the water displacement principle and graduated cylinders were used for this purpose. Additionally, a DC power supply is employed to provide energy to the reactor. Peristaltic pumps are utilized to ensure continuous and smooth circulation of the liquid, controlling the flow of the electrolyte. The entire system is equipped with electrodes made from waste batteries, which facilitate the production of hydrogen and chlorine gases during the reaction.

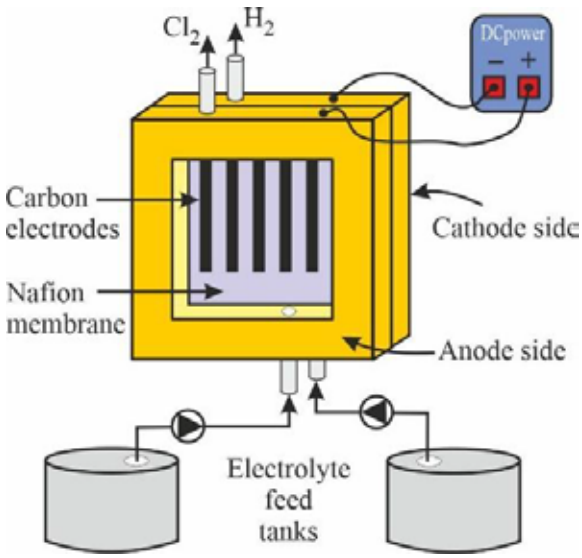

Fig. 1. The schematic representation of the experimental setup.

3. RESULTS AND DISCUSSION

In the study, hydrogen production from NaCl, $CaCl_2$ and $MgCl_2$ salts was investigated using the chlor-alkali method under conditions of 20°C temperature and 5 Volt cell voltage. The main body of the reactor was fabricated from Delrin polymer using CNC machining. A Nafion 117 membrane was used to separate the anode and cathode compartments, with carbon rod electrodes obtained from waste batteries used in both compartments.
Fig. 2 shows the outcomes achieved by placing NaCl solution in the anode compartment and pure water in the cathode compartment, maintaining a steady cell voltage of 5 V, an average current density of 0.30 A, and a temperature of 20°C. Hydrogen gas volumes of 10 cm³, 20 cm³, and 30 cm³ were generated and collected in the cathode section at time intervals of 5.30 minutes, 9.40 minutes, and 13.20 minutes, respectively.
Fig. 3 shows the outcomes achieved by placing $CaCl_2$ solution in the anode compartment and pure water in the cathode compartment, maintaining a steady cell voltage of 5 V, an average current density of 0.30 A, and a temperature of 20°C. Hydrogen gas volumes of 10 cm³, 20 cm³, and 30 cm³ were generated and collected in the cathode section at time intervals of 6.58 minutes, 13.54 minutes, and 21.42 minutes, respectively.
Fig. 4 shows the results from introducing $MgCl_2$ solution into the anode compartment and deionized water into the cathode compartment, with a stable cell voltage of 5 V, a consistent current density of 0.02 A, and a temperature of 20°C. Hydrogen gas volumes of 10 cm³, 20 cm³, and 30 cm³ were collected in the cathode section at time intervals of 45.32 minutes, 92.04 minutes, and 134.10 minutes, respectively.

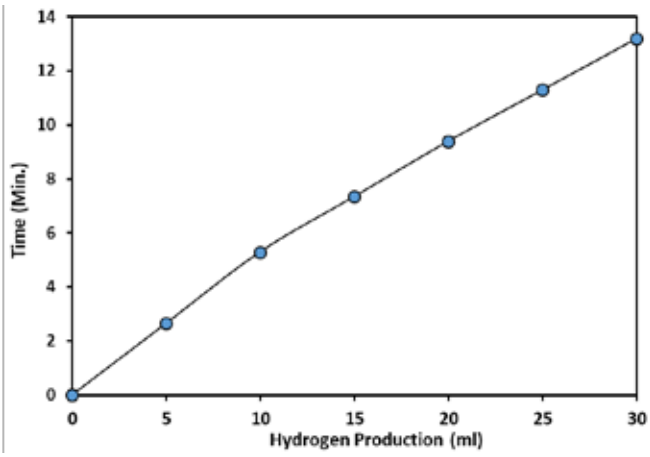

Fig. 2. Time-dependent hydrogen production (NaCl)

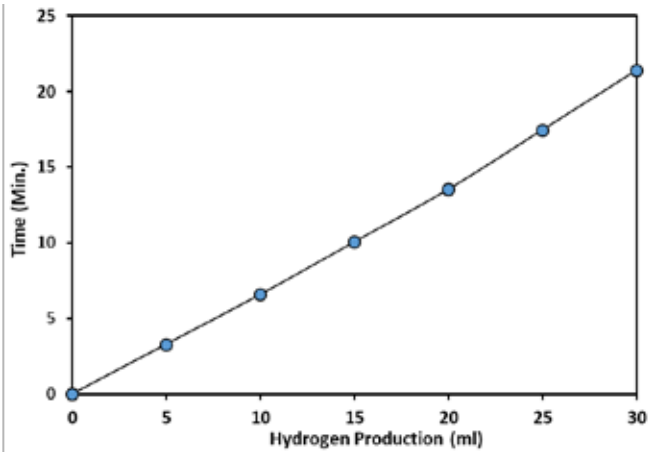

Fig. 3. Time-dependent hydrogen production ($CaCl_2$)

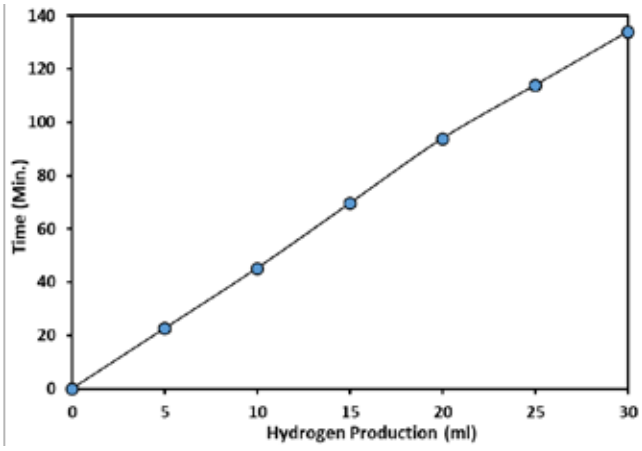

Fig. 4. Time-dependent hydrogen production ($MgCl_2$)

4. CONCLUSIONS

As a result, based on the experimental studies, when the hydrogen production performance of different electrolyte solutions was compared, 30 mL of hydrogen was produced in 13.20 minutes with an average current of 0.30 A using a 1 M NaCl solution, whereas the same amount of hydrogen was produced in 21.42 minutes with an average current of 0.16 A using a 1 M $CaCl_2$ solution. In contrast, when a 1 M $MgCl_2$ solution was used, the time required to produce 30 mL of hydrogen was significantly longer—134.10 minutes—with an average current of only 0.02 A. These results indicate that the $MgCl_2$ solution generated a much lower current during electrolysis and required considerably more time to produce

the same volume of hydrogen. Overall, it was observed that the most efficient hydrogen production, in terms of higher current and shorter duration, was achieved using the NaCl solution.

ABSTRACT
The need for energy is as old as human history. While early humans primarily used energy for heating, the Neolithic Age marked a transition to a settled lifestyle, shifting humanity from passive consumers to active producers. Since then, energy demand has steadily increased. Initially focused on production, energy consumption evolved by the 20th century to include comfort and convenience. During this period, fossil fuel-based energy became central to modern life, while concerns about environmental impacts led to growing interest in clean energy alternatives. Hydrogen energy has emerged as a promising solution in the search for sustainable energy, attracting attention from both engineers and social scientists. This study examines the social necessity of clean energy adoption, particularly the integration of hydrogen into natural gas systems, from a social policy perspective. Using data and models from previous studies, Aspen HYSYS simulation software was employed to analyze the physical properties and flow dynamics of hydrogen, natural gas, and their mixtures. A comparative literature review was also conducted to evaluate historical and current energy trends. Findings indicate that hydrogen integration is both strategically and technically viable, offering environmental benefits, economic efficiency, improved infrastructure utilization, and enhanced household welfare through its positive macroeconomic effects.

1. INTRODUCTION

Energy, commonly defined as the capacity to do work or perform tasks, is an indispensable component of human life due to its fundamental role in sustaining both universal and biological processes. In the modern era, energy has become more critical than at any other point in human history. It influences not only our quality of life but also the economy, environmental sustainability, and international relations [1]. Since the Industrial Revolution, the increased diversity and production of consumer goods have contributed to a dramatic, and often unpredictable, rise in the global population. This rapid population growth has, in turn, significantly escalated the demand for energy [2].

Although today's energy needs are met by a variety of sources, discussions increasingly center on the necessity for sustainable energy alternatives. At present, the majority of global energy demand is fulfilled by non-renewable and finite resources. These non-renewable sources are primarily categorized as fossil-based, followed by nuclear-based types. Fossil-based energy sources, which account for a substantial share of global energy consumption, include coal, oil, and natural gas. In contrast, renewable energy sources include hydropower, solar, biomass, wind, geothermal, wave/tidal, and hydrogen energy [3].

In particular, to address the ongoing reliance on fossil fuel-based energy, the use of natural gas, one of the primary energy sources, is projected to increase annually and maintain this upward trend in the coming years. Natural gas is composed of more than 90% methane, along with smaller amounts of ethane, propane, butane, and carbon dioxide. It is a colorless, odorless gas that is lighter than air. An analysis indicates that natural gas accounts for over 23% of global energy consumption [4]. However, natural gas is inherently a fossil-based and finite resource. Furthermore, its uneven geographic distribution and the resulting economic dependence hinder its accessibility and widespread use in certain countries. These limitations have prompted increased attention to energy efficiency. As a result, researchers across different disciplines continue to explore ways to improve both energy production and consumption efficiency. In this context, the concepts of "hydrogen" and the "hydrogen economy" have gained prominence.

Hydrogen is primarily regarded as a promising alternative in the transition to clean energy sources. Its classification as a "clean" energy source stems from the fact that its combustion produces only water and energy [5]. Composed of a single proton and one electron, hydrogen is the most abundant element in the universe [6]. Its potential as both a fuel and an energy carrier was recognized after the Industrial Revolution. Initially, it was used as fuel in internal combustion engines, later in diesel engines that utilized carbon and hydrogen compounds [7]. While not a primary energy source, hydrogen, as an energy carrier, holds significant potential to support and enhance the use of renewable energy systems [8]. In this context, the 1974 Hydrogen Economy Miami Energy Conference (THEME) marked a pivotal moment, establishing a shared vision for integrating hydrogen into future energy systems. Since THEME, efforts and research on hydrogen energy and the hydrogen economy have intensified considerably [9].

As a form of chemical energy storage, hydrogen is notable for its minimal environmental impact. However, the high cost of hydrogen storage remains a significant concern. To avoid these costs and reduce expenses associated with natural

gas usage, the injection of hydrogen into natural gas pipelines for use as fuel has emerged as a promising solution [10]. Integrating hydrogen into natural gas networks, due to its carbon-free nature, can help mitigate environmental issues such as air pollution and global warming [11], while also reducing the cost of natural gas for end users. This approach has the potential to lower overall energy costs and, consequently, reduce consumption-related expenditures. Nonetheless, it is important to recognize that there is an upper limit to the proportion of hydrogen that can be safely injected into natural gas pipelines [12]. These limitations must be carefully considered during cost-benefit analyses. Despite such constraints, the integration of hydrogen into natural gas infrastructure offers several key advantages, which can be summarized as follows:

- Significant reduction in greenhouse gas emissions can be achieved when hydrogen is produced from renewable resources.
- A decline in fossil fuel use, such as oil, can lead to reduced air pollution and enhanced air quality.
- Utilizing a natural gas-hydrogen blend for electricity generation can support the integration of renewable energy sources into existing energy systems and infrastructure.

2. METHODOLOGY

All calculations of the properties and flow rates of hydrogen, natural gas, and their 15% hydrogen-85% natural gas (by mole) blend were performed using Aspen HYSYS simulation software. The natural gas composition, adopted from a previous study [13], is presented in Table 1 alongside the blend composition. The simulation included the following components: CH_4, C_2H_6, C_3H_8, C_4H_{10}, C_5H_{12}, C_6H_{14}, CO_2, N_2 and H_2. The Peng-Robinson (PR) property package, selected for its efficiency and reliability, was used for all calculations, as detailed in Eq. (1) [14]. As shown in Table 1, methane (CH_4) is the dominant component in both cases, with a slightly lower concentration in the hydrogen blend (82.85% by mass, 78.45% by mole) compared to pure natural gas. This decrease is expected due to the inclusion of hydrogen, as methane is the primary combustible component in conventional natural gas.

Table 1. Compositions of natural gas and the hydrogen-natural gas blend used in the simulation.

	Mass Fractions (%)		Mole Fractions (%)	
	Blend	Natural Gas	Blend	Natural Gas
CH_4	82.85	84.53	78.45	92.29
C_2H_6	5.75	5.87	2.91	3.42
C_3H_8	2.76	2.82	0.95	1.12
C_4H_{10}	1.76	1.79	0.46	0.54

$$P = \frac{RT}{V-b} - \frac{a\alpha}{V(V+b)+b(V-b)} \quad (1)$$

Table 2 outlines the operating conditions and various key properties of natural gas, pure hydrogen, and the hydrogen-natural gas blend. All data were obtained from Aspen HYSYS under identical conditions (100 kPa and 15 °C), ensuring a consistent basis for comparison. Together, Tables 1 and 2 provide a comprehensive overview of how hydrogen blending alters the composition and fundamental properties of natural gas. These changes have significant implications for combustion efficiency, safety, transportation, and appliance compatibility, highlighting the importance of such analyses in evaluating hydrogen as a transitional fuel within existing gas infrastructure.

The data on hydrogen production and associated costs from Kayfeci et al., as cited in the study by Rasul and colleagues [15], are presented in Table 3. As shown, the cost information includes both operational expenses and fixed capital investment costs related to hydrogen production from fossil fuels. Assuming an average payback period of eight years for the fixed investment costs, listed under the “Capital Cost” heading in the table, the cost of hydrogen per kilogram was calculated by Kayfeci et al. [16].

3. RESULTS AND DISCUSSION

Based on the preceding analysis, Table 4 presents data on natural gas supplied for final household consumption in Türkiye, incorporating a 15% hydrogen blend. Monthly household consumption figures were calculated using Aspen HYSYS simulation software. Natural gas in households is primarily used for cooking, water heating, and space heating, representing a significant portion of household expenditures.

Tablo 4. Residential Natural Gas Consumption in Türkiye (2024) and NG+H_2 Simulation Values

Annual Total	19111.00		5751.18	16090.26	2839.46		5282.72		468.46

The data were compiled from the monthly reports of GAZBIR and EPIAŞ and were calculated by the authors.

Supplying households with a 15% hydrogen blend could reduce energy costs, allowing savings to be redirected toward other forms of consumption, potentially increasing national income through the multiplier effect [17]. In Türkiye, this shift could result in an estimated annual saving of $468.5 million, or approximately 8% of household natural gas spending, equivalent to 0.035% of the national income. With the 2024 national income projected at $1,323,255 million, reallocating these savings to other expenditures or investments could generate an additional $936.92 million in national income with an increase of 0.07%. These findings suggest that redirecting energy savings to broader household consumption can have a greater impact on economic growth than the original utility spending. Thus, blending hydrogen with natural gas to meet residential energy demand not only offers environmental benefits but also contributes to economic development. Promoting hydrogen integration is, therefore, a strategic step toward sustainability and growth.

4. CONCLUSIONS

This study examines the technical advantages of integrating hydrogen into natural gas systems, focusing on environmental sustainability and economic efficiency. Engineering analyses using Aspen HYSYS simulation software demonstrate that a natural gas mixture with 15% hydrogen is compatible with existing infrastructure, confirming its feasibility within current energy systems. This hydrogen-enriched blend enhances energy efficiency, reduces greenhouse gas emissions, and helps optimize energy costs. Hydrogen integration into natural gas pipelines significantly lowers the carbon footprint of energy systems and supports the efficient use of renewable energy resources. Engineering calculations confirm that a 15% hydrogen blend positively impacts both energy intensity and cost-efficiency. Economic modeling shows that this integration results in substantial savings on natural gas expenses, improving the cost-effectiveness of energy distribution. As a carbon-free element, hydrogen can address environmental challenges linked to fossil fuels and offers a strategic solution for enhancing long-term energy security. Additionally, incorporating hydrogen into existing infrastructure supports the economic sustainability of energy policy and fosters technological progress. In conclusion, hydrogen integration is a strategic and technically viable approach, enabling more efficient use of infrastructure, lowering costs, and promoting sustainability. It also improves household welfare at the micro level while contributing to macroeconomic growth through the multiplier effect.

ABSTRACT
For nearly three centuries, efforts have been ongoing to meet the growing energy demand that began with the Industrial Revolution. While technological advancements continue, energy policy and research increasingly emphasize clean and renewable sources. Fossil-based energy, still widely used, is both finite and environmentally harmful, making the shift to sustainable alternatives urgent. Electricity plays a central role due to its potential for clean end-use; however, challenges in its generation and storage persist. Hydrogen has emerged as a promising solution for clean energy storage. Though not a primary energy source, its role as an energy carrier strengthens its importance in future energy systems. Environmentally responsible hydrogen production and storage also carry broader societal implications. This study employs Aspen HYSYS simulation software, using adaptations from prior research, to simulate the properties and flow rates of hydrogen, natural gas, and their blends. The natural gas composition was obtained through a literature review. Economically, hydrogen-natural gas blends could offer advantages in future regulatory contexts, such as carbon taxation, due to their lower emissions. However, current findings show that electricity generation using hydrogen-natural gas blends remains more expensive than natural gas, making it economically unviable under present electricity generation conditions.

Keywords: Energy**,** Hydrogen, Electiricity

1. INTRODUCTION

The Industrial Revolution represents a pivotal turning point in humanity's energy demands and the utilization of energy from various sources. Prior to this period, both the concept of production and the associated production relationships were relatively rudimentary, and the role of energy and its sources in human life was arguably minimal. However, the transformation in production practices brought about by the Industrial Revolution introduced new energy sources and significantly increased the demand for energy. Initially, production relied on steam power [1], but it later progressed through distinct phases with the advent of electricity [2] and internal combustion engines [3]. In the contemporary era, clean and renewable energy has become one of the most widely debated topics. The emergence of hydrogen as a potential energy source, and the concept of a hydrogen economy, gained prominence following the Hydrogen Economy Miami Energy Conference (THEME) in 1974 [4], which marked a critical milestone in discussions on renewable energy.
Hydrogen, regarded as a significant alternative among clean energy sources, consists of a single proton and electron, and is the most abundant element in the universe [5-6]. In contemporary discussions on decarbonization, hydrogen is increasingly associated with economic frameworks and is widely viewed by researchers as a promising energy carrier of the future. Although the concept of the hydrogen economy is not new, it has gained renewed attention based on the idea that future energy demands could be met through hydrogen-based systems [7]. Importantly, hydrogen is not a primary energy source but rather an energy carrier [8]. In this context, Boretti (2021) argues that a hydrogen economy on its own may lack substantial impact, but it could serve as a valuable complement to a broader electricity-based economy [9].
Electric energy plays a vital role in contemporary society. It is a critical component in sectors such as heating, cooling, and water purification, offering environmentally sustainable solutions. There is considerable potential for generating electricity from renewable sources to mitigate environmental impact. However, as in many sectors today, fossil fuels remain a dominant source in electricity generation, resulting in severe environmental consequences [10]. At this point, hydrogen is increasingly emphasized as a chemical energy storage medium for storing electricity generated from renewable sources [11]. Currently, energy production and consumption are largely based on fossil fuels, which are responsible for approximately two-thirds of global greenhouse gas emissions. Therefore, substantial transformations in the energy sector are essential to advance the global energy transition toward a carbon-neutral society. Hydrogen, in this regard, has the potential to accelerate the shift to clean and renewable energy systems while enhancing the stability and reliability of power grids [12].
Regarding the ongoing transition to green and carbon-neutral energy vectors, natural gas (NG) and hydrogen are emerging as critical components of future energy systems. By the 2030s, although green hydrogen is expected to become a competitive solution among alternative energy sources, large-scale storage remains a significant challenge. Salt caverns, while effective, are geographically limited; compressed hydrogen has very low energy density and high storage costs; and hydrogen liquefaction requires approximately 10 kWh/kg (nearly one-third of hydrogen's lower heating value (LHV)) as well as extremely low cryogenic temperatures (-253 °C). Currently, green hydrogen cannot fully replace

natural gas as a long-term energy storage solution due to the lack of economically viable and scalable storage technologies. Therefore, the transition to a green hydrogen economy will be gradual, dependent on both technological advancements and economic feasibility. In the short- to mid-term, natural gas is expected to play a pivotal role in the energy transition due to its significantly lower carbon intensity compared to coal and petroleum-based fuels [13]. Integrated natural gas and hydrogen solutions may serve as an essential step in achieving a fully decarbonized energy system.

The ever-growing global population, along with the parallel rise in individual and societal needs, has driven energy demand to unprecedented levels. Despite significant technological advancements, humanity continues to rely heavily on fossil-based energy sources, which are finite and unsustainable. This reliance confronts societies with the dual challenges of resource depletion and escalating environmental degradation, both of which are becoming increasingly evident. In this regard, the transition to renewable and clean energy has emerged as a critical priority to reduce energy costs, preserve environmental quality, and mitigate the risks associated with resource scarcity. While electricity remains central to meeting modern energy demands, the ability to generate and store it in a renewable and environmentally friendly manner is of vital importance. Hydrogen, in this regard, stands out as a promising solution. Its potential to lower energy costs and enhance both societal well-being and economic resilience is of considerable significance.

This study aims to compare the costs of electricity generated in existing natural gas power plants in Türkiye when operated using a hydrogen-natural gas mixture. In this analysis, hydrogen will be integrated into the energy cycle at blending ratios of 15% and 30% [14]. The resulting electricity generation costs will then be compared, and the economic viability of this approach for the operating firm will be evaluated.

2. METHODOLOGY

All calculations to determine the properties and flow rates of hydrogen, natural gas, and their blend (comprising 15% hydrogen and 85% natural gas and 30% hydrogen and 70% natural gas by mole) were conducted using Aspen HYSYS simulation software. The natural gas composition was adopted from a previously reported study [15] and is presented in Table 1 alongside the blend composition. The components considered in the simulation included CH_4, C_2H_6, C_3H_8, C_4H_{10}, C_5H_{12}, C_6H_{14}, CO_2, N_2 and H_2. The Peng-Robinson (PR) property package, known for its high efficiency and reliability, was employed for the calculations, as described by Eq. (1) [16].

Table 1. Compositions of natural gas and hydrogen-natural gas blends used in the simulation.

	Mass Fractions (%)			Mole Fractions (%)		
	Blend (%15)	Blend (%30)	Natural Gas	Blend (%15)	Blend (%30)	Natural Gas
CH_4	82.85	80.56	84.53	78.45	64.60	92.29
C_2H_6	5.75	5.60	5.87	2.91	2.39	3.42

$$P = \frac{RT}{V-b} - \frac{a\alpha}{V(V+b)+b(V-b)} \quad (1)$$

Table 2 outlines the operating conditions and various key properties of natural gas, pure hydrogen, and the hydrogen-natural gas blend (%15 and %30). All data were obtained from Aspen HYSYS under identical conditions (100 kPa and 15 °C), ensuring a consistent basis for comparison. Together, Tables 1 and 2 provide a comprehensive overview of how hydrogen blending alters the composition and fundamental properties of natural gas. These changes have significant implications for combustion efficiency, safety, transportation, and appliance compatibility, highlighting the importance of such analyses in evaluating hydrogen as a transitional fuel within existing gas infrastructure.

In the study conducted by Rasul et al. [17], data on hydrogen production and associated costs, originally reported by Kayfeci et al., are presented in Table 3. As noted, the cost data include both operational expenses and fixed investment costs for hydrogen production from fossil fuels, particularly natural gas. Considering the average fixed investment costs (referred to as capital costs in the table) and assuming a payback period of approximately eight years for each option, the cost of hydrogen per kilogram was calculated by Kayfeci et al. [18].

3. RESULTS AND DISCUSSION

As of December 2024, Turkey has a total installed capacity of 24,673 MW in natural gas power plants. These facilities are combined cycle power plants, capable of generating electricity not only from natural gas combustion but also through the conversion of waste heat into steam. Additionally, by incorporating a third-stage steam recovery system, these plants have the potential to produce hydrogen. In this analysis, it is assumed that all natural gas power plants operate as combined cycle systems. The economic feasibility of a new scenario has been evaluated, wherein these plants produce hydrogen, and a portion of the hydrogen is integrated into the gas turbine fuel mixture (comprising both natural gas and hydrogen) during the initial stage of electricity generation. Based on the unit cost data presented in Table 3, the total fuel costs for plants utilizing hydrogen production have been recalculated and are presented in Table 4.

January	0.54	831.00	449.57	739.08	316.75	0.16	451.75
Total		13465.00	7184.54	11975.61	5132.41		7230.95

Under the specified assumptions, Table 4 compares the scenario in which natural gas power plants generate electricity using a fuel mixture of 30% hydrogen and 70% natural gas against the baseline scenario where plants operate with 100% natural gas. As observed, despite fluctuations in exchange rates, electricity production costs for plants using 100% natural gas remain more favorable than those using the hydrogen-natural gas mixture. In such a scenario, firms facing increased production costs may adopt a more rational strategy by selling the hydrogen through domestic distribution channels rather than using it for electricity generation. When the analysis is repeated for a 15% hydrogen blend, production costs are found to be approximately 50% lower compared to the 30% blend. As a result, power plants are unable to achieve the economies of scale necessary to significantly reduce costs. This inability to scale affects the anticipated economic benefits of increasing hydrogen content. Therefore, under present conditions, electricity generation using a hydrogen-natural gas mixture is not considered economically viable.

4. CONCLUSIONS

This study evaluates the use of hydrogen-natural gas blends in existing natural gas power plants in Turkey from both technical and economic perspectives. Simulations and analyses indicate that integrating 15% and 30% hydrogen blends into combined cycle plants is not economically viable under current conditions. From an economic perspective, the low carbon emission potential of hydrogen-natural gas blends may offer a competitive edge under future regulatory frameworks, such as carbon taxation. However, current analyses indicate that electricity production with H_2-natural gas blend remains costly and is not yet competitive with existing electricity generation costs based solely on natural gas. Considering capital investment payback periods and operational expenditures, hydrogen blending does not present a viable economic solution to produce electricity in the short term. In the future, increasing the cost-effectiveness of hydrogen through technological innovations and efficiency improvements may enable the achievement of economies of scale. In this regard, advancements in hydrogen production technologies, along with infrastructure investments, will be essential to facilitate a broader energy transition. It is crucial to implement both technological and economic policies that support the integration of hydrogen and natural gas in hybrid energy systems, thereby promoting more sustainable and environmentally responsible energy solutions.

ABSTRACT
This study comprehensively investigates a High-Temperature Proton Exchange Membrane fuel cell (HT-PEMFC) using a 3-D COMSOL Multiphysics model. HT-PEMFCs are promising energy conversion devices, offering higher efficiency and durability compared to low-temperature PEM fuel cells. In this work, a 3-D model of the HT-PEMFC was developed to simulate its performance under various operating conditions. The model was validated by comparing its results with experimental data from the literature, ensuring the accuracy and reliability of the simulations. Subsequently, the effects of different operating parameters such as the operating temperature and pressure on the performance of the fuel cell were systematically examined. The results provide valuable insights into optimizing HT-PEM fuel cell design and operation, highlighting key factors that influence efficiency and longevity.
Keywords: HT-PEMFC, COMSOL Multiphysics, 3-D Model

1. INTRODUCTION

Fuel cells are electrochemical devices that convert chemical energy directly into electrical energy with high efficiency and low emissions. Especially, HTPEMFCs have emerged as a key technology, offering advantages such as improved efficiency, better tolerance to fuel impurities, and enhanced durability compared to low-temperature counterparts [1]. The modeling and simulation of fuel cell performance are critical to understanding and optimizing their operation. A 3-D model allows for a more accurate representation of the complex phenomena occurring within a fuel cell, such as multi-species transport, electrochemical reactions, and heat management. By simulating these processes in detail, engineers and researchers can gain valuable insights into performance at various operating conditions, identify potential design improvements, and optimize fuel cell efficiency. There are three-dimensional HT-PEMFC models in the literature. For example: Das and Gibson [2] studied the impact of multi-species transport on HTPEMFC performance using a 3-D model at 180°C. Their model was validated with experimental data and explored the effects of membrane thickness and conductivity on fuel cell efficiency. Xia et al. [3] studied the effects of operating temperature, membrane thickness, and catalyst layer thickness on the performance of HT-PEMFCs using a 3-D COMSOL model. Their results showed that increasing temperature improves fuel cell performance, while decreasing catalyst layer thickness and membrane thickness enhance performance as well. Losantos et al. [4] developed a methodology for characterizing electrochemical parameters in HT-PEMFCs using non-invasive data, validated with a 40-cell stack. Their approach combines genetic algorithms with 3-D simulations to analyze thermodynamic behavior efficiently. This method also paves the way for future studies on efficiency loss and degradation analysis.
In this study, a 3-D HT-PEMFC model was developed using COMSOL Multiphysics, and the results were compared and validated against data from a study [5] found in literature. Following this validation, the effects of several operating parameters, including temperature and pressure, on the performance of the fuel cell were systematically investigated. The analysis aimed to provide a deeper understanding of how these parameters influence the overall performance of the HT-PEMFC, contributing valuable insights for optimization in real-world applications.

2. MATHEMATICAL MODELING

A three-dimensional, isothermal, single-phase model is created in this study to simulate the performance of a HT-PEMFC using a polybenzimidazole (PBI) membrane. Figure 1 shows the computational domain of HT-PEMFC. The computational domain includes PBI membrane, anode and cathode gas flow channels, anode and cathode gas diffusion layers (GDLs). The catalyst layers are considered to have negligible thickness and are treated as boundary conditions between the GDL and the membrane.

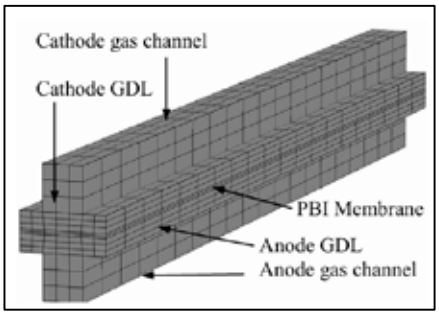

Fig 1. Computational domain of HT-PEMFC

The modeling assumptions for the HT-PEMFC include operating at temperatures above 100°C and around 2 atmospheric pressures, where water is only present in vapor form. Due to the unique properties of the PBI membrane, the water drag coefficient from the anode to the cathode is considered zero, unlike typical low-temperature PEM fuel cells with Nafion membranes. Additionally, proton transfer occurs via phosphoric acid doping in the membrane, the gas mixture is treated as ideal, the flow is incompressible and laminar, and the GDL is

assumed to be composed of isotropic and homogeneous porous materials [5]. The general governing equations (mass and momentum) used in the model are given below:

$$\nabla \cdot \boldsymbol{u} = 0 \quad (1)$$

$$\rho \boldsymbol{u} \nabla \cdot \boldsymbol{u} = \nabla[-p\boldsymbol{I} + \eta(\nabla \boldsymbol{u} + (\nabla \boldsymbol{u})^T)] \quad (2)$$

where $\boldsymbol{u}$ is the velocity vector of the gas mixture, m/s, ρ is the density of gas mixture, kg/m^3, p is the pressure, N/m^2, and η is the dynamic viscosity of the mixture, kg/m-s. The mass transport of multiple species throughout the entire computational domain, which includes both the gas channels and the gas diffusion layer, is modeled using the Maxwell-Stefan equation. This equation determines the fluxes of individual species based on their mass fractions. Below is the general expression of the Maxwell-Stefan equation [5]:

$$\nabla \cdot \left[-\rho w_i \sum_{j=1}^{N} D_{i,j} \left(\frac{M}{M_j}\left(\nabla w_j + w_j \frac{\nabla M}{M}\right) + (x_j - w_j)\frac{\nabla P}{P}\right)\right] = R_i \quad (3)$$

where $D_{i,j}$ is binary diffusion coefficient, x is the molar fraction, R_i is the reaction rate, w is the mass fraction, ρ is the density, and M is the molecular mass. In a PEM fuel cell, the total current is divided into two components: ionic current and electronic current. Protons move through the ionic conductor (membrane), creating an ionic current, while electrons flow solely through the solid electrode matrix, generating an electronic current. The equations governing current continuity are derived using Ohm's law [5].

$$\nabla \cdot (-\sigma_s \nabla \cdot \varphi_s) = 0 \quad (\textit{Electrons transport}) \quad (4)$$

$$\nabla \cdot (-\sigma_e \nabla \cdot \varphi_e) = 0 \quad (\textit{Protons transport}) \quad (5)$$

where φ is the phase potential, V; σ is the effective electric conductivity, S/m; and the subscribes s and e denote the solid phase property and electrolyte phase, respectively.

The fuel cell model described above is simulated using COMSOL Multiphysics software. The parameters for the base case utilized in the model are provided in Table 1.

Table 1. Operation and Geometric Parameters used in 3-D model [5]

Parameter	Value	Parameter	Value
Fuel Cell Temperature	100-180°C	Ionic Conductivity of membrane	7.86 S/m
Anode Stoichiometric Ratio	1.2	Membrane Thickness	100 µm
Cathode Stoichiometric Ratio	2	Electrical Conductivity of GDL	222 S/m
Open Circuit Voltage	0.93 V	Porosity of GDL	0.4
Pressure	101325 Pa	Permeability of GDL	1.18x10^{-11} m^2
Channel Patterns	Serpentine	Catalyst Layer Thickness	50 µm
Channel Cross Section Area	0.7844 mm^2	Anode exchange current density	10^5 A/m^2
Width of the shoulder	0.90932 mm	Cathode exchange current density	1 A/m^2

3. RESULTS AND DISCUSSION

In this section, the results of the 3-D modeling are first validated against the results of the reference study [5], and then the effects of operating temperature (100-180°C) and pressure (1 and 2.7 atm) are examined. Figure 2 shows the typical behavior of a fuel cell, where the cell voltage decreases as the current density increases due to activation, ohmic, and mass transport losses. In Figure 2, the polarization curves for T=180° at P=1 atm and P=2.7 atm are obtained from both numerical simulation and a reference study. The simulation results fit the reference study [5] results very well. Another key observation is that there appears to be no loss of concentration, even at elevated current densities. The reason for this can be explained by a high operational temperature where water exists in vapor form only.

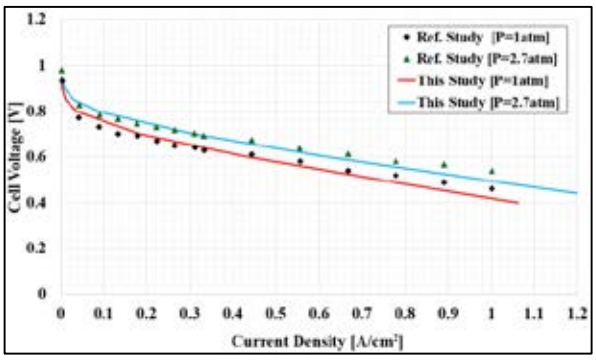

Fig. 2. Comparison of Polarization Curves with the Reference Study [5] at 180°C for 1 and 2.7 atm.

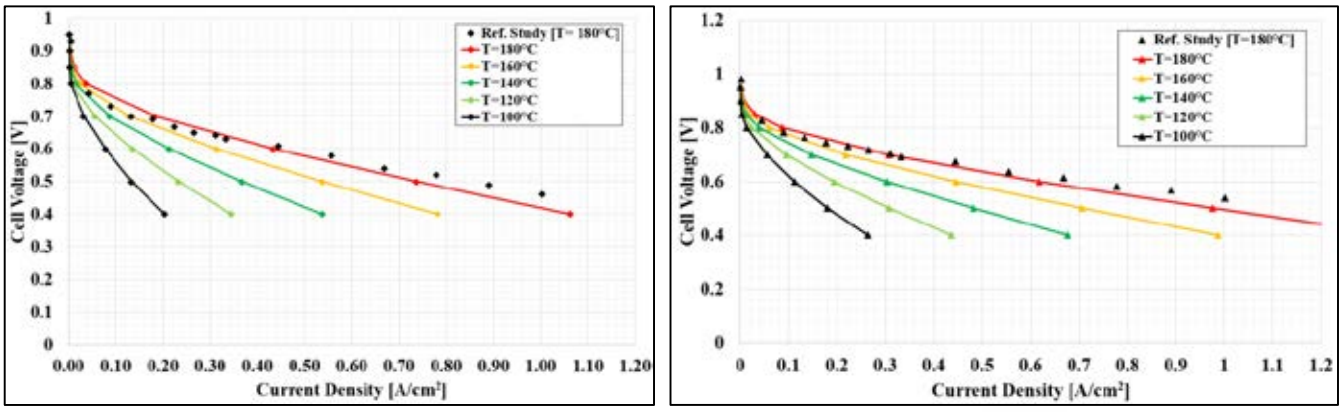
Figures 3-(a) and 3-(b) show the effects of operating temperature at 1 atm and 2.7 atm pressures, respectively. According to Figures 3-(a) and 3-(b), It is evident that increasing the operating temperature significantly improves the overall performance of the fuel cell. According to Figures, at higher temperatures, such as 180°C, the cell exhibits higher voltage values across the entire range of current densities. This enhancement is primarily due to improved reaction kinetics, increased proton conductivity of the membrane, and better water and heat management at elevated temperatures. In contrast, at lower temperatures, particularly at 100°C, the performance is notably reduced. This is attributed to slower electrochemical reaction rates and higher internal resistance, which result in greater voltage losses, especially at medium to high current densities.



(a) (b)

Fig. 3. The effects of operating temperature on the performance of HT-PEMFC at; (a)1 atm and (b) 2.7.

According to Figure 3-(a) (P=1 atm), at a current density of 0.2 A/cm², the cell voltage at 180°C is approximately 0.72 V, while at 100°C it drops to around 0.50 V, representing a significant improvement of about 44%. Similarly, at 0.6 A/cm², the voltage at 180°C remains around 0.57 V, whereas it is only about 0.4 V at 160°C. These observations confirm that operating the HT-PEMFC at higher temperatures leads to better efficiency and overall performance. According to Figure 3-(b) (P=2.7 atm), at a current density of 0.1 A/cm², the cell voltage is approximately 0.82 V at 180°C, while it drops to around 0.68 V at 100°C. This represents a voltage loss of nearly 17% due to lower temperature operation. At 0.3 A/cm², the voltage at 180°C is around 0.72 V, compared to 0.47 V at 100°C, indicating a performance improvement of over 50%. The performance gap becomes even more pronounced at higher current densities. At 0.6 A/cm², the cell voltage at 180°C remains at about 0.62 V, whereas it falls to approximately 0.36 V at 100°C showing a difference of nearly 72%. When comparing Figures 3-(a) (P=1 atm) and Figure 3-(b) (P=2.7 atm), it is evident that increasing the operating pressure significantly improves the performance of the HT-PEMFC at all temperatures. Higher pressure enhances the partial pressure of reactant gases, which leads to better electrochemical reaction kinetics, reduced mass transport limitations, and overall higher cell voltage for the same current density. For example, at 180°C and 0.6 A/cm², the cell voltage at 1 atm is approximately 0.57 V, while at 2.7 atm it rises to around 0.62 V, indicating an improvement of about 0.05 V (nearly 9%). Similarly, at 160°C and 0.6 A/cm², the voltage increases from ~0.50 V (1 atm) to ~0.55 V (2.7 atm), which is a 10% gain. At lower temperatures, such as 100°C, the improvement is also noticeable: at 0.3 A/cm², the voltage increases from ~0.47 V at 1 atm to ~0.51 V at 2.7 atm.

Figure 4-(a), (b), and (c) illustrate the spatial distribution of mole fractions for hydrogen (H_2), oxygen (O_2), and water (H_2O), respectively, within an HT-PEMFC. In Figure 4 (a), the mole fraction of H_2 is highest at the inlet and gradually decreases along the flow path, indicating hydrogen consumption at the anode during the electrochemical reaction. Figure 4 (b) shows a similar trend for O_2, where the mole fraction decreases from the inlet to the outlet, reflecting its consumption at the cathode to form water. In contrast, Figure 4 (c) displays an increasing mole fraction of H_2O along the flow path, confirming water production due to the electrochemical reaction. The streamlines represent the total flux and visualize how each species is transported through the cell. These results demonstrate the expected behavior of reactant consumption and product formation in the HT-PEMFC, highlighting effective species transport and reaction zones within the system.

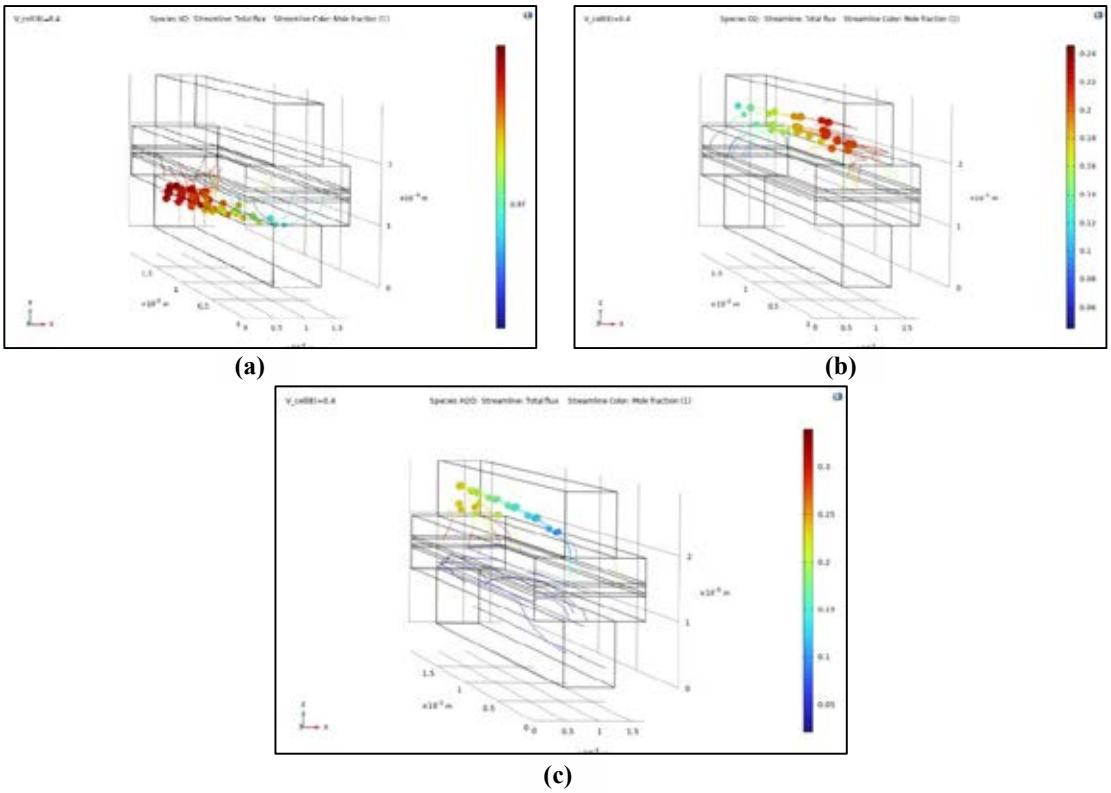


Fig. 4. Streamline representation of species transport and mole fraction distribution in an HT-PEMFC for (a) hydrogen (H_2), (b) oxygen (O_2), and (c) water (H_2O) (Streamlines indicate total flux, and colors represent local mole fractions.)

4. CONCLUSIONS

The main findings are given as:

- Higher operating temperatures (up to 180°C) significantly enhance HT-PEMFC performance by improving reaction kinetics, membrane conductivity, and water management, resulting in up to 72% higher cell voltage at high current densities compared to operation at 100°C.
- Increased operating pressure (from 1 atm to 2.7 atm) improves fuel cell performance across all temperatures by enhancing reactant partial pressures and reducing mass transport limitations, leading to up to 10% voltage gains at typical current densities.
- Mole fraction distributions confirm proper species transport within the cell: H_2 and O_2 are consumed along the flow path, while H_2O is produced and increases downstream, indicating effective electrochemical activity.

METAL-ORGANIC FRAMEWORKS FOR HYDROGEN STORAGE

Selçuk Demir
Recep Tayyip Erdoğan University, Faculty of Arts and Sciences, Department of Chemistry,
Rize, Turkey

selcuk.demir@erdogan.edu.tr

ABSTRACT

Metal-organic frameworks (MOFs) have emerged as highly promising materials for hydrogen storage, offering tunable porosity, exceptional surface areas, and tailored chemical functionality. This review highlights key advancements in MOF design strategies—including open metal sites, ligand functionalization, and lithium doping—that enable superior hydrogen adsorption capacities, with leading frameworks like NU-1501-Al and MOF-5 exceeding U.S. DOE 2025 targets (14 wt% and 51.9 g/L, respectively). Experimental and computational studies reveal critical structure-performance relationships, emphasizing the role of pore geometry (optimal 12–15 Å) and adsorption enthalpy (15–20 kJ/mol) in optimizing storage efficiency. While grand canonical Monte Carlo (GCMC) simulations and machine learning accelerate material discovery, challenges persist in stability, scalable synthesis, and system integration. Overcoming these barriers through interdisciplinary approaches will be essential for transitioning MOF-based hydrogen storage from laboratory breakthroughs to commercial reality in the clean energy landscape.

Keywords: Hydrogen storage, Metal-organic frameworks, Physisorption, Computational screening, DOE targets

1. INTRODUCTION

The growing global energy demand and climate change concerns have positioned hydrogen as a pivotal clean energy carrier. Despite its high energy density (142 MJ/kg)—three times that of fossil fuels—hydrogen's low density (0.07 g/cm³ in liquid form) and storage challenges limit practical applications. Conventional methods like high-pressure gas (700 bar) and cryogenic liquid hydrogen (-253°C) remain prevalent but pose significant safety risks and energy efficiency issues [1]. In this context, Metal-Organic Frameworks (MOFs), with their nanoporous structures and tunable chemical properties, offer a promising solution through physisorption-based storage, addressing these challenges effectively [2]. The 1292 publications obtained with searching the terms "metal-organic framework*" and "hydrogen storage" on Scopus is an indication of the interest in the subject (Figure 1). Figure 2 shows the comparison of the performances of different hydrogen storage techniques [3] with respect to the Department of Energy (DOE) targets [4].

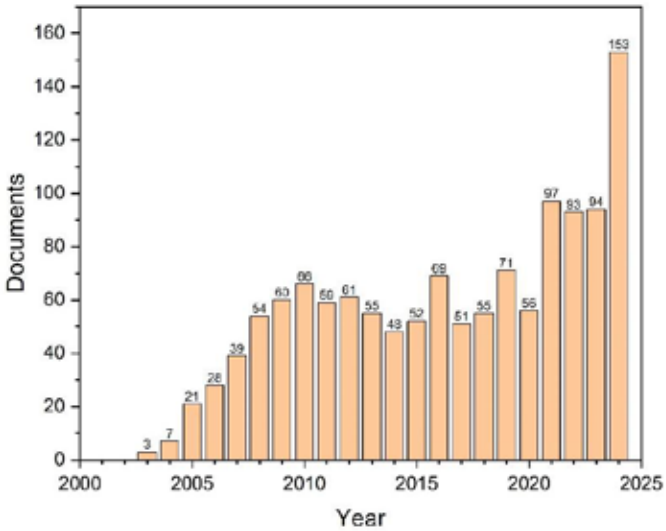

Fig. 1. Publications with topics "metal-organic framework*" and "hydrogen storage" searched in title, abstract and keywords (source: Scopus in April 2025)

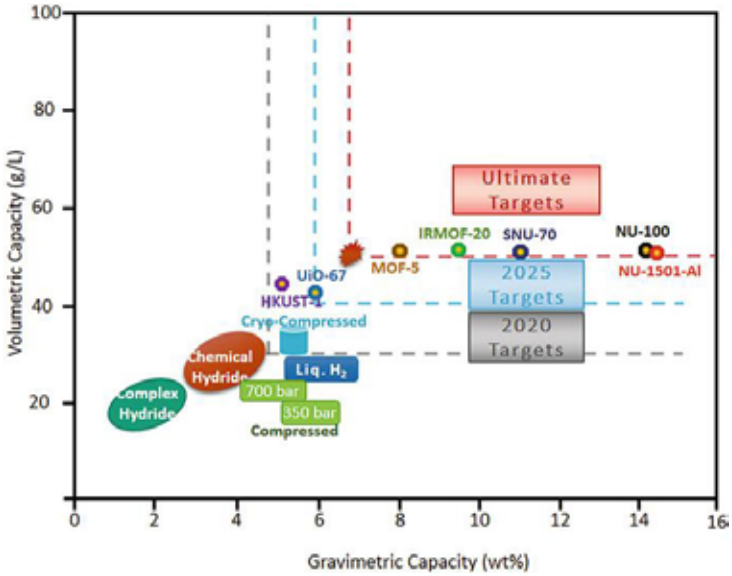

Fig. 2. Comparison of the performances of different hydrogen storage techniques with respect to the DOE targets. Hydrogen delivery capacities of the MOFs were used at material level in this figure, and when packing density at large scale is considered, a 25% decrease of capacity should be expected. (Reprinted with permission from ref. [3], Copyright 2022, Springer)

2. FUNDAMENTAL PROPERTIES AND DESIGN PRINCIPLES OF MOFS

The hydrogen storage performance of MOFs is governed by factors such as crystalline structure, pore geometry, and chemical functionality. Structurally, MOFs consist of three-dimensional networks formed by metal ions/clusters and organic linkers. Their most remarkable feature is the precise control over pore size and surface chemistry during synthesis. For instance, UiO-series MOFs exhibit surface areas exceeding 1000 m²/g with exceptional water stability, while triptycene-based frameworks like NU-1501 achieve surface areas beyond 7000 m²/g. Adsorption enthalpy (ΔH) is another critical parameter; an ideal range of 15–20 kJ/mol balances high capacity with room-temperature operability.

3. EXPERIMENTAL ADVANCES AND PERFORMANCE METRICS

Recent experimental studies have significantly enhanced MOF performance for hydrogen storage. MOFs with open metal sites (e.g., HKUST-1) or lithium doping (e.g., MFU-4l-Li) demonstrate strong interactions with hydrogen molecules, achieving capacities above 10 wt% at 77 K. Under pressure swing (100 bar → 5 bar) and temperature swing (77 K → 160 K) conditions, materials like MOF-5 and IRMOF-20 exhibit volumetric capacities exceeding 50 g/L—surpassing the U.S. DOE's 2025 targets [3]. However, industrial adoption faces difficulties such as air/moisture stability, large-scale synthesis costs, and system integration challenges. Practical considerations like packing density and thermal management in tank designs further complicate the adaptation of lab-scale performance to real-world applications.

4. COMPUTATIONAL METHODS AND MATERIAL DISCOVERY

The design possibilities of MOFs (millions of possible combinations) necessitates computational approaches. Grand Canonical Monte Carlo (GCMC) simulations are widely used to predict hydrogen adsorption behavior under varying conditions. Screening 130,000 hypothetical MOFs revealed optimal pore sizes (12–15 Å) and porosities (~90%) [5]. Machine learning models, particularly those using energy-based descriptors, can predict storage capacities with ~90% accuracy, guiding experimental efforts [6]. These tools accelerate the discovery of high-performance materials, such as MFU-4l-Li, which achieved a record deliverable capacity of 54 g/L (experimentally validated at 47 g/L).

5. FUTURE PROSPECTS AND CHALLENGES

Commercializing MOF-based hydrogen storage requires addressing material stability, production costs, and system-level optimization. Future research should focus on enhancing mechanical robustness (e.g., cross-linked structures), improving stability under ambient conditions, and standardizing large-scale synthesis protocols. Granular or pelletized MOF forms must retain porosity for practical use. Thermal management systems (e.g., phase-change materials) and performance under impure hydrogen streams also demand attention. Interdisciplinary collaborations (materials science, chemical engineering, and energy systems) will be key to unlocking MOFs' full potential in the hydrogen economy within the next decade.

ABSTRACT

Metal–organic frameworks (MOFs) composed of the bridging linkers and the metal ions are an very important class of porous materials employed for custom-designed purposes. Among the MOFs composed of carboxylate linkers, Zr-based MOFs have attracted great attention due to their high thermal and chemical stability, which are important for practical applications, including hydrogen (H_2) storage. Herein, using 6,6'-dimethyl-2,2'-bipyridine-5,5'-dicarboxylic acid (H_2Me_2bipy) we prepared a Zr-based MOF [MOF-553, $Zr_6O_4(OH)_4(Me_2Bipy)_6$] with usable Lewis basic sites of the linker. Later H_2 adsorption capacity of MOF-553 were measured at atmospheric pressure.

Keywords: Hydrogen storage, Metal-organic frameworks, Zirconium

1. INTRODUCTION

The increasing global energy demand and growing concerns about climate change have established hydrogen as a critical clean energy carrier. Although hydrogen boasts a high energy density (~142 MJ/kg) its low density (0.07 g/cm³ in liquid form) and storage challenges hinder practical applications. Traditional storage techniques, like high-pressure gas (700 bar) and cryogenic liquid hydrogen (-253°C), continue to be prevalent but pose considerable safety hazards and energy efficiency limitations [1]. Physisorption-based storage addressing these challenges effectively [2]. With their microporous structures and adjustable chemical properties, metal-organic frameworks (MOFs) offer a viable solution to these risks. MOFs are a highly versatile class of porous crystalline materials composed of metal nodes connected by organic linkers. Their tunable properties make them suitable for various applications, including hydrogen and natural gas storage, atmospheric water harvesting, and carbon capture. Among MOFs, zirconium-based frameworks (Zr-MOFs) stand out due to their exceptional thermal and chemical stability, attributed to the strong Zr(IV)-carboxylate bonds. A well-known example, UiO-66, and its expanded analogs like UiO-67(bipy), feature the robust $Zr_6O_4(OH)_4(COO)_{12}$ cluster.

Herein, prepared MOF-553 ([$Zr_6O_4(OH)_4(Me_2bipy)_6$]) has a high density of Lewis-basic sites for H_2 capture while achieving superior water stability. The methyl groups not only protect the framework but may also enhance H_2 affinity through additional host-guest interactions.

2. MATERIALS AND METHODS

Synthesis of UiO-67(Me_2Bipy) (MOF-553): MOF-553 was prepared as reported before [3]. H_2Me_2bipy (43.5 mg, 0.159 mmol) was placed in a beaker with 5 mL N,N-dimethylformamide (DMF) and dissolved via sonication. After the addition of a 5 mL DMF solution of $ZrCl_4$ (37.5 mg, 0.160 mmol), the mother solution was stirred for 10 min and formic acid (2 mL) was added. The solvent mixture was incubated at 120 °C for 24 h. After cooling to room temperature, the corresponding pale yellow materials were collected by vacuum filtration, washed with DMF (3 × 10 mL), followed by soaking in acetonitrile (MeCN) for 3 days, in which the solution was exchanged with fresh MeCN (10 mL) every 24 h. After 3 days of soaking, the solids were collected via vacuum filtration and dried under vacuum at 120 °C for 24 h.

3. RESULTS AND DISCUSSION

MOF-553 was prepared via the reaction of $ZrCl_4$ with H_2Me_2bipy in DMF as reported (Fig. 1a). It consists of the hexanuclear zirconium clusters, [$Zr_6O_4(OH)_4(COO)_{12}$], that is connected by 6 Me_2bipy linkers to 3D. The crystal structure suggests that MOF-553 has pores. The porosity verified via nitrogen adsorption experiments at -196 °C. Calculated BET surface area is 2164 m^2/g and the total pore volume is 0.39 cm^3/g for MOF-553.

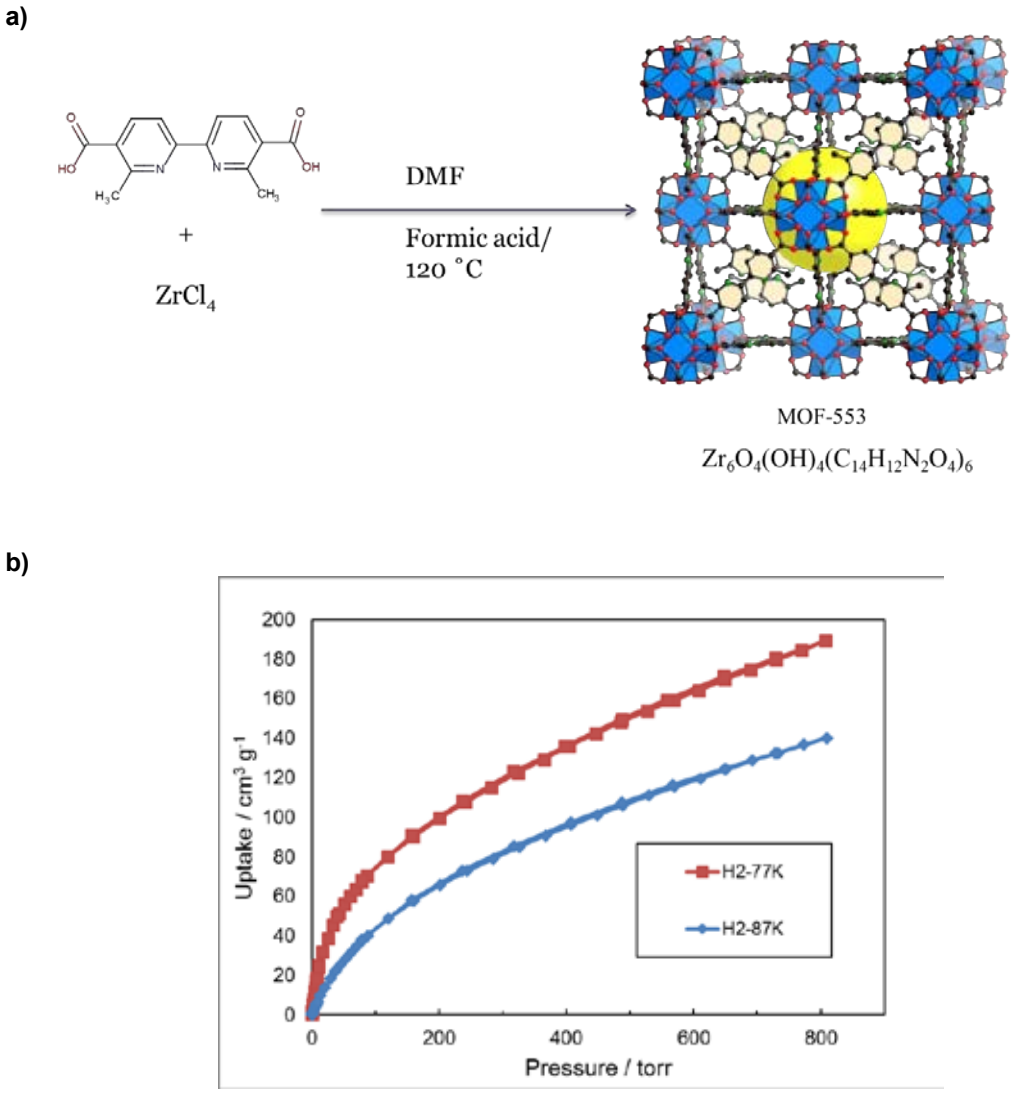

Fig. 1. Crystal structure (a) and H_2 adsorption isotherms of MOF-553 at 273 K (b)

4. CONCLUSIONS

The hydrogen uptake capacity of MOF-553 is 189.2 cm^3/g at 273 K and 807 torr pressure, and the calculated Qst value is 8.2 kJ mol^{-1}.

ABSTRACT Layered titanates, although they have large bandgaps, represent a fascinating class of two-dimensional (2D) materials with highly tunable structural and electronic properties, making them attractive candidates for advanced photocatalytic applications [1]. These materials, characterized by their perovskite-like layered frameworks, exhibit unique features such as ion-exchangeable interlayers, adjustable surface chemistry, and high theoretical surface area which needs to be activated by exfoliation. The intrinsic architecture of layered titanates allows for the precise manipulation of active sites and offers abundant opportunities to overcome the longstanding limitations of bulk photocatalysts, such as poor charge separation and limited surface reaction kinetics, and the large bandgaps.
One of the most promising strategies to unlock the full photocatalytic potential of layered titanates is through exfoliation and single atom loading, which can yield ultrathin nanosheets with dramatically increased specific surface area and exposed active facets. These exfoliated nanosheets provide ideal platforms for the rational design of photocatalysts at the atomic scale, including the immobilization of single-atom catalysts (SACs) [2]. The incorporation of single atoms into the 2D titanate matrix maximizes atomic utilization and introduces well-defined active sites, thereby enhancing charge carrier dynamics and catalytic selectivity.
Furthermore, the native interlayer spaces and surface defects of layered titanates can serve as interatomic cavities for hosting guest species such as water molecules, hydrogen and oxygen to conduct the watersplitting reaction (**Figure 1**). On the other hand, this can modulate the local electronic environment, leading to the formation of a mid-gaps and further contribute to photocatalysis. These confined sites offer favorable conditions for charge accumulation, adsorption, and activation of reactants — particularly for the photocatalytic hydrogen evolution reaction (HER). When synergistically combined, exfoliation, single-atom loading, and cavity engineering enable the construction of advanced photocatalysts with superior light-harvesting ability, optimized reaction pathways, and enhanced long-term stability.

ABSTRACT Environmental pollution and the growing demand for clean, renewable energy have intensified research into photocatalysts such as titanium dioxide (TiO_2), known for its affordability, non-toxicity, and chemical stability. However, the anatase phase of TiO_2 has a wide band gap and suffers from rapid electron-hole recombination, limiting its photoactivity under sunlight. To overcome these limitations, we synthesized CeO_2-TiO_2 heterojunctions by calcination at 600°C, 700°C, 800°C, and 900°C. Cerium oxide (CeO_2), a rare-earth oxide with high UV absorption and excellent electron transport properties, was combined with TiO_2 to enhance charge separation and light harvesting. X-ray diffraction (XRD) fig1.c , analysis confirmed the formation of Ce-Ti bonds and effective integration between the two oxides. The resulting heterojunctions exhibited type-II band alignment, which promoted charge separation and suppressed recombination. Photocatalytic performance was evaluated using methylene blue (MB) as a model organic pollutant, and photoelectrochemical behavior was studied using linear sweep voltammetry (LSV) fig1.a, b. Among all synthesized samples, the CeO_2-TiO_2 composite prepared at 800°C showed the highest performance, suggesting enhanced electron transfer and improved photocatalytic activity [1]. These findings demonstrate the potential of temperature-optimized CeO_2-TiO_2 heterostructures in solar energy conversion and environmental remediation applications [2,3].

ABSTRACT Porous and highly tunable materials such as metal–organic frameworks (MOFs) represent an appropriate platform to enhance photocatalytic and photoelectrochemical performance [1]. A well-known wide-bandgap semiconductor, titanium dioxide (TiO_2), was synthesized by the sol–gel method and employed as a photoactive substrate in the current study. Three different MOFs like Fe-MOF, Ni-MOF, and Nd-MOF were then uniformly coated onto the surface of TiO_2 to form composite photocatalysts. Photoelectrochemical activity of the resulting MOF/TiO_2 heterostructures was measured by performing linear sweep voltammetry (LSV) under chopped illumination (Figure1). Light-responsive current behavior was displayed by all composite samples, with intriguing differences in the magnitude and reversibility of the photocurrent. Among the samples, Fe-MOF/TiO_2 showed the highest photocurrent response, with Ni-MOF/TiO_2 demonstrating a similar response, indicating increased interfacial electron transfer and charge separation facilitated by the MOF coatings. Conversely, Nd-MOF/TiO_2, despite a higher baseline current, responded comparatively weaker and less clearly to light, most likely due to variations in its electronic structure or interaction with the TiO_2 substrate. These outcomes demonstrate that rational MOF–semiconductor composite design holds great promise for the creation of next-generation photoelectrocatalysts, particularly to produce sustainable hydrogen and other solar-driven energy-related conversions [2,3].

ABSTRACT

This study addresses the challenges of sub-synchronous (SSOs) in weak AC networks with high renewable energy penetration, focusing on the effectiveness of hybrid energy storage systems (HESS). By combining hydrogen-based energy storage with electric double-layer capacitors (EDLCs), HESS provides comprehensive damping for slow and fast oscillatory dynamics. Simulation results demonstrate the hybrid system's ability to mitigate grid instability caused by step changes in solar insolation, transmission line disconnections, and sudden load variations. The findings highlight significant improvements, including a 70% reduction in oscillation amplitude, enhanced phase stability, and quicker recovery times, underscoring HESS as a critical solution for stabilizing weak grids.

Keywords: Hydrogen energy systems, hydrogen-based grid stabilization, hybrid hydrogen energy solutions, renewable energy sources

1. INTRODUCTION

The worldwide transition to renewable energy sources (RES) has been crucial in alleviating climate change and diminishing reliance on fossil fuels. Photovoltaic power plants (PvPPs) and hydrogen-based energy storage systems (HESS) are among the most promising RES technologies. These systems have become essential to contemporary power networks owing to their efficiency, scalability, and ecological advantages. Nonetheless, their incorporation into weak alternating current (AC) networks has posed considerable hurdles, especially regarding the preservation of grid stability. Weak AC networks, defined by low short-circuit ratios (SCRs), are particularly susceptible to disturbances, rendering them prone to sub-synchronous oscillations (SSOs) [1]. If unmitigated, these oscillations can destabilize the grid, disrupt operations, and diminish the overall efficiency of power systems. The growing integration of RES in contemporary energy systems has altered conventional grid dynamics. In contrast to traditional synchronous generators that offer intrinsic inertia via mechanical coupling, RES, such as photovoltaic power plants, rely on inverter-based generation units. These inverters, albeit efficient, lack physical inertia and replicate grid dynamics through sophisticated control mechanisms. SSO, generally occurring within the frequency range of 10–60 Hz, results from intricate feedback interactions between grid dynamics and the control systems of inverters, including phase-locked loops (PLLs) and current control loops (CCLs). SSO in weak AC networks are dynamic phenomena that amplify with time, leading to significant repercussions such as equipment failure, voltage instability, and potential large-scale blackouts [2]. The principal factors leading to SSOs are inverters' dynamic properties, weak grids' low inertia, and inadequately calibrated control systems. These oscillations become crucial in weak AC networks with significant RES penetration. Traditional synchronous generators are frequently supplanted with IBRUs, eliminating the physical connection between generation units and the grid, hence exacerbating instability. Furthermore, the nonlinear behavior of inverters during grid disruptions complicates the prediction and mitigation of SSOs. The incorporation of PvPPs and HESS in weak AC networks intensifies these difficulties. Voltage and frequency instability frequently occur due to the substantial alteration of the grid's impedance profile by the presence of PvPPs [3]. This increased sensitivity to voltage and frequency fluctuations often results in oscillatory modes that are challenging to control. Furthermore, weak grids lack the intrinsic damping properties of synchronous generators, rendering them less capable of mitigating oscillations. These problems highlight the necessity of designing sophisticated mitigation measures to guarantee weak AC networks' steady and dependable functioning.This study aims to investigate the underlying causes of SSOs in weak AC networks with significant RES integration, create a hybrid energy storage system that integrates hydrogen storage with EDLCs for effective oscillation reduction, and validate the proposed solution. This research seeks to enhance the existing knowledge on RES integration and grid stability while providing practical guidance for implementing hybrid systems in weak alternating current networks.

2. METHODOLOGY

The simulation model captures the dynamic interactions between the components of a weak AC network and its response to disturbances. Key elements include the PvPP, HESS, and EDLCs, modeled through differential equations that reflect their operation. The power output of a PvPP is dependent on solar insolation and is expressed as [4]

$$P_{PvPP} = \eta_{MPPT} * G * A * \eta_{conv}$$

Where P_{PvPP} is photovoltaic power output, η_{MPPT} represents the efficiency of MPPT, G is solar irradiance, A is the area of the solar panel, and η_{conv} is the inverter efficiency. The inverter dynamics are described by [5]

$$I_{inv} = \frac{V_{ref} - V_{grid}}{Z_{inv}}$$

I_{inv} is the inverter current, V_{ref} is the reference voltage, V_{grid} is the grid voltage, and Z_{inv} is the inverter impedance. The hydrogen storage component of the HESS is modeled as a first-order dynamic system

$$\frac{dH}{dt} = \frac{\eta_{e1} P_{ex}}{LHV_{H2}} - \frac{\eta_{fc} P_{def}}{LHV_{H2}}$$

Here, H is the hydrogen level, P_{ex} is the excess power supplied to the electrolyzer, Pdef is the power deficit provided by the fuel cell, ηe1 is the electrolyzer efficiency, ηfc is the fuel cell efficiency, LHV_{H2} is the lower heating value of hydrogen. The capacitor equation governs the EDLC operation

$$Q = C * V$$

Here, Q is the charge, C is capacitance, and V is the voltage. The rate of power exchange is given by

$$P_{EDLC} = \frac{dQ}{dt} * V$$

The voltage and current in the network are modeled using Kirchhoff's Voltage Law (KVL)

$$\sum V = 0 \rightarrow V_{source} = V_{load} + V_{line}$$

The impedance of the transmission line is given by

$$Z_{line} = R_{line} + jX_{line}$$

Here, Rline and Xline are the resistance and reactance of the transmission line, respectively. The short-circuit ratio is given by

$$SCR = \frac{S_{SC}}{S_{load}}$$

S_{sc} is the short-circuit apparent power and S_{load} is the load apparent power. Step changes in solar irradiance create power fluctuations in the PvPP. The insolation is modeled as a time-varying function

$$G(t) = G_0 + \Delta G * u(t)$$

G_0 is the baseline irradiance, ΔG is the step change, and u(t) is the unit step function.

3. RESULTS

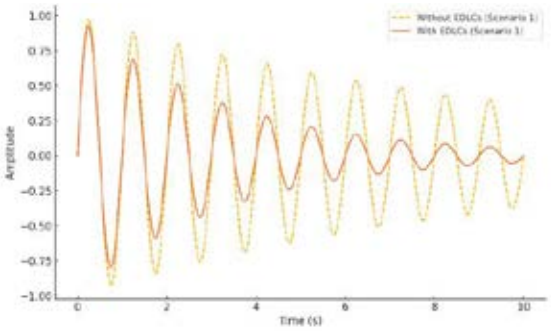

Figure 1. Oscillation amplitude after step changes in solar insolation

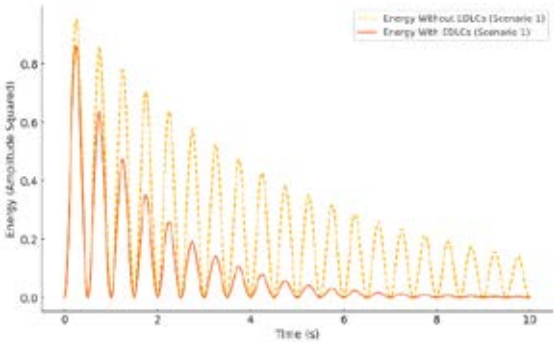

Figure 2. Energy dissipation after step changes in solar insolation

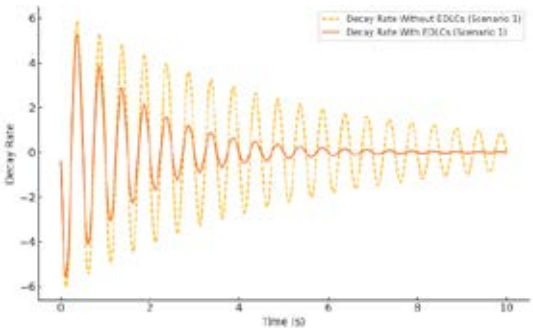

Figure 3. The decay rate of oscillations after step changes in solar insolation

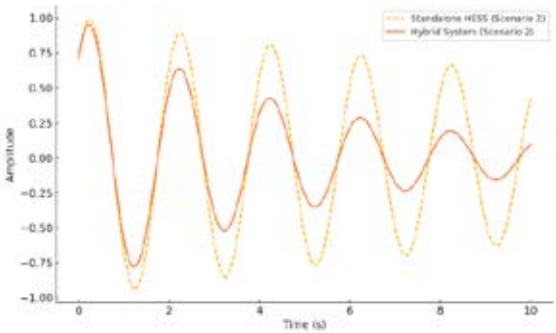

Figure 5. Stability after transmission line disconnection

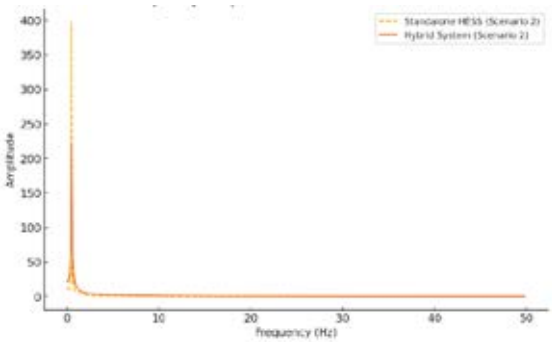

Figure 6 Frequency response after transmission line disconnection

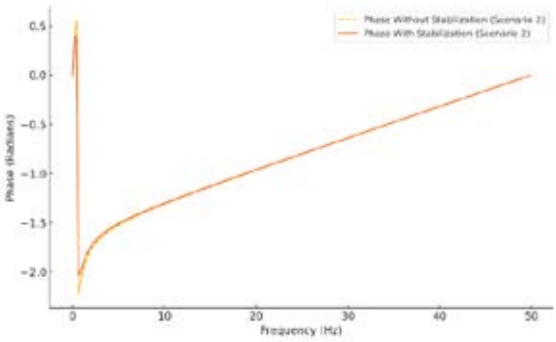

Figure 7 Phase stabilization after transmission line disconnection

Table 1. Performance Metrics Comparison

Metric	Without HESS	With HESS	Improvement (%)
Amplitude Reduction (%)	0	60-70	60-70
Frequency Deviation (Hz/s)	0.05-0.06	0.015-0.02	66.67-70
Energy Dissipation Reduction (%)	0	65-70	65-70

4. CONCLUSION

Integrating HESS into weak AC networks offers a transformative solution to mitigate SSO and enhance grid stability. By dynamically managing slow oscillations with hydrogen storage and fast oscillations with EDLCs, HESS achieves robust damping across a wide frequency spectrum. Simulation results validate the system's effectiveness, demonstrating reductions in oscillatory amplitude, improved voltage and frequency stability, and faster stabilization under critical disturbances. These findings emphasize the scalability, adaptability, and necessity of HESS for ensuring reliable operation in renewable energy-dominated grids, paving the way for broader implementation in weak network configurations.

BAYESIAN OPTIMIZATION FRAMEWORK FOR HOSTING CAPACITY EVALUATION IN HYDROGEN-ELECTRICITY INTEGRATED NETWORKS

Sulman Shahzad[1], Heybet Kilic[2]
[1]Department of Electrical Engineering, Islamia University of Bahawalpur, Bahawalpur 63100, Pakistan

ABSTRACT

This paper presents a Bayesian optimization framework to evaluate the hosting capacity in hydrogen-electricity integrated networks, specifically for hydrogen fuel cell vehicles (HFCVs). The hosting capacity quantifies the maximum number of HFCVs an integrated hydrogen-electricity system can accommodate while ensuring operational safety, stability, and efficiency. The evaluation process is influenced by complex interactions between distributed hydrogen supply networks (DHSNS) and power distribution networks (PDNS), with electrolysers that consume substantial amounts of electricity for hydrogen production and exhibit nonlinear, time-varying behavior under varying thermal and electrical conditions. Statistical simulations based on real-world data show that the proposed method improves hosting capacity assessment accuracy by up to 25% over conventional models, which fail to consider the bidirectional dependencies between the electricity and hydrogen subsystems. By leveraging a Bayesian approach, the framework efficiently explores the design space. It identifies optimal configurations under varying system conditions, offering a robust tool for energy management in integrated hydrogen-electricity networks.

Keywords: Electrolyzer, power distribution networks, hydrogen refueling stations, fuel cell, hosting capacity

1. INTRODUCTION

The swift proliferation of hydrogen fuel cell cars (HFCVs) and their incorporation into energy networks have posed considerable hurdles for energy management systems. The core of this change is the assessment of hosting capacity, which identifies the maximum number of hydrogen fuel cell vehicles (HFCVs) that an integrated hydrogen-electricity network can accommodate without jeopardizing operating safety and efficiency [1]. Assessing hosting capacity is a complex task, affected by technological, operational, and environmental aspects across hydrogen and power networks. The interrelated dynamics of distributed hydrogen supply networks (DHSNs) and power distribution networks (PDNs) complicate the assessment procedure. Electrolyzers, essential for hydrogen generation in DHSNs, need substantial electricity and demonstrate nonlinear behaviors affected by temperature and electrical circumstances. Probabilistic approaches, like Monte Carlo simulations and polynomial chaos expansion (PCE), provide a sophisticated approach by modelling uncertainty [2]. Nonetheless, Monte Carlo simulations are resource-intensive, necessitating numerous iterations to get precision. PCE is concurrently afflicted by the "curse of dimensionality," wherein computational expenses increase exponentially with the number of random variables. Considering these constraints, there is an urgent requirement for more sophisticated, data-efficient, and scalable approaches to manage the intricacies of integrated hydrogen-electricity networks. Bayesian optimizations (BO) present a formidable alternative, providing considerable benefits compared to conventional approaches. Bayesian optimization (BO) is a probabilistic optimisation method that employs Gaussian process regression (GPR) to represent uncertainty and iteratively enhance solutions [3]. This method is appropriate for assessing hosting capacity, where data scarcity and high-dimensional uncertainty pose significant obstacles.

2. PROPOSED STRATEGY

A unique methodology utilizing Gaussian process regression (GPR), Bayesian optimisation (BO), and a Multi-objective genetic algorithm (MOGA) is offered to tackle the issues in hosting capacity evaluation for integrated hydrogen-electricity networks. This framework model's uncertainty enhances hosting capacity and reconciles trade-offs between hydrogen and electricity network limitations. The hosting capacity (HC) can be described by equation (1) [4]

$$HC = max\left(\sum_{i=1}^{N} H_i\right) \tag{1}$$

where H_i is the hydrogen production at node i in the grid, and N represents the total number of grid nodes where hydrogen integration is possible. A Gaussian process (GP) defines a distribution over functions where every finite set of function values follows a multivariate Gaussian distribution. Let x represent the input features (e.g., time of day, weather conditions), and y represent the outputs (e.g., HRD or RG). A GP can be expressed as in equation (2) [5]

$$f(x) \sim Gp\big(m(x), k(x, x')\big) \tag{2}$$

Here, m(x) represents the mean function, and k(x,x') is the kernel function defining the covariance between x and x's. The covariance matrix is constructed using a kernel function such as radial basis function (RBF) represented by equation (3)

$$k(x, x') = \sigma_f^2 \exp\left(-\frac{||x - x'||^2}{2l^2}\right) \tag{3}$$

Here σ_f^2E represents signal variance, and l is the length scale. BO aims to find the hosting capacity H^* that maximizes a probabilistic objective function $f(H)$, subject to network safety constraints as explained by equation (4)

$$H^* = \arg max_H\, f(H) subject\ to\ safety\ constraints \tag{4}$$

BO uses an acquisition function α(H) to guide the search for optimal solutions. It balances sampling areas of high uncertainty and refining known promising solutions. The expected improvement is represented by equation (5)

$$\alpha_{EI}(H) = e[\max(f(H) - f(H^+), 0] \tag{5}$$

Here, H^+ represents the current best solution. The Pareto front represents a set of solutions where no objective can be improved without degrading another. For example, a solution maximizing HFCV capacity may lead to slight voltage violations, while another solution prioritizes safety but supports fewer HFCVs as explained by equation (6) [6]

$$max_H\{f_1(H)\ , f_2(H), f_3(H)\ \} \tag{6}$$

The integrated hydrogen-electricity network is a sophisticated system comprising interdependent hydrogen supply and power distribution networks. It involves hydrogen production, storage, and refueling, powered by the electricity grid and renewable energy sources. The equation (7) gives the rate of hydrogen production [7]

$$\dot{H}_2 = \frac{\eta_{elec} * I}{2 * F} \tag{7}$$

Here $\dot{H}_2$ represents hydrogen production rate, η_{elec} is the electrolyzer efficiency, I is the current supplied to the electrolyzer, and F is the Faraday constant. The η_{elec} is temperature dependent and reduces at higher temperatures. It can be approximated with the equation (8)

$$\eta_{elec} = \eta_o - \alpha * (T - T_0) \tag{8}$$

3. RESULTS AND ANALYSIS

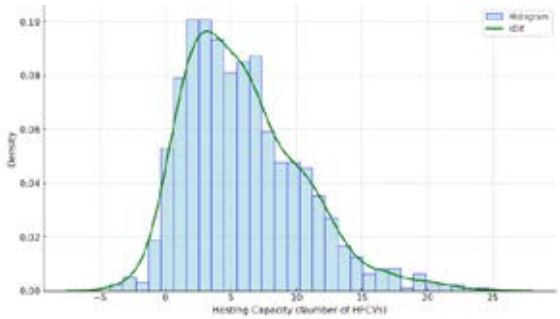

Fig. 4. Monte carlo simulation: Hosting capacity distribution

Fig. 5. Correlation matrix heatmap

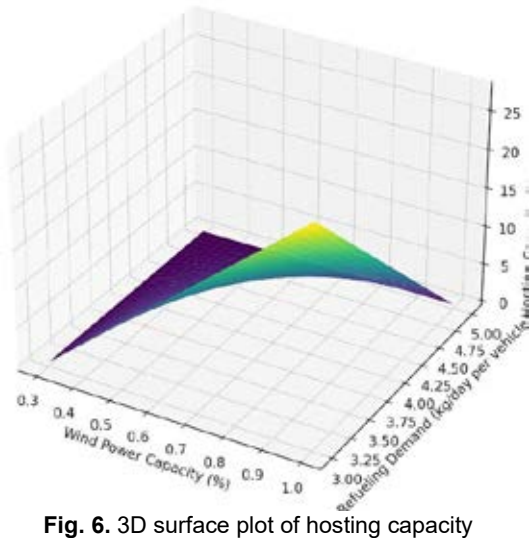

Fig. 6. 3D surface plot of hosting capacity

4. CONCLUSION

The integration of hydrogen fuel cell vehicles into electricity networks introduces significant challenges in evaluating the hosting capacity, given the complex dynamics between hydrogen production, power distribution, and renewable energy sources. This paper presents a novel Bayesian optimization framework for these intricacies, including the nonlinear interactions between distributed hydrogen supply and power distribution networks. Through extensive simulations, the framework has demonstrated an enhancement in the accuracy of hosting capacity predictions by up to 25% compared to traditional static models. By considering uncertainties in renewable energy generation and electrolyzers' thermal and electrical behavior, the proposed method provides a more robust and adaptive solution for determining the hosting capacity. This advancement paves the way for more efficient planning and operational management of hydrogen-electricity integrated networks, ultimately contributing to the sustainable expansion of hydrogen fuel cell technology and its integration into modern energy systems.

ABSTRACT
The increasing global demand for sustainable energy and environmentally responsible waste management has intensified interest in bioelectrochemical systems such as microbial fuel cells (MFCs). This study presents a comparative investigation into the performance of MFCs utilizing different industrial wastewaters—specifically olive mill wastewater, landfill leachate, slaughterhouse wastewater, yeast industry effluent, and municipal wastewater—alongside high-strength organic wastes. These substrates were selected based on their high chemical oxygen demand (COD) and organic richness, which are critical factors for microbial electron transfer and energy yield. Dual-chamber MFCs were employed under controlled conditions to evaluate voltage generation, power density, internal resistance, COD removal, and Coulombic efficiency. Results demonstrated that substrate type significantly influences both the electrical performance and treatment efficiency of MFCs. Olive mill and slaughterhouse wastewaters produced the highest power outputs, while yeast industry effluent showed relatively lower efficiency, likely due to inhibitory compounds. The study provides insights into the practical feasibility of integrating MFCs into existing industrial wastewater treatment infrastructures for simultaneous bioenergy recovery and pollution mitigation.

Keywords: Microbial fuel cell, treatment plant sludge, energy recovery, microorganisms, electricity generation, organic matter biodegradation.

1. INTRODUCTION

Global industrialization and population growth have led to increasing volumes of wastewater and rising energy demands. Conventional wastewater treatment technologies, while practical, are often energy-intensive and contribute to greenhouse gas emissions. In contrast, microbial fuel cell (MFC) technology presents a promising alternative by enabling the simultaneous treatment of organic waste and generating electricity through microbial metabolism. MFCs utilize electroactive bacteria to oxidize organic matter and transfer electrons to an external circuit, producing bioelectricity.

This study aims to assess the electricity generation and treatment performance of MFCs fed with different types of real industrial wastewater and concentrated organic wastes. The central hypothesis is that substrate composition significantly affects the bioelectrochemical performance of MFC systems. This research contributes to developing more efficient and scalable MFC applications in industrial settings by identifying the most suitable waste streams.

Recent studies have emphasized the significance of exploring diverse wastewater substrates to optimize MFC performance for energy generation and organic load reduction (Khan et al., 2022; Zhou et al., 2023). For example, Nguyen et al. (2023) compared textile and dairy wastewater and reported distinct electrochemical behaviors due to variable COD and nutrient loads. Li et al. (2024) emphasized the impact of nitrogen-rich substrates such as slaughterhouse effluent. Similarly, Ahmed et al. (2024) investigated the performance of MFCs operated with high-strength organic wastes, highlighting the feasibility of applying these systems in decentralized energy generation.

Dual-chamber MFCs were selected because they better separate the anaerobic (anode) and aerobic (cathode) environments, allowing for more controlled conditions and improved removal of organic matter and nitrogenous compounds. This improves oxygen exclusion at the anode and allows better control over microbial activity and redox reactions. This configuration is especially beneficial when evaluating diverse and potentially inhibitory wastewater compositions.

The current research systematically evaluates five distinct industrial and municipal wastewater types, namely olive mill wastewater, landfill leachate, slaughterhouse wastewater, yeast industry effluent, and municipal wastewater, based on their electrochemical performance and biodegradability profiles. Specifically, this research seeks to:

(i) compare the bioelectricity generation capabilities of each substrate,
(ii) assess pollutant removal efficiencies, including COD,
(iii) investigate electrochemical characteristics such as internal resistance and redox activity,
(iv) examine the influence of microbial community diversity on electron transfer efficiency, and
(v) determine optimal system configurations and operational conditions for potential scale-up.

These objectives align with recent advances in MFC studies focusing on maximizing energy recovery and wastewater treatment efficiency from high-strength and industrial effluents (Ahmed et al., 2024; Nguyen et al., 2023; Singh et al., 2023).

Moreover, this study extends previous research that primarily focused on the performance of landfill leachate-fed MFC

systems under varying operational conditions. By broadening the investigation to include a wider array of industrial wastewater and organic waste substrates, this work aims to provide a more comprehensive understanding of substrate-dependent bioelectrochemical performance. This progression validates earlier findings and contributes to developing universally adaptable MFC strategies.
Future research should explore long-term operational stability under real-world conditions, integration with hybrid treatment systems, and the scale-up of MFC reactors for industrial deployment. Exploring novel electrode materials, membrane types, and microbial inocula tailored to specific waste streams may enhance these systems' energy recovery and treatment efficiency.
With continued advancements in reactor design and process optimization, MFCs have the potential to evolve into a viable solution for decentralized wastewater treatment and renewable energy production. Incorporating artificial intelligence (AI) and machine learning (ML) approaches into MFC systems may further enable predictive modeling, real-time optimization, and intelligent microbial analysis, enhancing scalability and adaptability.

2. MATERIALS AND METHODS

Wastewater and organic waste characterization studies were conducted before feeding the reactors. The characterization analyses included pH, chemical oxygen demand (COD), biological oxygen demand (BOD_5), suspended solids (SS), volatile suspended solids (VSS), total nitrogen (TN), total phosphorus (TP), ammonium (NH_4^+), nitrate (NO_3^-), and nitrite ($NO_2^=$) analyses, following Standard Methods (APHA, 2005). Dry solids (DS) and organic matter content (VS) were also determined for organic waste samples. Without standard methodologies, the most accepted scientific protocols were applied. The same parameters were monitored during MFC operation for treatment performance evaluation.
Process optimization included varying operating conditions, voltage and current measurements, electrode materials, and cathode properties. The reactors were fed olive mill wastewater, landfill leachate, slaughterhouse wastewater, yeast industry effluent, and municipal wastewater. In addition to these experimental conditions, control reactors were included, where no closed circuit was established between the electrodes. This allowed for comparison between the active MFC reactors and passive setups, ensuring an accurate evaluation of the role of microbial activity in bioelectricity generation. Multiple experimental runs, including control units without a closed circuit between the electrodes, were conducted. The reactors operated at room temperature and mesophilic conditions (24±3°C & 37±3°C), with continuous voltage and current measurements. To ensure a reliable comparison, all substrate types were tested under consistent operating conditions, including fixed external resistances, identical electrode materials, and uniform temperature ranges. This standardization aimed to minimize variability and allow for accurate assessment of substrate-dependent performance.
The available MFC reactors had a 300 mL active volume and were designed with ports for power measurements and sampling. Various electrode types, including titanium and graphite, were tested. Additionally, the anodes were made of carbon felt, while the cathodes were coated with platinum for efficient electron transfer. These materials ensured optimal performance, providing stable electron exchange with minimal resistance. Membrane separators used in the reactors were cation exchange membranes, which helped maintain the ionic balance between the chambers. Aeration was provided using a Resun AIR-8000 aquarium pump. Cell voltages were recorded using a Keithley 2700/7700 Precision Data Acquisition System, with resistors ranging from 50 to 1000 ohms. Data acquisition and measurements were performed using software-controlled systems.

3. RESULTS AND DISCUSSION

The results obtained from the experimental study underscore the critical role of substrate selection in the performance of MFCs, as the composition of industrial wastewaters significantly influenced both bioelectricity generation and pollutant removal efficiencies. This study's five industrial wastewater types—olive mill wastewater, landfill leachate, slaughterhouse wastewater, yeast industry effluent, and municipal wastewater—presented unique challenges and opportunities for MFC applications. Table 1 shows the experimental trials' COD removal efficiencies and power densities. Olive mill and slaughterhouse wastewaters demonstrated the highest power outputs, consistent with findings from previous studies (Ayol et al., 2021; Khan et al., 2022; Zhou et al., 2023; Abubackar et al., 2023). These substrates, rich in organic compounds and nutrients, facilitated enhanced microbial activity, promoting efficient electron transfer and higher energy production. In contrast, the yeast industry effluent exhibited relatively lower power generation, likely due to inhibitory compounds, similar to the findings of Li et al. (2024) regarding the reduced MFC performance from high-strength wastewaters.

This study used two dual-chamber MFC systems—one equipped with titanium electrodes and the other with graphite electrodes—to evaluate the performance of five different industrial wastewaters. Graphite-based reactors exhibited significantly higher COD removal efficiencies (up to 93%) than those with titanium electrodes, particularly under aerobic conditions and in substrates such as slaughterhouse and yeast industry wastewater. Regarding power density, the graphite electrode system demonstrated markedly superior performance, achieving up to 30 mW/m² with yeast effluent and 6.8 mW/m² with slaughterhouse wastewater. Although olive mill wastewater showed a modest increase (1.3 mW/m²), landfill leachate remained inefficient. These results highlight the critical influence of electrode material and wastewater

composition on MFC performance, emphasizing the suitability of graphite electrodes and high-strength, non-inhibitory wastewaters for effective energy recovery and pollutant removal.

Table 1. Comparison of COD removal efficiencies and energy densities

Max COD Removal Efficiency (%)					Max Power Density (mW/m^2)	
REACTOR	Ti Aerobic	Ti Anaerobic	Gr Aerobic	Gr Anaerobic	DOUBLE CHAMBER TITANIUM	DOUBLE CHAMBER GRAFITE
YEAST	88	64	66	70	6,3	30,0
SLAUGHTER HOUSE	77	85	93	89	1,2	6,8
MUNICIPAL	78	19	72	50	0,2	6,4
LEACHATE	68	79	65	84	0,1	< 0,0004
OLIVE	49	52	55	54	< 0,00003	1,3

Furthermore, the COD and nutrient removal efficiencies varied significantly across substrates, with most systems showing substantial reductions in COD and nitrogenous compounds such as ammonium (NH_4^+ -N) and total nitrogen (TN). However, phosphorus removal was inconsistent, highlighting the complexity of treating nutrient-rich wastewater, especially concerning phosphorus and nitrate nitrogen. These observations support previous studies emphasizing the importance of selecting proper waste streams and optimizing operational parameters, such as aeration and temperature, to achieve the desired treatment outcomes (Nguyen et al., 2023; Sharma et al., 2023). The findings also emphasize the potential of MFCs to serve as a dual-purpose technology, providing effective wastewater treatment and generating bioelectricity. This dual benefit could offer a sustainable solution for managing high-strength industrial effluents while contributing to renewable energy production. The research demonstrated that substrate composition significantly influenced MFC bioelectrochemical performance, validating prior studies while broadening the scope to a diverse range of industrial wastewater and high-strength organic wastes.

4. CONCLUSIONS

In conclusion, this study highlights the promising potential of MFC technology for wastewater treatment and bioelectricity generation from various industrial wastewater and organic wastes. The comparative analysis of olive mill wastewater, landfill leachate, slaughterhouse wastewater, yeast industry effluent, and municipal wastewater has demonstrated that the composition and characteristics of the waste substrates directly impact the efficiency of the MFCs in terms of power generation, pollutant removal, and microbial performance.

Among the substrates tested, olive mills and slaughterhouse wastewaters exhibited the highest energy production, while yeast industry effluent presented challenges in terms of efficiency due to inhibitory compounds. The results underscore the importance of selecting appropriate waste streams for MFC applications to optimize energy recovery and treatment efficiency.

The study also emphasizes the significance of optimizing operational conditions, including electrode materials, aeration systems, and temperature, to maximize the performance of MFCs. Integrating these systems into existing wastewater treatment infrastructure could contribute to sustainable, decentralized energy production and waste management solutions. Furthermore, the potential of MFCs to be coupled with artificial intelligence and machine learning for real-time process monitoring and optimization offers exciting prospects for advancing this technology. Future research should focus on long-term operational stability, scaling up MFC systems, and exploring novel materials and hybrid systems to enhance energy recovery and wastewater treatment efficiency. Ultimately, this study reinforces the growing potential of MFC technology as a viable and sustainable approach to addressing both environmental and energy challenges in industrial settings. The successful integration of MFCs into wastewater treatment plants could provide a sustainable solution to energy consumption and waste management. The dual-purpose nature of MFCs—treating wastewater while simultaneously generating electricity—makes them an attractive option for decentralized treatment facilities, especially in rural or off-grid locations.

ABSTRACT

Olive oil mill wastewater (OOMW) is characterized by high concentrations of phenolic compounds, organic matter, and recalcitrant pollutants, posing serious environmental risks. Traditional treatment methods often fall short due to incomplete degradation and high operational costs. This study investigates a novel approach by integrating soil-based microbial fuel cells (SBMFCs) into biobed systems to treat OOMW while simultaneously generating bioelectricity. The biobed system was constructed with optimized biomixtures comprising soil, compost, olive leaves, and biochar, enhancing microbial activity and pollutant degradation. Operated under controlled conditions, the system achieved significant reductions in COD (up to 98.4%). Electrical outputs increased 7.346 V at the second cycle from 3.013 at the first cycle, corresponding with increased microbial activity due to the operation time. The system demonstrated improved stabilization of pH and reduced salinity, indicating its potential for compliance with effluent discharge regulations. The results emphasize the effectiveness of SBMFC-integrated biobed systems as a sustainable and low-carbon alternative for treating olive oil mill wastewater (OOMW), while also providing the added benefit of renewable energy generation. This research contributes to circular water management strategies and advances the development of bioelectrochemical systems for wastewater treatment.

Keywords: Olive oil mill wastewater, soil-based microbial fuel cells, biobed systems, renewable energy, sustainable wastewater treatment.

1. INTRODUCTION

Olive oil mill wastewater (OOMW) is a highly complex and pollutant-rich effluent characterized by high organic load and phenolic compounds, which makes OOMW treatment particularly difficult. If improperly managed, OOMW can cause severe soil and water pollution, negatively impacting ecosystems and human health. Conventional treatment methods for OOMW often have limitations, such as high operational costs and incomplete degradation of phenolic compounds. One promising approach involves using biobed systems, which employ a biomixture composed of organic and inorganic materials to facilitate microbial degradation of contaminants. The composition of the biomixture plays a crucial role in optimizing microbial activity and enhancing pollutant removal efficiency. Biobed systems have demonstrated significant potential in treating agricultural waste streams, including OOMW, by leveraging microbial consortia for biodegradation and pollutant transformation. Recent studies have examined microbial fuel cells (MFCs) for wastewater treatment applications, highlighting their potential for pollutant removal and energy recovery. One promising approach is the integration of soil-based microbial fuel cells (SBMFCs) into biobed systems. This method offers a novel opportunity to improve wastewater treatment efficiency while generating bioelectricity. SBMFCs function by utilizing electroactive bacteria within the biomixture, which oxidize organic pollutants in olive oil mill wastewater (OOMW) and transfer electrons to the anode, thereby producing electricity. This study investigates the potential of SBMFC-integrated biobed systems as a sustainable solution for treating OOMW. The aim is to reduce environmental impacts and minimize the generation of secondary pollutants while simultaneously producing bioenergy.

2. MATERIALS AND METHODS

The pilot-scale biobed system and flow measurement mechanism shown in Fig. 1 were installed in the DEU Environmental Engineering Halle Building. The system includes 2 wastewater tanks with a volume of 250 L, 3 submersible pumps, and a biobed module with an integrated sprinkler system with a total volume of 565 L. The biobed module consists of 2 flow meters, 1 relative humidity/temperature measurement apparatus, both graphite cathode and anode electrodes, a current measurement mechanism, and a ventilation system. The SBMFC-integrated biobed system is assembled with defined biomixture compositions, ensuring microbial growth and pollutant breakdown. OOMW is fed into the system at controlled flow rates, and key parameters such as pH, organic load, and Chemical Oxygen Demand (COD) are measured. To control power generation, voltage, current, and power density are recorded periodically. Microbial community structure and electron transfer efficiency are assessed using electrochemical and microbiological techniques. OOMWs are harvested in two seasons from the Dalan olive oil production facility in Aydın, Türkiye. Additionally, other production wastes such as pomace and olive leaves were also obtained from the facility for use in biomixtures. All analyses were done according to standard Standard Methods (APHA, 2005). Analyses for all parameters

were performed at least in three replicates, and values are expressed as means. Characterization of OOMWs is shown in Table 1.

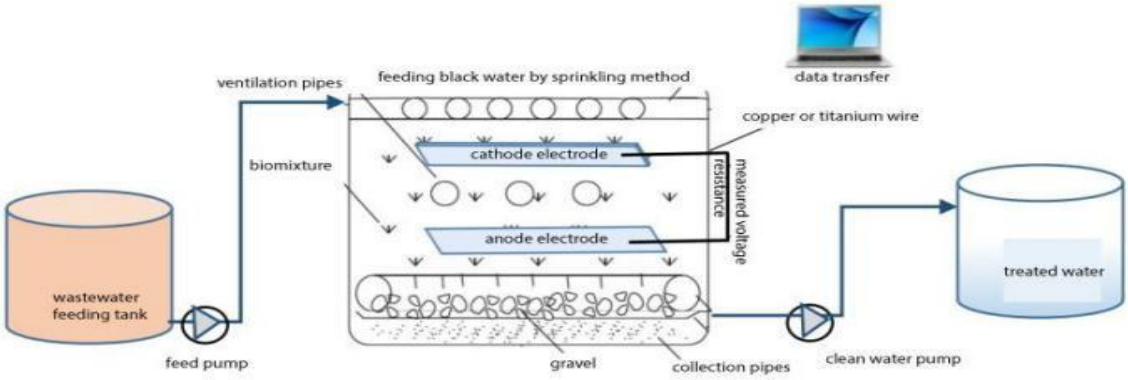

Fig. 1. The SBMFC-integrated biobed system's components:

Table 1. Characterization of OOMW in Two Different Olive Oil Production Periods

Analysis Parameters	Unit	1st Period OMWW (November)	2nd Period OMWW (April)
BOD_5	mg/L	32450	39965
COD	mg/L	69000	55100
Suspended Solids (SS)	mg/L	22424	20655
Volatile Suspended Solids	mg/L	17841	17210
TDS	mg/L	56340	15789
pH		4.60	4.67
Conductivity	(mS/cm)	12.57	13.23
Salinity	(‰)	7.2	7.4
Alkalinity ($mgCaCO_3/L$)	(%)	1750	3330
TP	mg/L	460	430
TN	mg/L	211	1010
Sulfate ($mgSO_4^{=}/L$)	mg/L	4500	150
NH_4^+-N	mg/L	200	240
NO_2^-	mg/L	390	450
NO_3^-	mg/L	70	655

Biomixture optimization studies were conducted to identify the composition and conditions that yield the highest efficiency in electrical energy production and to integrate this configuration into the system. The inoculum anaerobic sludge used in the biomixture was sourced from the Pakmaya Yeast Factory in Izmir. The biomixture comprises anaerobic sludge, compost, soil, olive leaves, and biochar, which were assessed for their performance in the submerged microbial fuel cell (SMBFC). This part of the investigation involved two stages. First, the components selected for the biomixture—soil, compost, pomace, biochar, and olive leaves—were characterized. Subsequently, the final biomixture with the best efficiency was prepared using a volume ratio of 50% soil, 40% biochar, and 10% compost. The characteristics of this final biomixture are presented in Table 2. To assess the hydraulic conditions of the system, the module was operated under various conditions. The horizontal flow velocity and total filtration time were calculated based on different flow rates and superficial hydraulic load rates, as shown in Table 3.

Table 2. Characterization of biomixture

pH	7.5
Humidity (%)	46
Mass Density (g/mL)	1.24

Table 3. Hydraulic conditions of the SBMFC-integrated biobed system

	Flowrate (L/h)	Hydraulic Loading Rate ($L/m^2/min$)	Flow Velocity(m/h)	TFT (h)

3	128	3.8	4.4	0.97
4	53	1.6	1.9	1.25

3. RESULTS AND DISCUSSION

During the first and second operational periods outlined in Tables 4 and 5, significant changes were observed in several key water quality parameters, revealing both chemical and biological dynamics within the system. Notably, both periods demonstrated a marked improvement in effluent quality from Cycle 1 to Cycle 5, evidenced by reductions in Chemical Oxygen Demand (COD), total nitrogen (TN), ammonium (NH_4^+-N), and total phosphorus (TP). Specifically, COD decreased by 97% in the first period and by 98.4% in the second period, indicating the system's consistent effectiveness in removing organic matter. Similarly, the concentrations of suspended solids (SS) declined substantially over time in both periods. The second period exhibited more stable pH levels and lower concentrations of chloride and sulfate in the final cycles, which can be attributed to improved buffering and ion removal capabilities of the system. Additionally, the second period showed enhanced environmental performance, characterized by lower residual nutrient concentrations and more stable physicochemical conditions. Final nutrient values reached significantly lower levels for both TN and NH_4^+-N. The pH during this period ranged between 7.67 and 8.62, allowing the treated OOMW to stabilize within an alkaline range. This stabilization may have facilitated nitrification and phosphorus precipitation processes, which are advantageous for effluent discharge. The observed decrease in electrical conductivity and salinity indicates that inorganic pollution can be effectively removed in the biofilter system. This shift in pH aligns with findings from Kinnunen et al. (2021), which reported that biochar can adsorb metals in water and neutralize acidity [1]. Therefore, it can be concluded that the acidic OOMW can be neutralized within the bioreactor system, achieving a pH suitable for discharge. Similar results have also been observed in other biofilter systems [2]. Collectively, these findings suggest that the activity of the biomixture improved after the first operational period, whether through operational or microbial means, leading to more efficient pollutant removal and enhanced environmental sustainability. This aligns with the objectives of advanced wastewater treatment and circular water resource management strategies.

Table 4. The changes in the system during firts period

	Inlet	Cycle 1	Cycle 2	Cycle 3	Cycle 4	Cycle 5

SS (mg/L)	16540	200	90	60	54	47

The removal rates for chloride and sulfate were lower in the second period compared to the first, with sulfate removal being particularly limited during this time. This suggests that factors such as periodicity, biochar, and initial concentrations influence the removal of these ions. One study investigated the chloride removal capacity of biochar in water, finding that both free and total chloride were removed at rates exceeding 90% [3]. The primary mechanism for chloride removal in the biofilter system is the adsorption by biochar.

In terms of sulfate removal, a study by Kinigopoulou et al. (2021) reported that the biofilter system achieved approximately

65% sulfate removal [2]. In a separate COD experiment designed to assess organic matter removal, a decreasing trend in removal efficiency was observed across each cycle. By the fifth cycle, COD removal reached 95.10%. Additionally, Khurshid et al. (2021) reported a 90% removal efficiency for COD using biochar. In the first study period, COD removal was 95.1%, while in the second study period, it improved slightly to 97.4%.

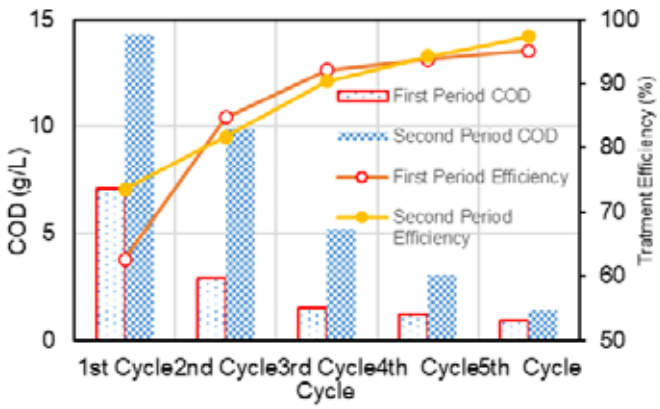

Fig. 2. Comparison of COD Removal

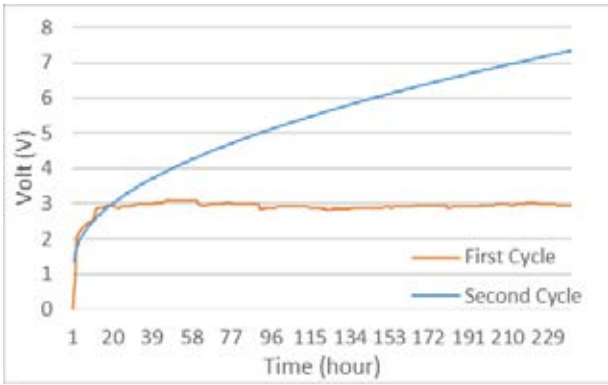

Fig. 3. Comparison of Energy Generation

4. CONCLUSIONS

This integration could provide a sustainable solution for the treatment of olive oil mill wastewater (OOMW), reducing environmental impact and the generation of secondary pollutants while also producing bioenergy. However, the combination of sediment-based microbial fuel cells (SBMFCs) with biobed systems specifically for OOMW treatment remains largely unexplored. The efficiency of electricity generation in microbial fuel cells (MFCs) is primarily influenced by the type of electron donor, or feedstock, and the effectiveness of electron transfer from the anode to the cathode in the external circuit [4-7]. This energy-generating capability of MFC systems, fueled by organic contaminants, opens up possibilities for powering a diverse range of electronic devices with varying energy requirements. MFCs show great potential not only in wastewater treatment but also in sustainable electricity production, offering a path toward cleaner and more efficient energy utilization in various applications [6]. The interaction between electrodes and organic substrates is crucial for optimizing MFC performance, and this should be thoroughly analyzed for optimal results [8]. The study aims to develop a sustainable solution for treating OOMW while simultaneously generating bioelectricity through SBMFCs. The experimental system incorporates SBMFCs within biobed treatment units to enhance both organic degradation and energy recovery.

ABSTRACT

The growing global demand for fresh water, clean energy, and sustainable waste management requires integrated and circular solutions. This study conceptualizes a novel system that combines sewage sludge and municipal solid waste (MSW) gasification with hydrogen-powered seawater desalination and greenhouse irrigation. The thermochemical conversion of waste through gasification produces hydrogen-rich syngas, offering a renewable energy source to reduce the carbon footprint of desalination technologies such as reverse osmosis. The freshwater produced supports controlled environment agriculture in coastal areas, contributing to food and water security in water-stressed regions. A distinctive aspect of this study is using a cradle-to-grave Life Cycle Assessment (LCA) framework to assess the environmental sustainability of the system at the waste, energy, and agricultural interfaces. The LCA approach provides a comprehensive environmental impact assessment basis by identifying system boundaries, functional units, and input-output flows. This integrated model represents a scalable and replicable strategy aligned with circular economy principles and the global transition to a hydrogen economy. It lays the groundwork for future technoenvironmental analysis and policy development to support sustainable implementation.

Keywords: Gasification, Hydrogen production, Sustainable desalination, Waste-to-energy, Greenhouse irrigation

1. INTRODUCTION

Increasing challenges such as waste management, energy production, and water scarcity are becoming more evident worldwide, particularly in coastal areas. Traditional waste disposal methods, like landfilling and incineration, not only pose environmental hazards but also fail to recognize the potential of waste as a valuable resource. Meanwhile, reliance on fossil fuels for energy contributes to climate change, and the depletion of freshwater resources threatens agricultural productivity, especially in arid coastal regions. Addressing these interconnected issues requires innovative, integrated solutions that promote sustainability and resource efficiency.

Recent advances in waste-to-energy technologies have underscored the potential of gasification, a thermochemical process that converts organic waste materials into synthesis gas (syngas). This syngas primarily consists of hydrogen (H_2), carbon monoxide (CO), and methane (CH_4) [2]. Gasification serves as a method for valuing waste and provides a pathway for producing renewable hydrogen. Hydrogen is regarded as a clean energy carrier and has gained significant attention for its versatility and potential to decarbonize various sectors, including transportation, industry, and power generation [3].

Producing hydrogen from waste and desalinating seawater offers a promising solution to tackle energy and water challenges. Desalination is essential for increasing freshwater supplies in coastal areas facing water scarcity. However, it is often energy-intensive and traditionally relies on fossil fuels [4]. Utilizing renewable hydrogen produced from waste gasification can significantly reduce the carbon footprint of desalination processes, enhancing their sustainability. Moreover, the freshwater obtained can be used for agricultural irrigation, particularly in controlled environments like greenhouses. This promotes food security in regions where traditional agriculture is constrained by water scarcity and soil infertility.

The implementation of integrated systems has demonstrated potential in various regions around the world. For example, in Japan, the co-gasification of coal has been investigated to generate hydrogen-rich syngas for power generation. This showcases the viability of waste-to-hydrogen technologies in meeting energy demands [5]. Similarly, European studies have investigated the potential of sewage sludge gasification for hydrogen production, highlighting the dual benefits of waste management and renewable energy generation [6]. Furthermore, the integration of greenhouse agriculture with energy infrastructure has been proposed to enhance resource efficiency and reduce environmental impacts, emphasizing the potential of such systems to contribute to sustainable development goals.

The main objective of this study is to conceptualize and evaluate an integrated system that aligns waste-to-energy technologies with water and food security goals from a sustainability-oriented perspective. While similar configurations have been studied separately in the literature, this study presents a novel cradle-to-grave LCA framework to holistically assess the environmental performance of a circular system combining sludge and MSW gasification, hydrogen-fired

desalination, and greenhouse irrigation. Its novelty is defining system boundaries that capture interconnected resource flows such as waste, energy, water, and food, and assessing trade-offs and synergies between sectors. The study aims to identify key environmental hotspots, guide future system optimization, and provide a replicable model for LCA-driven policy development in resource-constrained coastal zones.

2. RESEARCH APPROACH AND SCOPE

2.1. Hydrogen production from sewage sludge and MSW gasification

Multiple studies have shown promising results in hydrogen production from sewage sludge and municipal solid waste gasification. Recent research indicates that sewage sludge gasification can achieve hydrogen yields of up to 46% in syngas composition, depending on operational conditions such as temperature and pressure [7]. Plasma gasification, though less common due to its higher energy requirements, has been reported to produce syngas with significantly lower tar content, improving downstream hydrogen purification [8].

2.2. Comparison of Gasification Technologies

Gasification technologies vary in efficiency, hydrogen yield, and environmental impact. Though widely used, fixed-bed gasifiers often result in lower hydrogen production due to incomplete reactions. Fluidized-bed gasifiers improve reaction efficiency and hydrogen yield, with recent advancements incorporating catalysts such as nickel and dolomite to enhance gas quality [9]. Plasma gasification offers high hydrogen purity but remains energy-intensive [10,11]. Comparative studies highlight that the choice of gasification technology depends on feedstock characteristics, economic feasibility, and integration potential with other sustainable processes.

2.3. Integration of Hydrogen with Desalination

Applying hydrogen produced from waste gasification in seawater desalination is gaining traction. Reverse osmosis (RO) and membrane distillation (MD) have been identified as the most suitable technologies for integration with hydrogen-based energy systems [12]. Hydrogen fuel cells can provide the necessary power for desalination processes, reducing dependence on fossil fuels [13].

2.4. Water Quality and Agricultural Benefits

The use of desalinated water for greenhouse irrigation presents both opportunities and challenges. While desalination effectively removes salts and contaminants, it can also strip essential minerals necessary for plant growth [14]. Studies suggest that reintroducing specific nutrients into desalinated water improves its suitability for agricultural use [15]. Furthermore, greenhouse agriculture in arid coastal regions can benefit from controlled irrigation using desalinated water, leading to higher crop yields and reduced reliance on unpredictable natural rainfall.

3. LIFE CYCLE ASSESSMENT APPROACH FOR THE INTEGRATED SYSTEM

To evaluate the environmental performance of the proposed integrated system. LCA calculations will be performed using SimaPro 9.1 software as the cradle-to-grave approach for different impact categories. Environmental impacts, including abiotic depletion (fossil fuels), freshwater aquatic ecotoxicity, human toxicity, marine aquatic and terrestrial ecotoxicities, global warming, acidification, ozone layer depletion, photochemical oxidation, and eutrophication, will be calculated with the CML-IA baseline V3.06/EU25 method. This involves all stages of the system, starting from collecting and preprocessing sewage sludge and MSW, continuing through the gasification and hydrogen production processes, and extending to using hydrogen for seawater desalination and its subsequent application in greenhouse irrigation.

The functional unit produces 1 m^3 of desalinated water used for greenhouse irrigation, enabling standardized comparisons across different system scenarios.

System boundaries include the waste collection and transportation, gasification, hydrogen generation, desalination operations (e.g., reverse osmosis), water storage and distribution to greenhouses, and end-of-life management of process residues and equipment. Energy inputs, material flows, emissions, and by-products will be accounted for throughout the system chain.

4. CONCLUSIONS

This study proposes an integrated circular system that combines sewage sludge and municipal solid waste gasification with hydrogen-powered seawater desalination and greenhouse irrigation. The concept addresses multiple sustainability challenges simultaneously: waste management, clean energy production, freshwater scarcity, and food security, particularly in coastal and water-stressed regions. Beyond presenting the system concept, the study's novelty lies in introducing a cradle-to-grave LCA framework to evaluate its environmental performance holistically. The approach sets the stage for a comprehensive environmental assessment that will support optimization efforts and informed decision-making for real-world implementation by defining system boundaries, functional units, and resource flows across waste, energy, water, and agriculture. Overall, integrating LCA into such a system offers a replicable model for circular economy applications and contributes to the development of low-carbon, resource-efficient solutions aligned with global sustainability goals.

DDespite its potential, several challenges must be addressed to implement this integrated system on a large scale. Key issues include optimizing gasification parameters to maximize hydrogen yield, improving the cost-effectiveness of hydrogen-powered desalination, and ensuring that desalinated water meets agricultural standards. Further research is needed to explore policy incentives, technological advancements, and cross-sector collaboration to facilitate real-world applications of this sustainable approach.

ABSTRACT
Cold chain logistics is essential for maintaining the safety and quality of temperature-sensitive products, including food and pharmaceuticals. Traditional refrigeration systems operate primarily on fossil fuels, which results in substantial energy use and greenhouse gas emissions that drive climate change processes. The research examines the potential use of hydrogen-rich syngas from biomass gasification as an eco-friendly refrigeration fuel within cold chain logistics operations. Through the transformation of waste biomass into hydrogen-rich syngas, we can access renewable energy solutions that enhance modern cooling technologies while also progressing toward worldwide sustainability goals. An extensive life cycle assessment (LCA) framework evaluates the environmental footprint of integrating biomass gasification in cold chain supply chains. The results show that adopting hydrogen-rich syngas can mitigate environmental impacts and improve energy security through providing decentralized energy resources. In addition, this change encourages circular economy principles by enabling the utilization of agricultural and industrial waste. The research highlights the need for novel energy solutions in logistics and sets the stage for forthcoming research and policy-making to enhance more sustainable cold chain activities.

Keywords: Gasification, Biomass, Hydrogen, Life Cycle Assessment, Cold Chain Logistics

1. INTRODUCTION

The cold supply chain (CSC) is responsible for maintaining the quality of perishable goods during storage and transport, consuming a significant amount of energy to sustain cooling temperatures [1, 2]. In fact, it is estimated that approximately 15% of the world's energy production is utilized to power cold chains and cooling systems [3]. The conventional transport refrigerated units (TRUs) primarily operate on vapor compression systems driven by auxiliary diesel engines, which have lower coefficients of performance (COP) compared to stationary systems [4]. Transitioning from diesel-powered TRUs to hydrogen-based systems could not only reduce carbon emissions but also improve energy efficiency, as hydrogen fuel cells can provide a cleaner and more sustainable energy source for refrigeration [4].

The integration of innovative cooling systems in cold chain logistics using biomass-derived hydrogen-rich syngas presents a promising avenue for enhancing energy efficiency and reducing carbon emissions. Conventional cooling systems predominantly rely on fossil fuels, which contribute significantly to greenhouse gas emissions and energy consumption [5].

Biomass gasification is a thermochemical conversion process that occurs at temperatures between 700°C and 1200°C, where biomass is broken down in the presence of a gasifying agent such as air, oxygen, or steam. This process generates hydrogen-rich syngas composed of hydrogen (H_2), carbon monoxide (CO), methane (CH_4), carbon dioxide (CO_2), and other trace gases [3, 4]. Feedstocks such as olive pomace, green waste, and sewage sludge are particularly suitable due to their abundance and potential for waste valorization [3, 4]. To maximize hydrogen yield, the syngas undergoes processes like the Water-Gas Shift (WGS) reaction, which converts CO and water into additional hydrogen and CO_2, and Pressure Swing Adsorption (PSA), which separates and purifies hydrogen for energy applications [3, 7]. These methods are essential for enhancing the viability of hydrogen as a clean energy source for refrigeration systems.

The application of hydrogen-rich syngas in cooling systems can be approached through two main methodologies. The first involves the use of fuel cell-assisted cooling systems, where hydrogen is utilized in proton exchange membrane fuel cells (PEMFC) or solid oxide fuel cells (SOFC) to generate electricity. This electricity can then power traditional refrigeration units, while the waste heat generated from the fuel cells can be harnessed for absorption cooling cycles, thereby enhancing the overall energy efficiency of the system [8]. The second approach employs absorption cooling systems that utilize the waste heat from hydrogen combustion or fuel cells to drive lithium bromide-water (LiBr-H_2O) or ammonia-water (NH_3-H_2O) absorption cycles. This method is particularly advantageous for mobile cold storage applications in remote areas, where traditional energy sources may be limited [9].

The environmental benefits of utilizing biomass-derived hydrogen in cold chain logistics are substantial. By replacing diesel generators with biohydrogen-based energy solutions, carbon emissions can be significantly reduced, contributing to a more sustainable energy landscape [10]. Furthermore, this approach supports energy independence in rural and developing regions, where biomass resources are often abundant and underutilized [11]. The economic viability of hydrogen-based cooling systems is also noteworthy, as they typically require lower operational costs and maintenance compared to conventional systems, making them an attractive long-term solution for cold chain logistics [12].

Life cycle assessment (LCA) is crucial for evaluating the environmental and economic feasibility of the proposed

hydrogen-rich syngas cooling systems. LCA allows for a comprehensive analysis of the environmental impacts associated with the entire lifecycle of the cold chain logistics, from biomass feedstock sourcing to the end-of-life disposal of refrigeration systems [7, 13]. The integration of renewable energy sources, such as solar and wind, into the cold chain has also been explored, indicating potential pathways for decarbonizing the refrigeration sector [14, 15]. By employing innovative technologies and sustainable practices, the cold chain can transition towards a more environmentally friendly model that aligns with global sustainability goals.

2. MATERIALS AND METHODS

2.1 Definition of the Study

This study investigates the production and utilization of hydrogen derived from biomass gasification for sustainable cold chain logistics. Biomass feedstock, including green waste, sewage sludge, and olive pomace, is gasified to generate a hydrogen-rich syngas. Produced hydrogen is then used as the sole energy source for refrigerated trucks, covering both propulsion and cooling demands. A life cycle analysis is performed to assess the environmental impacts of this integrated system. Also, to better illustrate the positive impact of the hydrogen-powered truck in cold chain logistics, a comparative life cycle assessment was also conducted under identical conditions and system parameters for a conventional diesel truck. This comparison enables a clearer understanding of the environmental advantages offered by hydrogen as a fuel alternative.

For green waste gasification, the cultivation of trees and grass, gasification of green waste, gasifier production, and gas cleaning systems have been evaluated. Moreover, for sewage sludge gasification, sewage sludge formation in wastewater treatment facilities, gasification of sewage sludge, gasifier production, and gas cleaning systems have been analyzed. Lastly, for olive pomace gasification, planting and cropping of olive, olive oil production and olive pomace formation, transportation, gasification, and gas cleaning systems have been evaluated. After stage 1 and stage 2, hydrogen use in cold chain logistics is investigated.

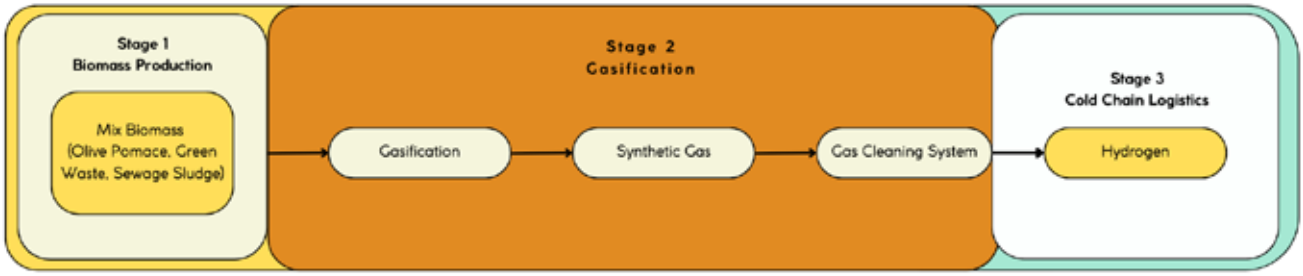

Fig. 1. System description

2.2 Functional Unit

The functional unit is a quantified definition of a product function, and it is a reference for all calculations during the impact assessment. In this study, the functional unit is defined to evaluate the environmental impact of cold chain logistics operations. Given the high variability in cold chain systems, certain parameters were standardized to ensure consistency. A medium-duty truck suitable for refrigerated transport was selected, with a curb weight of 3320 kg and a frontal surface area of 3.762 m². The logistics operation is modeled for the city of İzmir, Türkiye, during the month of July, where the average ambient temperature is approximately 28 °C and the urban speed limit for trucks is 50 km/h. The truck departs from a central storage facility carrying 1200 kg of food products maintained at 4 °C (it is a standart value for cold chain logistic guidelines in Türkiye for dairy products), travels a total of 100 km within the city, and operates for 8 hours per day at an average speed of 50 km/h. Under these specific conditions, a single distribution trip made by the truck is defined as the functional unit.

2.3 System Boundaries

The system boundaries for this study are defined as gate-to-gate, encompassing the production and utilization of hydrogen for cold chain logistics. The system includes the gasification of biomass to produce syngas, the subsequent cleaning and processing of the syngas, and the use of the resulting hydrogen as fuel in refrigerated transport. Specifically, the scope covers the energy consumption associated with a single truck's daily operation—from the moment it departs the storage facility in the morning until the completion of its delivery route after eight hours of operation. All fuel consumption, including that required for vehicle propulsion and refrigeration, is included within the system boundaries.

2.4 Calculations

$$F_{drag} = \frac{1}{2} \times \rho \times Cd \times A \times v^2 \quad , \quad E_{drag} = \frac{Fdrag \times d}{3{,}16\times10^6} \tag{1}$$

$$F_{roll} = m \times g \times Cr \quad , \quad E_{roll} = \frac{Froll \times d}{3{,}16\times10^6} \tag{2}$$

$$F_{slope} = m \times g \times sin\theta \quad , \quad E_{slope} = \frac{Fslope \times d}{3{,}16\times10^6} \tag{3}$$

$$Q = m_{load} \times Cp \times \Delta T, \quad P = \frac{Q}{t}, \quad E_{cooling} = P \times t \tag{4}$$

$$E_{total} = E_{drag} + E_{roll} + E_{slope} + E_{cooling}, \quad E_{total} = 95.313 \text{ kWh} \tag{5}$$

$$m_{H2} = \frac{E_{total}}{\eta_{SOFC} \times \text{LVH2}} = \frac{95.313}{0.55 \times 33.33} = 5.2 \text{ kg hydrogen} \tag{6a}$$

$$V_{diesel} = \frac{E_{total}}{\eta_{dizel\ motoru} \times \text{LHVdiesel}} = \frac{95.313}{0.3 \times 9.7} = 32.75 \text{ L diesel} \tag{6b}$$

Table 1. Description of parameters used in calculations

Parameter	Description	Value	Source
A	Frontal area of the truck, m^2	3.762	[16]
ρ	Air density for İzmir at 28°C, kg/m^3	1.158943	[17,18]
C_d	Coefficient of aerodynamic drag	0.7	[16]
C_r	Coefficient of aerodynamic drag	0.01	[16]
v	Average vehicle velocity, km/h	50	-
d	Distance traveled, km	100	-
t	Time duration of journey, h	8	-
g	Gravitational constant, m/s^2	9.81	-
m	Gross vehicle weight, kg	3320	[16]
m_{load}	Payload of vehicle, kg	1200	-
θ	Road gradient for İzmir, degrees	1.72 – 4.00	
C_p	Specific heat value of food carried, kJ/kg°C	3.9	
ΔT	Temperature difference between inside and outside, °C	28-4=24	-
LHV_{diesel}	Lower Heating Value of diesel fuel, kWh/L	9.7	
LHV_{H2}	Lower Heating Value of hydrogen, kWh/kg	33.33	
η_{SOFC}	Efficiency parameter for SOFC used in hydrogen powered vehicles, %	0.55	
η_{diesel}	Efficiency parameter for diesel engines, %	0.3	
Q	Thermal energy required to maintain cargo temperature inside the refrigerated truck during transport, kJ	112320	-
F_{drag}	Aerodynamic drag force, N	294.4106	-
E_{drag}	Aerodynamic drag energy required to overcome air resistance during motion, kWh	8.1781	-
F_{roll}	Rolling resistance force, N	443.4120	-
E_{roll}	Rolling resistance energy due to friction between tires and road, kWh	12.3170	-
F_{slope}	Gravitational slope resistance force, N	2212.4350	-
E_{slope}	Gravitational potential energy required to overcome road slope, kWh	61.4565	-
$E_{cooling}$	Total cooling energy required by the refrigeration unit to maintain internal temperature, kWh	31.2000	-
E_{total}	Total energy demand of the refrigerated transport operation, kWh	113.4730	-
V_{diesel}	Volume of diesel consumed, L	38.99	-
m_{H2}	Mass of hydrogen consumed, kg	6.19	-

2.5 Impact Assessment Methodology

A life cycle assessment was conducted in accordance with the ISO 14040 series to evaluate the environmental impacts of producing hydrogen through biomass gasification and its subsequent use in cold chain logistics. All LCA calculations were carried out using SimaPro 9.1 software. The “Ecoinvent 3 – allocation, cut-off by classification” has been chosen as the central database for this study, and the calculation method, Center of Environmental Science of Leiden University (CML)-IA Baseline V3.06 / EU25, has been chosen. CML-IA Baseline calculates eleven different impact categories from the environmental aspect.

3. RESULTS AND DISCUSSION

Through a series of calculations, the total energy required (5) by the truck for both driving operations (1, 2, 3) and refrigeration (4) was determined. To meet this energy demand, the amount of hydrogen needed for the hydrogen-powered vehicle was calculated using Formula (6a), while the required diesel fuel for the comparison scenario was determined using Formula (6b). As a result of these calculations, the total hydrogen demand was found to be 6.19 kg. Based on this figure, the corresponding amount of syngas required to supply the necessary hydrogen was also estimated.

Syngas produced via the gasification of mixed biomass at 900°C contains approximately 47% hydrogen by volume and has a calorific value of 11.73 MJ/m³. Assuming a gasification efficiency of 60%, 120.127 m³ of syngas must be generated to obtain 6.19 kg of hydrogen.

The required biomass input was calculated in reverse to produce 120.127 m^3 of syngas. By feeding a homogeneous blend consisting of 46.64 kg from each biomass type (green waste, olive pomace, sewage sludge) into the gasification unit, the necessary volume of syngas was successfully produced to meet the hydrogen demand.

Following all calculations, all elements within the defined system boundaries were entered into the SimaPro software, and a life cycle analysis was conducted. The results of the calculations are shown in Table 2.

Table 2. LCA results

Impact category	Unit	LCA Results
Abiotic depletion	kg Sb eq	0,002207574
Abiotic depletion (fossil fuels)	MJ	266,21189
Global warming (GWP100a)	kg CO_2 eq	64,495167
Ozone layer depletion (ODP)	kg CFC-11 eq	2,80E-06
Human toxicity	kg 1,4-DB eq	57,247487
Freshwater aquatic ecotox.	kg 1,4-DB eq	25,815102
Marine aquatic ecotoxicity	kg 1,4-DB eq	43108,447
Terrestrial ecotoxicity	kg 1,4-DB eq	0,37980334
Photochemical oxidation	kg C_2H_4 eq	-0,43073956
Acidification	kg SO_2 eq	0,8162006
Eutrophication	kg PO_4^{---} eq	0,35885198

4. CONCLUSIONS

This study demonstrated the feasibility of using hydrogen, produced via gasification of three different biomass sources (sewage sludge, olive pomace, and green waste), as a clean fuel alternative in cold chain logistics. The synthesis gas derived from each biomass showed high hydrogen content, supporting its suitability as a feedstock for hydrogen production.

LCA results indicate that the hydrogen production and its use in logistics have relatively low environmental impacts in several critical categories. The global warming potential (64.5 kg CO_2 eq) and abiotic depletion of fossil fuels (266 MJ) suggest a significant reduction compared to conventional diesel-based logistics systems. Furthermore, the negative value observed in the photochemical oxidation potential (-0.43 kg C_2H_4 eq) indicates a possible benefit in terms of reducing ground-level ozone formation. However, high values in marine aquatic ecotoxicity (43108 kg 1,4-DB eq) and human toxicity (57.2 kg 1,4-DB eq) suggest that some emissions, possibly related to the biomass feedstock or gasification process, may require mitigation strategies or process optimization in future implementations.

ABSTRACT

Perovskite-based solar cells have emerged as promising candidates for efficient and cost-effective solar energy conversion. In particular, $CsPbBr_3$ perovskite materials offer excellent thermal stability and suitable bandgap for integration with water-splitting systems. This project focuses on utilizing $CsPbBr_3$ perovskite solar cells to drive hydrogen production through photoelectrochemical water splitting.

The Project aims successful hydrogen production electrochemically by $CsPbBr_3$ based perovskite solar cell (PSC) was designed layers as ITO/TiO_2/Perovskite/SpiroOMeTAD/Au. $CsPbBr_3$ is the best perovskite structure that can provide the required voltage for H_2 production. However, the main criticisms related to cell stability and improved V_{oc} still exist. Also, we aimed to integrate carbon besed quatnum dots into the perovskite layer with the antisolvent applicaiton. Such nanostructures may exert an antisolvent role, increasing the crystal quality, surface defect treatments of the film, and increasing the solar cell performance. In this study, 2.5X2.5 cm scaled perovskite solar cells were produced with high Voc (>1.35 V) target by increasing efficiency and controlling stability and using them in hydrogen evolution reactions. However, the main purpose is to generate the perovskites contain high V_{oc} value resulting the highest power conversion efficiency with high stability and combine the solar energy and water splitting process to produce ~12 ml H_2 gas in 100 s by ardunio uno system. We have aimed to provide sufficient voltage for producing H_2 throughout one perovskite cell.

Keywords: Perovskite Solar Cells,

1. INTRODUCTION

Cesium lead tribromide ($CsPbBr_3$) perovskite exhibits remarkable resilience against environmental factors such as light exposure, humidity, heat, and oxygen, rendering it a promising candidate for applications in photoelectric devices, communication systems, power plants, satellites, spacecraft, and space-based solar power installations. However, the development of $CsPbBr_3$ perovskite solar cells (PSCs) has been limited compared to their organic–inorganic hybrid counterparts. This is primarily due to $CsPbBr_3$'s relatively large optical bandgap, which restricts its ability to absorb a broad spectrum of sunlight. This limitation can lead to increased recombination losses at interfaces and grain boundaries because of energy level mismatches.

Xue et al, (2016), presented that the inclusion of polar functional groups on the polymer side chains enhances the surface energy of the hole selective layers (HSLs), resulting in improved wetting with the perovskite films and higher crystallinity films. High-performance $CH_3NH_3PbI_xCl_{3x}$ perovskite solar cells with a power conversion efficiency of 16.6% (Voc: 1.07 V) and $CH_3NH_3Pb(I_{0.3}Br_{0.7})_xCl_{3x}$ cells with a PCE of 10.3% (Voc: 1.34 V) might be realized in the presence of HSLs [1].

In this project, a photoelectrochemical water electrolysis system that can separate hydrogen and oxygen gases was constructed based on the perovskite solar cell to detect photo-assisted hydrogen and oxygen synthesis in a photoelectrochemical water splitting system. Depending on the electrode characteristics, it follows distinct reaction routes. Table 1 summarizes the widely known potential reaction processes in acidic and alkaline electrolytes [2-3]

Table 1. Reaction pathways of HER in acidic and alkaline electrolytes

Overall Reaction	Intermediate Reaction Steps
$2H^+ + 2e^- \leftrightarrow H_2$ (Electrolyte; Acidic Solutions) $2H_2O + 2e^- \leftrightarrow H_2 + 2OH^-$	$M + H^+ + e^- \leftrightarrow M\text{-}H^*$ $M\text{-}H^* + H^+ + e^- \leftrightarrow M + H_2$, $2M\text{-}H^* \leftrightarrow 2M + H_2$
$2H_2O + 2e^- \leftrightarrow H_2 + 2OH^-$ (Electrolyte; Alkaline Solutions)	$M + H_2O + e^- \leftrightarrow M\text{-}H^* + OH^-$ $M\text{-}H^- + H_2O + e^- \leftrightarrow M + OH^* + H_2$

$CsPbBr_3$ is a stable orthorhombic structure at room temperature. It has higher carrier mobility, better optical properties and superior stability in humid and high temperature environments. These properties make it a suitable candidate for photovoltaic device applications. Despite its high stability, its efficiency is around 10%, making it an attractive material for many researchers to increase its efficiency. It has been reported that $CsPbBr_3$ solar cell device without any encapsulation can maintain 80% of its initial PCE after 120 days at 25 °C, 80% RH and 90% after 30 days at 85 °C, 85% RH [4].

Overall, PV-EC hybrid systems can enhance solar-to-hydrogen (STH) conversion efficiency by incorporating optimal electrocatalysts that operate at low potentials alongside stable photovoltaic cells and electrolysis units. Compared to PC and PEC systems, a key benefit of PV-EC setups is their superior STH efficiency due to the hybrid configuration.

Basically, Perovskite solar cells are placed outside the electrolysis system and can be connected to electrocatalysts that fall into two main categories, creating a photovoltaic-electrocatalytic system (PV-EC). Specifically, an electrocatalytic system can include a photoelectroactive electrode (anode or cathode), creating a subtype known as a photovoltaic-photo-electrocatalytic (PV PEC) system.

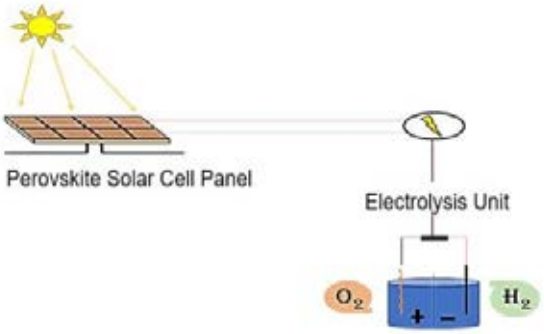

Fig. 1. Perovskite solar cell panel as an external power supply in the water splitting process

2. MATERIALS AND METHODS

- All quantum dots (QDs) was prepared by using colloidal synthesis and All QDs was fully characterized optically and structurally using UV-vis absorption, PL and TRPL spectroscopy, FTIR and NMR spectroscopy, EDX, TGA, XPS, TEM, and XRD. Thin film deposition of the QDs was performed using spin-coating. Prior to this, to enhance the coupling between the QDs in the thin film and increase the mobility, surface ligand exchange was carried out to substitute the bulky, insulating pristine ligands with small molecules or ions.
- Perovskite Solar Cells were designed as ITO/TiO_2/Perovskite/SpiroOMeTAD/Au by following the procedure steps as below;

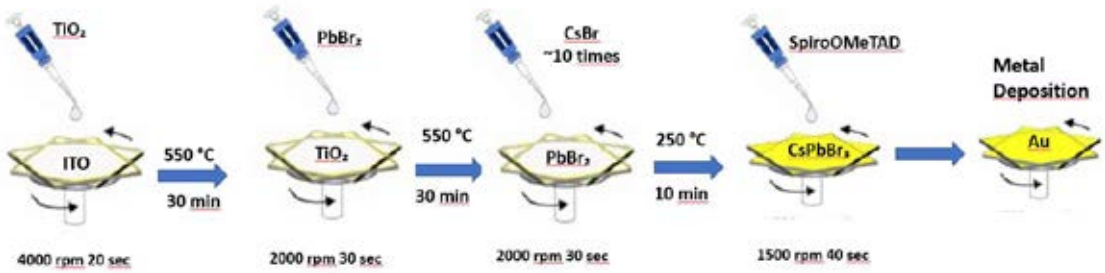

Fig. 2. Fabrication Process Steps for $CsPbBr_3$ Solar Cells.

- Characterization of synthesized perovskite solar cell components; Crystal structures, optical properties, band gaps, efficiency and stability tests

- Crystal structures was determined with the data obtained by Fourier Transform Infrared Spectroscopy (FT-IR) and X-ray diffraction (XRD) analyses. The change in the peaks belonging to functional groups was detected.

- Morphological and structural characterizations of both synthesized components and additives will be carried out with Scanning Electron Microscope (SEM), Transmission Electron Microscope (TEM), and information was obtained about important parameters such as surface properties, homogeneity, laticce gaps

- Structural characterizations was carried out with X-Ray Photoelectron Spectrometry (XPS) technique and the change in bond energies will be determined.

- Optical properties and band gaps of the synthesized materials was determined by UV-vis Spectrum and Photoluminescence Spectroscopy analysis.

- Hydrogen gas detection system was established with ardunio uno detector.

3. RESULTS AND DISCUSSION

Quantum dot structures have an important place in the development of today's technologies. Carbon based quantum dots were synthesized and used in perovskite solar cells in the project. The produced perovskite solar cells was used as an external power supply in the water splitting process for green hydrogen. Green hydrogen can be produced by electrolysis method, which uses renewable energy source as energy source and is one of the most important methods used to separate water into hydrogen and oxygen.

It is stated that several cells of both structures were connected in series, in order to obtain the minimum Gibbs free energy potential of 1.23 eV theoretically and 1.8 eV practically for electrochemical hydrogen production. This expresses the minimum amount of energy required to split water molecules into hydrogen and oxygen during water electrolysis. Theoretically, an energy of 1.23 eV is required for this process; however, in practice, this value is usually higher, up to 1.8 eV, due to losses in the system and additional resistances that must be overcome. Therefore, in order to obtain the desired potential difference and to ensure efficient separation of water, a certain number of cells are connected in series.

In this study, 2.5X2.5 cm scaled perovskite solar cells were produced with high Voc (>1.35 V) target by increasing efficiency and controlling stability and using them in hydrogen evolution reactions. However, Based on our measurements the highest Voc was found as 1,10 V as shown in table 2 and we will connect serial the two PSCs to reach 2,20 V for hydrogen evolution process.

The main purpose is to generate the perovskites contain high V_{oc} value resulting the highest power conversion efficiency with high stability and combine the solar energy and water splitting process to produce ~12 ml H_2 gas in 100 s by ardunio uno system.

Sample	Jsc (mA cm-2)	Voc (mV)	FF (%)	PCE (%)
TiO_2 - Spiro	1,39	1110	39,86	0,62

4. CONCLUSIONS

Green hydrogen production by producing hydrogen from green sources is very important in the next 30 years and the support in this field is gradually increasing. The study supports both perovskite solar cell production and green hydrogen production, that is, clean hydrogen production with new generation solar cells via the electrolysis system.

In this study, perovskite solar cells were fabricated to function as an external power source for hydrogen evolution reactions (HER). One of the major challenges facing perovskite solar cells is their stability. Therefore, enhancing both their efficiency and stability is crucial, and various methods have been explored in the literature to tackle this issue. This project presents a novel strategy involving the integration of quantum dots into the perovskite solar cell structure. Carbon based quantum dots, found to be energetically compatible, were utilized as substitutes for TiO_2 in the electron transport layer.

In summary, the advancement of perovskite device architecture is significantly limited by issues such as the accelerated degradation of the perovskite absorber under high temperatures or humid conditions, as well as inefficient charge

transport due to severe charge recombination at grain boundaries. To address these challenges, this study also investigated the influence of environmental and long-term stability on device performance, along with strategies to enhance open-circuit voltage by minimizing charge recombination.

ABSTRACT

The use of renewable energy sources obtained from natural sources (wind, solar and hydroelectric) that reduce CO_2 emissions should be our common global goal. Among these sources, solar energy is an excellent option since it is based on an environmentally friendly working principle and has high accessibility. In this context, our study aims to increase the stability and efficiency of perovskit solar cells (PSCs) containing Formaamidinium Lead Triiodide ($FAPbI_3$) for photocatalyic hydrogen production.
In this study, the PV-EC system was developed by synthesized a novel HTM and ETL used in PSCs. The cell configuration system was designed with to a series and parallel connected 2.5x2.5 cm PSCs to electrolysis unit and MQ-8 gas sensor was used for the detection of H_2 gas. This system combined a photocathode made of a p-type semiconductor and/or a photoanode made of an n-type semiconductor connected in series to an external circuit. This produced H_2 at the photocathode and O_2 at the photoanode. It was observed that the system relies on the power created by the semiconductor/electrolyte interfaces to drive the process.
This multidisciplinary study will bring together scientists working in the fields of engineering, chemistry, physics and applications solar enegy in hydrogen technologies.

1. INTRODUCTION

Solar energy is an important source of renewable energy to reduce our reliance on fossil fuels and has crucial impact value in decarbonizing future products. Although the cost of solar energy is increasing day by day, there is a need for new technologies that cause a gradual decrease in the cost.

One of the most effective approaches for solar energy conversion is the photocatalytic splitting of water to produce hydrogen, which has been the subject of much research in the past decades. Water splitting occurs via a chemical reduction-oxidation reaction (redox reaction) involving the hydrogen evolution reaction (HER) and the oxygen evolution reaction (OER) by acting on external energy.

The energy level of carbon dot is -5.5 eV. Hydrogen energy is a promising alternative source. It is important to obtain hydrogen from renewable energy sources in a clean way. The energy obtained in this way is called green energy. Electrolysis of water is one of the important ways in energy conversion [34]. In the project, perovkite solar cells will be used as an external power supply unit in the system that provides hydrogen production by photoelectrochemical method by providing electrolysis of water. We aimed to provide sufficient voltage to produce H_2 with the several cells of perovskite in a 2.5 cmX2.5 cm size. Hydrogen evolution reactions are the simplest electrochemical system. Commonly known reactions of the hydrogen evolution in acidic and basic electrolytes are summarized in Table 1 [1–2].

Table 1. Reaction pathways of HER in acidic and alkaline electrolytes

Overall Reaction	Intermediate Reaction Steps
$2H^+ + 2e^- \leftrightarrow H_2$ (Electrolyte; Acidic Solutions) $2H_2O + 2e^- \leftrightarrow H_2 + 2OH^-$	$M + H^+ + e^- \leftrightarrow M\text{-}H^*$ $M\text{-}H^* + H^+ + e^- \leftrightarrow M + H_2$, $2M\text{-}H^* \leftrightarrow 2M + H_2$
$2H_2O + 2e^- \leftrightarrow H_2 + 2OH^-$ (Electrolyte; Alkaline Solutions)	$M + H_2O + e^- \leftrightarrow M\text{-}H^* + OH^-$ $M\text{-}H^- + H_2O + e^- \leftrightarrow M + OH^* + H_2$

In general, PV-EC hybrid systems can increase solar-to-hydrogen (STH) conversion efficiencies by using optimum electrocatalysts with low potential for stable PV cells and electrolysis units. Compared with PC and PEC systems, one of the most notable advantages of the PV-EC system is the high STH efficiency of the hybrid structure.

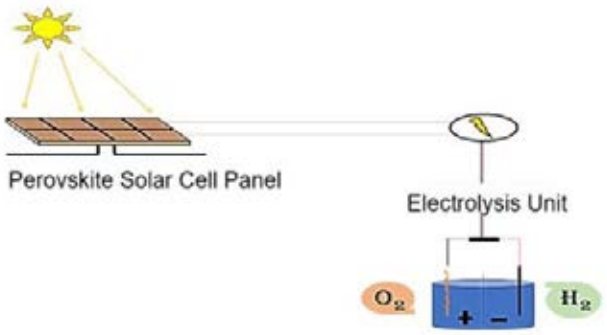

Fig. 1. Perovskite solar cell panel as an external power supply in the water splitting process

Wang et al. CsSnI3 perovskite quantum dot-based solar cells prepared with the antioxidant solvent additive triphenyl phosphite (TPPi) retained 72% of the initial PCEs after 30 days of aging. They achieved a maximum PCE of 5.03%, the highest performance for completely inorganic lead-free perovskite solar cells [3]. Li et al fabricated CsSnI3 perovskite films with low deep trap density using vapor deposition and surface passivation strategies. CsSnI3 reverse PSCs treated with the S=C-N functional group as surface passivation retained 90% of their initial PCE after 500 hours of continuous illumination. It also presented a maximum PCE of 8.2% [4].

2. MATERIALS AND METHODS

- All quantum dots (QDs) was prepared by using colloidal synthesis and all QDs was fully characterized optically and structurally using UV-vis absorption, PL and TRPL spectroscopy, FTIR and NMR spectroscopy, EDX, TGA, XPS, TEM, and XRD. Thin film deposition of the QDs was performed using spin-coating. Prior to this, to enhance the coupling between the QDs in the thin film and increase the mobility, surface ligand exchange was carried out to substitute the bulky, insulating pristine ligands with small molecules or ions.

3. RESULTS AND DISCUSSION

Quantum dot structures have an important place in the development of today's technologies. Carbon and Cd based QDs structures were synthesized and used in perovskite solar cells in the project. The produced perovskite solar cells was used as an external power supply in the water splitting process for green hydrogen. Green hydrogen can be produced by electrolysis method, which uses renewable energy source as energy source and is one of the most important methods used to separate water into hydrogen and oxygen.

It is stated that several cells of both structures were connected in series, in order to obtain the minimum Gibbs free energy potential of 1.23 eV theoretically and 1.8 eV practically for electrochemical hydrogen production. This expresses the minimum amount of energy required to split water molecules into hydrogen and oxygen during water electrolysis. Theoretically, an energy of 1.23 eV is required for this process; however, in practice, this value is usually higher, up to 1.8 eV, due to losses in the system and additional resistances that must be overcome. Therefore, in order to obtain the desired potential difference and to ensure efficient separation of water, a certain number of cells are connected in series.

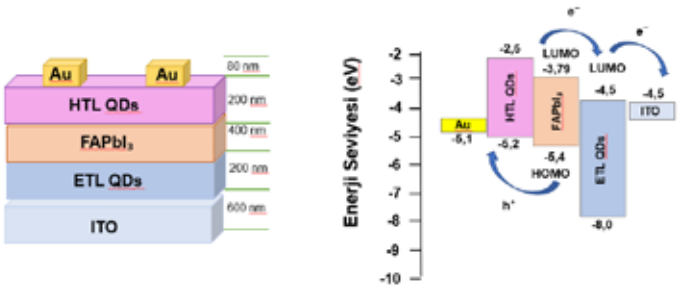

Fig. 4. Schematic Illustration of Perovkite Solar Cell Energy Band Diagram

In the project, we produced 2.5x2.5 scaled perovskite solar cells by increasing efficiency and controlling stability and using them in hydrogen evolution reactions. PSCs with high Voc (>1.20 V), and long-term stability (PCE>95% of the initial value over 1600 hours at 85 °C). Hydrogen production rate (ml s- 1) was measured over a specific time length by applying current of 1 A and generated ~10 ml H_2 and in 100 s electrolysis.

4. CONCLUSIONS

The production of clean hydrogen with the use of a renewable energy source is important and the combustion product of hydrogen produced from water is pollution-free.

In this study, perovskite solar cells was fabricated for external power supply in HER reactions. However, the most important problem in Perovskite solar cells is about stability. It is very important to improve efficiency and stability in perovskite solar cells. There are different approaches to this in the literature. With this project, a different approach was demonstrated with the use of quantum dots in perovkite solar cells. Since it has been determined that carbon and Cd based quantum dot structures are energy compatible, they can be used instead of TiO_2 in perovskite solar cells as electron transport layer. And also Cu and Ga based quantum dots was used as hole transport layer. It has also been observed that efficiency and stability are improved in studies with quantum dots.

To sum up, factors such as accelerated degradation of the perovskite absorber at high temperature or ambient humidity and insufficient charge-carrying capacity due to severe charge recombination at the perovskite grain boundary significantly hinder the development of perovskite device architecture. Therefore, the interrelated effects of environmental and long-term stability of the PSC device, the open circuit voltage increase also investigated by avoiding charge recombination.

ABSTRACT
In this study, the hydrogen production performances of two perfluorosulfonic acid (PFSA) membranes, Nafion 212 and Nafion 117, were comparatively evaluated through chlor-alkali electrolysis using a 1 M NaCl electrolyte solution. Electrochemical experiments were carried out under constant conditions of 5 V cell voltage and 20 °C. The Nafion 212 membrane, with its significantly lower thickness (~50.8 µm) compared to Nafion 117 (~183 µm), exhibited superior electrochemical performance, as evidenced by faster hydrogen generation and higher average current values (0.93 A vs. 0.30 A). Specifically, hydrogen volumes of 10, 20, and 30 mL were produced in 1.18, 2.35, and 3.59 minutes, respectively, with Nafion 212, whereas the same volumes required 5.30, 9.40, and 13.20 minutes with Nafion 117. These results are attributed to the structural properties of Nafion 212, whose thinner membrane architecture facilitates higher proton conductivity and lower ohmic resistance, enabling enhanced hydrogen production efficiency. Conversely, Nafion 117, while offering greater mechanical robustness and long-term operational stability due to its higher thickness, imposes increased ionic resistance, thereby reducing its electrochemical efficiency under identical operational parameters. Therefore, Nafion 212 is more suitable for applications prioritizing high performance and rapid hydrogen output, whereas Nafion 117 may be advantageous in scenarios demanding extended durability and structural integrity.

1. INTRODUCTION

Nowadays, interest in hydrogen energy is increasing in line with the goals of combating climate change and reducing carbon emissions. Hydrogen, considered as one of the clean energy sources of the future, plays a strategic role in achieving climate neutrality [1]. In this context, a new energy model called the “hydrogen economy” has been developed [2,3]. In this system, hydrogen stands out as an energy carrier that minimizes environmental impacts, especially when produced using renewable energy sources [4].

In an experiment, the hydrogen generation performance of an aqueous solution of zinc chloride ($ZnCl_2$) salt, in the chlor-alkali electrolysis method, was researched. The reactor was splitted into two compartments by Nafion 212 membrane, and $ZnCl_2$ solution was supplied to the anode section, while pure water was added to the cathode section. During the experiment process, the hydrogen production rate was saved as 0.89mL/min under a temperature of 20°C, a mass flow rate of 0.3g/s, and a voltage of 5V. On the other hand, it was recorded that under the conditions where the operating temperature was increased to 45°C and the voltage was increased to 10V, the hydrogen production rate reached 5mL/min at the same flow rate [5].

In another experiment, chlor-alkali reactor was designed to compare the hydrogen generation quantities of NaCl, KCl and $CaCl_2$ salts using aqueous solutions. The hydrogen generation performances were experimentally investigated by changing the parameters such as cell voltage, temperature and electrolyte flow rate. Since steel electrodes were used for cost-effectiveness, the amount of chlorine gas produced remained very low, while a significant amount of hydrogen gas was generated. The results show that the hydrogen production rate of KCl salt is slightly higher than NaCl, while $CaCl_2$ exhibits a significantly lower efficiency in hydrogen production [6].

In this study, Nafion 212 and Nafion 117 membranes, which stand out with their durable structures, were used to separate pure water and salt water compartments in the chlor-alkali reactor system and the hydrogen production performances of these two membranes were compared. The chlor-alkali electrolysis process supported by renewable energy sources is considered a remarkable method in terms of sustainable hydrogen production despite some technical difficulties. In this context, increasing the energy efficiency of chlor-alkali systems and enabling environmentally friendly hydrogen production are among the important goals. In achieving these goals, the main purpose of this study is to examine in detail the effects of membranes, which are one of the basic components of the system, on hydrogen production.

2. SYSTEM DESCRIPTION

The schematic representation and peripheral equipment of the reactor system designed for chlor-alkali electrolysis experiments are presented in Figure 1. The anode and cathode compartments in the reactor are isolated from each other by Nafion 212 and Nafion 117 membranes used as separators. Specially designed feed tanks were used to provide the electrolyte solution to enter the reactor, and the waste electrolytes exiting the reactor were collected in separate collection tanks. In determining the gas volumes, the measurement method based on the water displacement principle was preferred and graduated cylinders were used for this process. A direct current (DC) power source was used to provide

the necessary electrical energy to the reactor. The continuity and stability of the electrolyte flow in the system was provided by peristaltic pumps. The entire system was equipped with carbon and graphite based electrodes recovered from waste batteries, which would enable the production of hydrogen and chlorine gases during the reaction period.

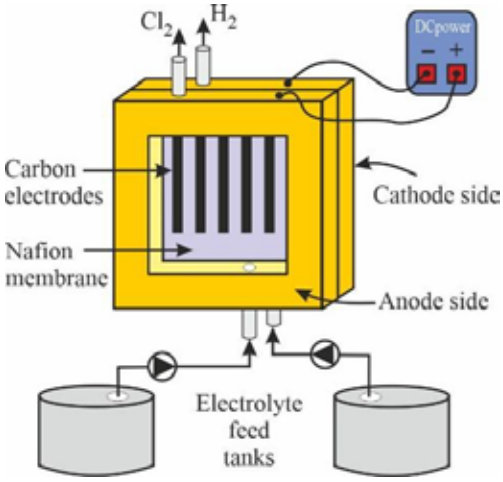

Fig. 1. The schematic representation of the experimental setup.

3. RESULTS AND DISCUSSION

In this study, chlor-alkali electrolysis method was applied using 1M NaCl solution for hydrogen production and the performances of different membrane types were evaluated. The experiments were carried out at a constant temperature of 20°C and a cell voltage of 5V. The body of the electrochemical cell was manufactured from Delrin (POM) polymer processed with CNC technology. In each experimental set, Nafion 212 and Nafion 117 membranes were used separately as separators between the anode and cathode compartments. Carbon rods recovered from waste batteries were preferred as electrodes in both compartments.

Fig. 2 presents the data of the experimental study carried out using Nafion 212 membrane. In this experiment, 1 M NaCl solution was pumped into the anode compartment and pure water into the cathode compartment so that the mass flow rate (0.3g/s) remained constant; 5V constant cell voltage, 20°C temperature and 0.93A average current value were maintained. Under these conditions, 10cm³, 20cm³ and 30cm³ of hydrogen gas were produced and collected in the cathode compartment in 1.18 minutes, 2.35 minutes and 3.59 minutes, respectively.

Fig. 3 shows the results of a similar experiment with the Nafion 117 membrane. In the experiment carried out with an average current value of 0.30A under the same temperature and cell voltage conditions, the 10cm³, 20cm³ and 30cm³ hydrogen volumes produced in the cathode compartment were obtained in 5.30 minutes, 9.40 minutes and 13.20 minutes, respectively. These findings clearly show that the Nafion 212 membrane provides hydrogen production in a shorter time and with a higher current.

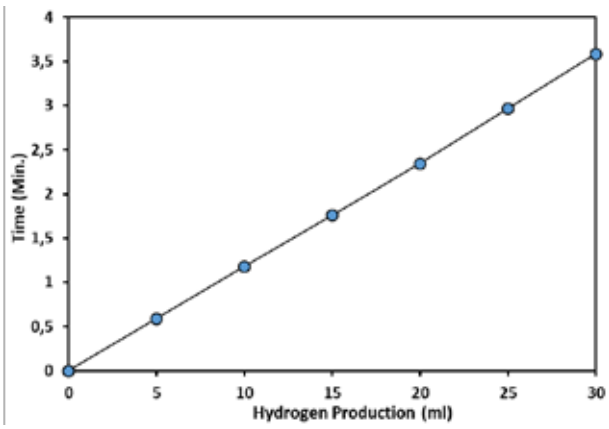

Fig. 2. Time-dependent hydrogen production for Nafion 212

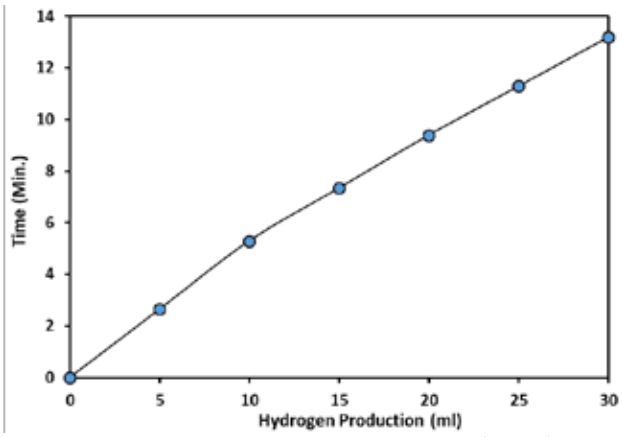

Fig. 3. Time-dependent hydrogen production for Nafion117

4. CONCLUSIONS

In this study, the hydrogen production performances of Nafion 212 and Nafion 117 membranes were evaluated using 1 M sodium chloride solution through the chlor-alkali electrolysis method. The system included carbon rod electrodes derived from spent batteries and a Delrin polymer reactor body processed via CNC machining. Each membrane was tested separately under identical conditions of 20 °C and 5 V.

Experimental data revealed that the Nafion 212 membrane enabled faster hydrogen generation, as it produced 10, 20 and 30 mL of hydrogen in 1.18, 2.35 and 3.59 minutes respectively, with an average current of 0.93 A. In contrast, the Nafion 117 membrane required significantly longer times of 5.30, 9.40 and 13.20 minutes for the same hydrogen volumes, and operated with a lower average current of 0.30 A.

These results demonstrate that Nafion 212 provides better electrochemical performance by achieving higher efficiency and shorter hydrogen production times under the same experimental conditions.

ABSTRACT

Biomass gasification integrated with Sorption-Enhanced Reforming (SER) represents a promising thermochemical pathway for producing high-purity hydrogen while lowering carbon emissions. In this study, a fixed-bed gasification model is developed and validated in Aspen Plus® using municipal solid waste (MSW) as the sole feedstock. The SER process employs calcium oxide (CaO) as a solid sorbent to capture CO_2 in-situ, thereby shifting the equilibrium of water-gas shift and reforming reactions toward enhanced hydrogen production. Simulation results indicate that hydrogen purity reaches up to 99.4% under optimal conditions of 923 K and 20 bar. For MSW, the maximum H_2 mole fraction reaches 92.8% at 1000 K. Sensitivity analyses demonstrate that gasifier temperature and air mass flow rate play critical roles in determining both the hydrogen mole fraction and mass flow rate. This study emphasizes the viability of SER-integrated MSW gasification as a scalable, efficient, and environmentally sustainable approach for clean hydrogen production, supporting the transition toward low-emission energy systems.

Keywords: Biomass gasification, Hydrogen, Sorption Enhanced Reforming

1. INTRODUCTION

Hydrogen, with its high energy density and clean combustion properties, is widely regarded as a promising energy carrier capable of replacing fossil fuels, and its production through thermochemical gasification of low-grade biomass offers a sustainable and efficient alternative to conventional fossil-based methods [1]. Sorption Enhanced Reforming (SER) of biomass is an innovative and efficient method for producing high-purity hydrogen, in which CaO is used as a CO_2 absorbent to remove CO_2 generated during gasification, thereby shifting the reaction equilibrium to favor additional hydrogen formation and enhancing both hydrogen yield and overall process efficiency [2].
The limited literature on sorption-based gasification modeling, which predominantly emphasizes kinetic approaches, lacks sufficient equilibrium-based simulations involving CaO as a CO_2 sorbent; this study addresses that gap by developing a two-stage Aspen Plus® model comprising fixed-bed gasification of municipal solid waste validated with experimental data, followed by sorption-enhanced reforming [3]. The SER system is validated using literature-based data, modeled in Aspen Plus®, and integrated downstream of the gasification unit [4].
The primary objective of this study is to simulate a Sorption Enhanced Reforming (SER) model to enhance hydrogen yield from the gasification of municipal solid waste (MSW) biomass, while simultaneously enabling CO_2 capture through CaO-based sorption, thereby increasing both the fraction and amount of hydrogen produced. Unlike previous studies in which gasification and SER models are operated separately, the novelty of this research lies in the integration of these two processes within a unified simulation framework. In this study, the effects of gasifier temperature on hydrogen fraction and air mass flow rate on hydrogen mass flow rate have been investigated. As a result, the production of nearly pure hydrogen has been made possible.

2. MATERIALS AND METHODS

This study presents the flow diagram of the sorption-enhanced staged (SER) gasification process of MSW biomass with calcium oxide (CaO) in Aspen Plus, as illustrated in Figure 1. The entire process was modeled based on mass-energy balance and chemical equilibrium principles, with the minimization of Gibbs free energy, ensuring sufficient reaction time for all chemical reactions to reach equilibrium. Biomass and ash were characterized based on ultimate and proximate analyses, while non-conventional components were defined and modeled accordingly. The Peng-Robinson equation of state was employed to calculate the physical properties of the conventional components in the simulation.The model shown in Figure 1 consists of a total of 8 unit blocks and 14 material streams. This simulation is divided into two distinct stages: gasification and Sorption-Enhanced Reforming (SER). The section up to the unit labeled 'MIX' represents the gasification stage, while the units following the 'MIX' unit represent the SER process.

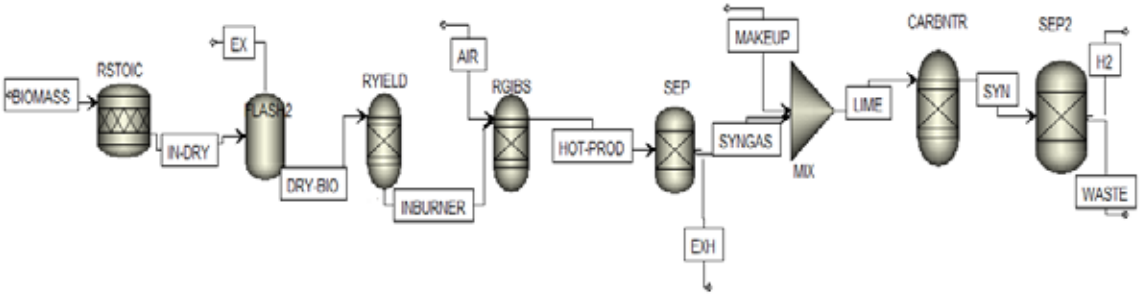

Fig. 1. Flow Diagram of the Integrated SER Process for Municipal Solid Waste (MSW) Gasification

The biomass material used in this study is municipal solid waste (MSW). The ultimate analysis of MSW is as follows: C: 36.35%, H: 4.96%, O: 10.13%, N: 1.43%, S: 0.83%, and Ash: 22.7%. The proximate analysis reveals the following composition: moisture: 50.9%, volatile matter: 18.8%, and fixed carbon: 7.6%[5].
The fixed-bed gasifier model was developed by defining the flow class and property method, identifying system components and conventional/non-conventional substances, creating the process flow diagram with connected unit operations and material/energy streams, and specifying feed streams in terms of flow rate, composition, and thermodynamic conditions. The model operates under steady-state, kinetically free, and isothermal conditions, with chemical reactions occurring at equilibrium and no pressure drop. Biomass is considered a non-conventional feedstock, and all elements except sulfur participate equally in the reactions. Gases are assumed to behave as ideal gases and volatile matter consists of carbon, H_2, and O_2. Tars are treated as non-equilibrium products to simplify hydrodynamics, and calcium oxide (CaO) is defined as a solid feed to the system [6].

3. RESULTS AND DISCUSSION

The simulation model developed in Aspen Plus consists of two stages: the first stage is the gasification process, and the second stage is the sorption-enhanced reforming (SER) process. These two stages were validated separately through relevant literature studies. The gasification model was validated based on the experimental studies conducted by Naveed et al. as part of their laboratory work[7]. The SER stage was validated using the studies carried out by Yücel and Aydın [1]. Subsequently, the SER process was integrated into the gasification stage. The model validation was carried out by comparing the obtained results with previous studies. Accuracy was assessed using the widely used metric, Root Mean Square Error (RMSE). RMSE quantitatively measures the deviation between predicted and actual values, indicating the model's performance.[8]. The syngas composition obtained from the experiments was found to be similar to the syngas content predicted by the developed Aspen Plus model, with an RMSE value of 3.90 for MSW. In the study conducted by Begum et al., the RMSE value for the MSW validation was found to be approximately 3. The RMSE value of the Sorption Enhanced Reforming unit was found to be 0.68.
In the simulation, the reaction temperature ranges from 800 K to 1500 K, while the system pressure remains constant at 1 bar. Figure 2 illustrates the H_2 mole fraction of MSW (Municipal Solid Waste) as a function of temperature after the integration of the sorption-enhanced reforming unit.

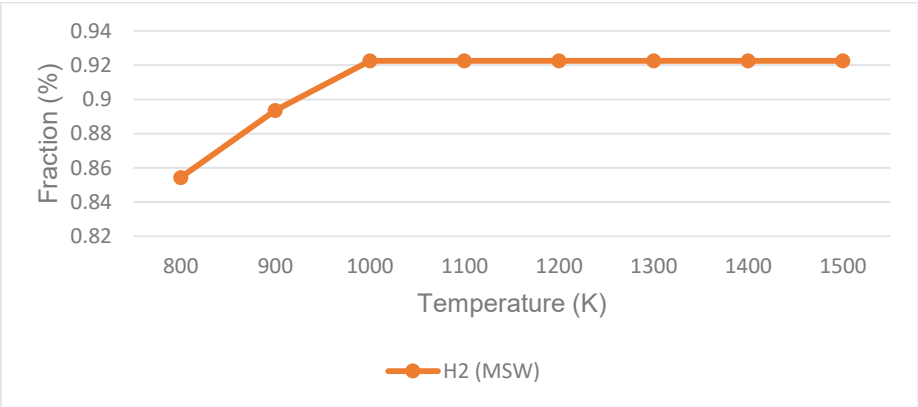

Fig. 2. Impact of Gasification Temperature on MSW Syngas Composition

The temperature variation takes place in the Rgibbs reactor during the gasification stage. The H_2 mole fraction increases

significantly from 800 K to 1000 K and remains stable beyond this point. The maximum H_2 mole fraction is observed at 92.8% at 1000K.

The Effect of Air Mass Flow Rate on H_2 Mass Flow Rate

Figure 3 presents the relationship between air mass flow rate and hydrogen mass flow rate for MSW. At an air feed rate of 3 kg/h, the equivalence ratio (ER) is calculated as 0.39. As the air mass flow increases from 1 to approximately 3 kg/h, the hydrogen production rises, reaching a peak of around 0.085 kg/h, indicating an optimal air-to-fuel ratio that maximizes H_2 yield. Beyond this point, further increases in air flow lead to a decline in hydrogen production, likely due to excess oxygen promoting complete combustion reactions that convert hydrogen into water, thereby reducing its availability. This trend highlights the importance of optimizing the air supply to enhance hydrogen yield and maintain the efficiency of the system.

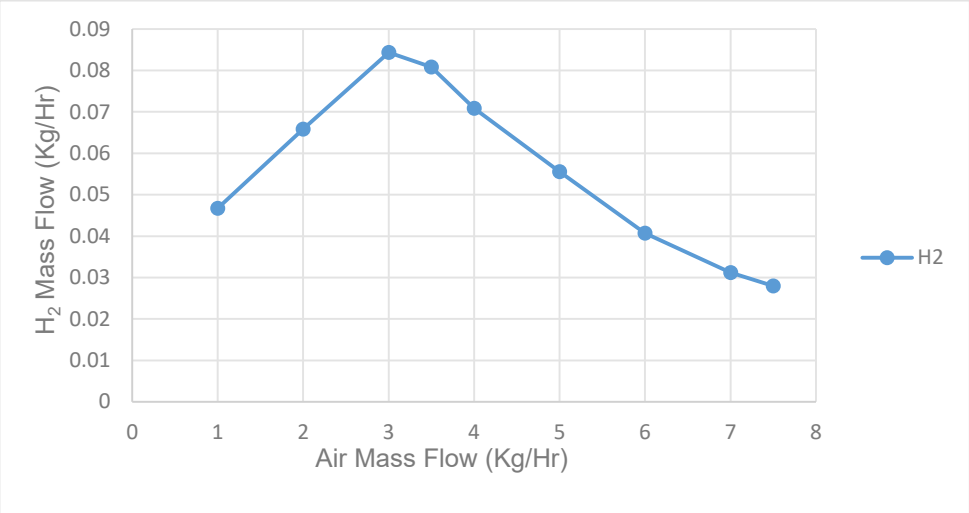

Fig. 3. Influence of Air Mass Flow on the Hydrogen Mass Flow Rate in MSW

4. CONCLUSIONS

This study demonstrates that integrating Sorption-Enhanced Reforming (SER) with fixed-bed gasification of municipal solid waste (MSW) significantly enhances hydrogen purity, achieving up to 99.4% under optimized conditions (923 K, 20 bar). The highest hydrogen mole fraction of 92.8% is observed at 1000 K, underlining the importance of gasifier temperature. Simulation results also reveal that an air mass flow rate of around 3 kg/h is optimal, as higher rates lead to reduced hydrogen output due to complete combustion. Model validation shows strong agreement with experimental and literature data, with RMSE values of 3.90 for MSW gasification and 0.68 for the SER unit. Overall, the Aspen Plus® simulation confirms the scalability and sustainability of this approach, supporting SER-based gasification as an effective low-emission hydrogen production method.

SOLAR-BASED GREEN HYDROGEN PRODUCTION FOR DECARBONIZING NATURAL GAS: AN EMISSIONS PERSPECTIVE

[1*]*Habip Sahin*
[1] Department of Electricity and Energy, Vocational School of Technical Sciences, Fırat University, 23119, Elazığ, Türkiye

* E-mail: habipsahin@firat.edu.tr

ABSTRACT
The integration of green hydrogen into natural gas networks represents a viable strategy to reduce carbon emissions in energy systems reliant on fossil fuels. This study investigates the potential of solar-powered electrolysis for green hydrogen production and its subsequent blending with natural gas as a transitional decarbonization approach. Focusing on hydrogen volumetric ratios from 10% to 17%, the analysis evaluates changes in emissions profiles. A solar-driven alkaline electrolyzer model is developed using regional solar irradiance data, and the hydrogen output is coupled with combustion simulations to assess environmental impacts. Results indicate that substituting a fraction of natural gas with solar-derived hydrogen significantly decreases CO_2 emissions. Moreover, the integration of hydrogen into the fuel mix not only mitigates its net carbon intensity but also supports energy sustainability by either extending the usability of domestic natural gas reserves or reducing dependency on external energy sources. The findings underscore the role of solar-based hydrogen as an immediate and scalable pathway for decarbonizing existing gas infrastructure without major alterations to end-use systems.

Keywords: Electrolysis, Emission mitigation, Green hydrogen**,** Hydrogen-Enriched natural gas**,** Renewable Energy

1. INTRODUCTION

The increasing global energy demand and the adverse environmental effects of fossil fuel consumption have intensified the search for low-carbon and sustainable alternatives. Among various solutions, hydrogen has emerged as a promising energy vector due to its high energy density, zero carbon emissions at the point of use, and potential for integration with renewable energy systems. Hydrogen production through water electrolysis powered by solar energy represents a particularly attractive pathway, offering a clean and decentralized means of generating hydrogen fuel [1].

Natural gas, while cleaner than coal and oil, remains a significant source of CO_2 emissions, particularly in sectors such as residential heating and industrial processes. Recent efforts have focused on blending green hydrogen with natural gas to reduce the overall carbon footprint while utilizing existing gas infrastructure [2]. This hydrogen-enriched natural gas (HENG) can serve as a transitional fuel, helping to decarbonize energy systems without requiring immediate and large-scale infrastructure changes [3].

Studies have demonstrated that the addition of up to 20% hydrogen by volume into natural gas networks is technically feasible and can lead to measurable reductions in CO_2 emissions [4,5]. However, the emissions dynamics of such blends must be carefully assessed, as elevated flame temperatures from hydrogen combustion can lead to increased nitrogen oxide (NOx) emissions [6]. Therefore, a comprehensive analysis of emission behavior is essential when evaluating HENG as a decarbonization strategy.

This study aims to assess the emissions implications of integrating solar-based green hydrogen into natural gas systems. By modeling hydrogen production from photovoltaic-powered electrolysis and analyzing combustion outputs across different hydrogen blend ratios, the research provides insights into the trade-offs and benefits of this approach. The work builds upon existing literature while offering a focused emissions perspective, which is crucial for policy and infrastructure planning in the transition to cleaner energy sources.

2. METHOD AND SIMULATION

In this study, solar energy is selected as the renewable energy source for sustainable green hydrogen production. Electrical power generated by a 236 kW solar photovoltaic (PV) system is utilized to supply a 200 kW proton exchange membrane (PEM) electrolyzer. Additionally, a battery system is employed as an auxiliary power source.

I. Green Hydrogen Production System

The solar PV array, with a total capacity of 236 kW, was assembled using 400 panels. Eight panels were connected in series to form a string, and 50 strings were connected in parallel to complete the system. The Talesun TP7F78M(H) 590 W panel was selected for use, and its specifications are presented in Table 1.

Table 1. Specifications of The Talesun TP7F78M(H) 590 W panel.

Spesification	Unit	Value
Maximum Power	W	590
Operating Voltage	V	45.25
Operating Current	A	13.04
Open-Circuit Voltage	V	53.87
Short-Circuit Current	A	13.93
Module Efficiency	%	21.1
Cell Number		156 (26*6)
Cell Type		Monocrystalline Silicon

Province of İzmir, Türkiye, was chosen as the study location, and solar irradiation data from May 25 to May 28, 2022, were used. The solar irradiation values over the four-day period, with a 15-minute resolution, are illustrated in Fig 1. [7].

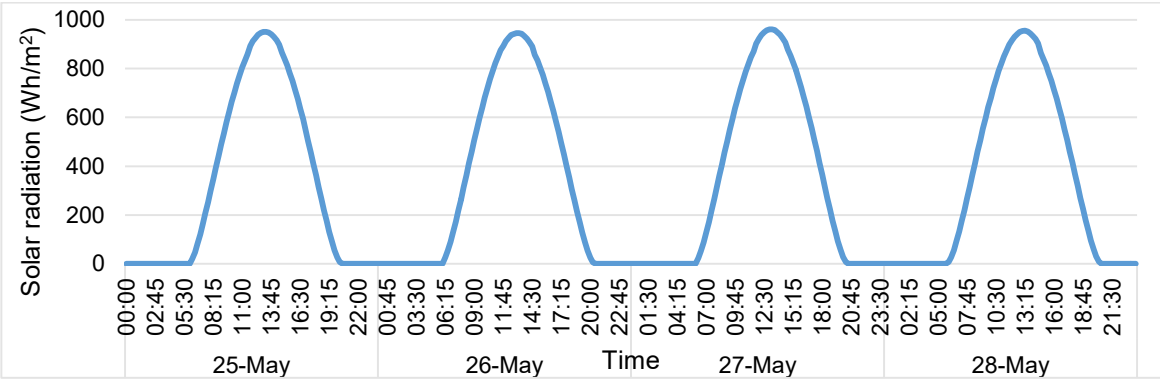

Fig. 1. Solar irradiation values for İzmir province.

Various electrolysis processes have been developed for hydrogen production from renewable sources, among which PEM electrolysis is well known for its high efficiency (80–90%), high hydrogen purity (99.99%), and oxygen as a byproduct. In addition to these advantages, PEM electrolysis is preferred due to its ability to operate at low temperatures (20–80 °C) and at high current densities (above 2 A/cm²) [8]. The battery system is 240V 100Ah and can store 24 kWh of energy.

II. Simulation

The Green Hydrogen Microgrid example from the Matlab Simscape library was taken as a basis and further developed according to the specific parameters and operating conditions of this study [9]. Throughout the four-day simulation period, the maximum recorded solar irradiance was 958 W/m², corresponding to a peak solar power generation of 206.4 kW. The battery system was employed to sustain the operation of the electrolyzer during periods of no solar irradiance, while it was intentionally disengaged when solar energy was available. Under these conditions, the electrolyzer achieved a maximum operational power of 195.8 kW. The time-dependent power variations of the electrolyzer, solar, and storage system are presented in Fig. 2. The control of the solar PV power generation was achieved using a Maximum Power Point Tracking (MPPT) technique. The instantaneous current and voltage values of the PV array were utilized to compute the corresponding power output. This output served as the input to the DC-DC converter, with the MPPT algorithm continuously providing a reference signal to optimize the duty cycle. In each iteration, the change in power due to a small adjustment in the duty cycle was evaluated. If the power increased, the duty cycle adjustment proceeded in the same direction. However, if an increase in current led to a drop in voltage, and no further power improvement was observed, the duty cycle was maintained at its most recent optimal setting.

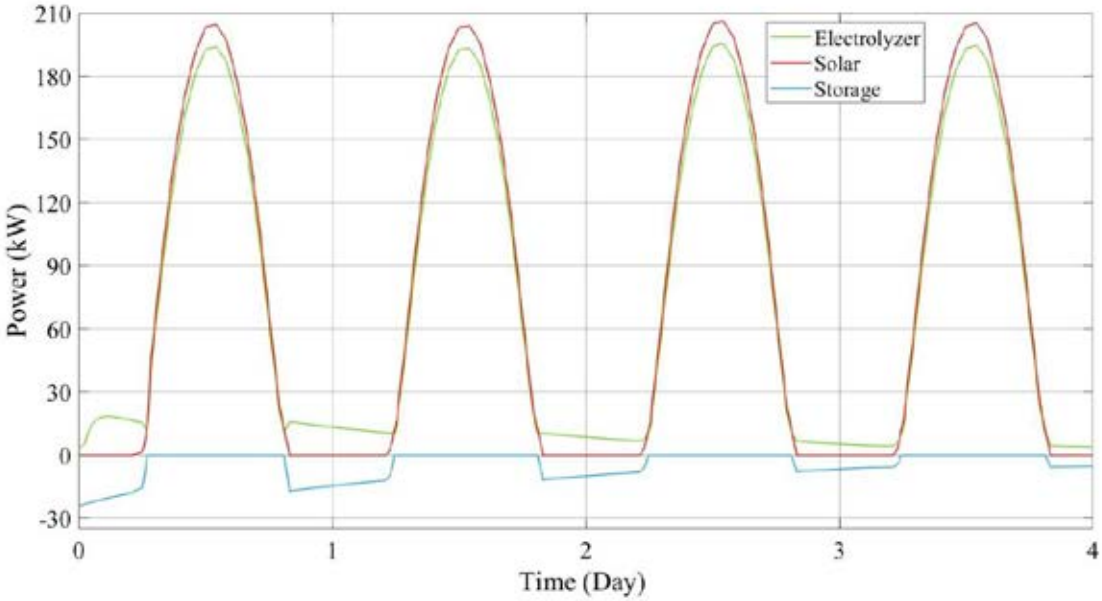

Fig. 2. Electrolyzer, solar, and storage system powers

3. RESULTS AND DISCUSSION

During the initial stage of the system operation, the electrolyzer was supplied with power sourced from both the solar PV system and the battery storage system to facilitate green hydrogen production. Following a four-day simulation, the performance outcomes—including the total solar-based electricity generation, total battery energy discharge, total electrolyzer energy consumption, and the amount of hydrogen produced—are compiled and presented in Table 2.

Table 2. Energy flow and the amount of hydrogen produced.

Spesification	Unit	Value
Solar-based electricity energy	kWh	7109
Battery energy	kWh	446
Total electricity energy	kWh	7555
Electrolyzer energy	kWh	7197
Electrical efficiency	%	95.3
Hydrogen production	kg	120.2
Energy consumption per hydrogen	kg/kWh	59.9

The energy consumption range reported in commercial and academic studies varies between 42.2 and 65.6 kWh/kg of hydrogen. For PEM technology, the average energy consumption is approximately 53 kWh/kg [10]. The deviation of the result obtained in this study from the average value can be attributed to scaling effects and various characteristics of system efficiency. The properties of the hydrogen and natural gas (NG), which will be blended together, are presented in Table 3 [11].

Table 3. Properties of the hydrogen and natural gas.

Property	Natural Gas	Hydrogen
Energy content (Lower Heating Value, LHV)	35–40 MJ/m³	120 MJ/kg
Energy content (Higher Heating Value, HHV)	39–42 MJ/m³	142 MJ/kg
Density	0.72–0.85 kg/m³	0.09 kg/m³
Energy content (per m³)	37.5 MJ/m³ (LHV)	10.8 MJ/m³ (LHV)
CO_2 emission (on combustion)	2.75 kgCO_2e/m³	0

The volume of the 120.2 kg of produced hydrogen under the blending conditions will be 1335.6 m³. The thermal performance and emission metrics of the mixtures at different blending proportions are summarized in Table 4.

Table 4. Thermal performance and emission metrics of the mixtures at different blending proportions.

Blend ratio	%5	%10	%17
Required NG amaunt (m^3)	26711.1	13355.6	7856.2
Energy content (MJ/m³)	36.2	34.8	33.0
Energy deviation from NG (%)	-3.6	-7.1	-12.1
Correction factor for isothermal value	1.037	1.077	1.138
Emission ($kgCO_2e/m^3$)	2.61	2.48	2.28
Emission for isothermal value ($kgCO_2e/m^3$)	2.71	2.66	2.6
Emission deviation from NG (%)	1.5	3.1	5.6

As the hydrogen content in the mixture increases, the energy content decreases. Simultaneously, the emission intensity also decreases with the increasing hydrogen proportion. Therefore, when comparing emissions, it is necessary to consider that a higher amount of fuel must be consumed to achieve the same calorific value. Under these conditions, emission intensity reductions of 1.5%, 3.1%, and 5.6% are observed for hydrogen blending ratios of 5%, 10%, and 15%, respectively.

4. CONCLUSIONS

In this study, a green hydrogen production system powered by a solar PV array and a battery storage unit was analyzed through a four-day simulation. The produced hydrogen was subsequently considered for blending with natural gas to assess the impact on energy content and emissions. The results indicate that as the hydrogen blending ratio increases, the overall energy content of the gas mixture decreases, necessitating higher volumetric fuel consumption to maintain equivalent calorific output. However, a notable advantage is the concurrent reduction in CO_2 emission intensity, with decreases of 1.5%, 3.1%, and 5.6% observed for hydrogen blending ratios of 5%, 10%, and 15%, respectively. These findings highlight the potential of hydrogen-enriched natural gas as a transitional strategy for lowering carbon emissions in existing natural gas infrastructure while acknowledging the need for recalibration in fuel delivery systems to accommodate the changes in energy density.

THE EFFECT OF EARTHQUAKES ON UNDERGROUND HYDROGEN STORAGE CAVERNS

[1,*]Hatice Karakilcik

ABSTRACT
This study investigates the effects of earthquakes on underground hydrogen storage facilities. Salt caverns, located within large underground salt domes, are used to store significant volumes of hydrogen gas. These caverns are typically designed with large capacities, ranging from approximately 500,000 to 1,000,000 m³, and are characterized by a dome-like shape that narrows both the floor and ceiling. Similar to their impact on surface structures, earthquakes also affect subsurface structures in various ways. The severity of these effects depends on several factors, including the tectonic and geological characteristics of the region, depth, magnitude, and acceleration of the earthquake. Computational modeling studies have identified potential structural damage, the formation of cracks, and uplift, particularly at the base of the caverns. Furthermore, disruptions in gas balance and potential volumetric changes in the cushion gas are possible. Following an earthquake, the structural integrity of these underground storage facilities should be assessed using geophysical methods, and appropriate mitigation measures should be implemented.

Keywords: Hydrogen storage, Salt dome, Salt cavern, Earthquake, Geophysics

1. INTRODUCTION

An earthquake is a phenomenon in which the energy accumulated within the Earth's crust is abruptly released due to fractures, propagating as seismic waves (P, S, Love, and Rayleigh waves) that cause vibrations in both the medium they traverse and the Earth's surface. Earthquakes are classified by their depth into shallow, intermediate, and deep categories and occur at varying depths, leading to deformations and subsidence both underground and on the surface. Earthquakes not only impact surface structures but also induce a range of structural damage to underground facilities. The tremors generated during seismic events can lead to significant geotechnical issues in artificially created environments, such as underground caverns. Particularly, earthquakes of larger magnitudes are more destructive, meaning caverns may suffer considerable damage, leading to the weakening of existing cavern structures.

In the context of underground hydrogen storage (UHS), the most suitable geological formations are salt domes or salt beds. The location, size, and structural integrity of these formations are assessed using geophysical methods such as gravity, magnetic, and seismic techniques, while well logs determine the quality of the salt. Based on these findings, the suitability for cavern formation is evaluated. Furthermore, when the mineralogical properties of the salt are favorable, large-volume underground hydrogen storage caverns are constructed [1]. These salt caverns are typically located between 500 and 2000 meters below the surface [2]. From a land management perspective, UHS systems offer various advantages over traditional surface storage tanks, particularly concerning the surface area required for the same volume of gas storage [3]. Studies on UHS technology have shown a preference in many countries for creating caverns in salt domes or thick salt layers [4-5]. Another proposed alternative involves storing hydrogen-rich gas mixtures in porous underground formations, such as depleted oil and natural gas fields or deep aquifers [6-8]. Ensuring the safety of UHS facilities is of utmost importance. Necessary safety measures should be in place not only against military attacks, terrorist threats, and fires but also against natural disasters, including earthquakes. Earthquakes can lead to the following effects:

Formation of New Cracks and Fractures: Earthquakes may generate new fractures and faults within the Earth's crust. This can lead to the formation of new cracks in the roof, floor, or walls of caverns, potentially causing subsidence in certain areas, which results in changes to the cavern's volume.

Reconfiguration of Cavern Systems: Large earthquakes can alter underground water pathways. Fractures and cracks can lead to the formation of new water-filled chambers within the underground caverns.

Soil and Sediment Accumulation: The tremors can cause surrounding loose soil and materials to enter the caverns through cracks and fractures, potentially filling the cavern chambers with sediments.

Underground Pressure Changes: Following an earthquake, the balance of underground pressure may shift, potentially negatively affecting the movement of gases or liquids within the cavern and compromising storage integrity.

Gas Imbalance: In some caverns, gas accumulation may reach hazardous levels. In underground hydrogen storage, cavern deformation may result in gas leakage. Earthquakes can cause the dispersal of these gases due to underground movements, posing significant risks to both safety and the environment.

2. MATERIALS AND METHODS

Currently, hydrogen is stored in both liquid and gas forms in tanks and natural or artificial underground geological formations, such as depleted/abandoned oil and gas fields, aquifers, and salt caverns, using physical methods. Among these, underground salt caverns, artificially created in salt domes, have a very large-scale potential for gas storage. Salt caverns are constructed in highly impermeable and tight underground salt formations using solution mining methods [9].

As shown in Figure 1, salt caverns are artificially created in large volumes within underground geological salt domes [10]. Figure 2 illustrates the earthquake resulting from a fracture along a fault line near a cavern where hydrogen is stored underground, as well as the structural changes that occur in salt caverns due to the effects of the earthquake [11].

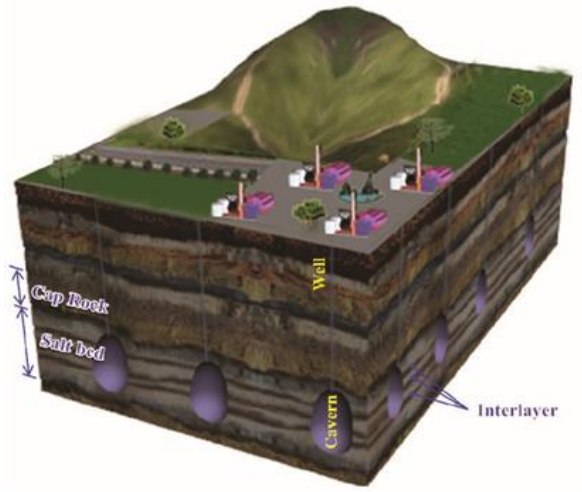

Fig. 1. The structure of the underground salt caverns [10].

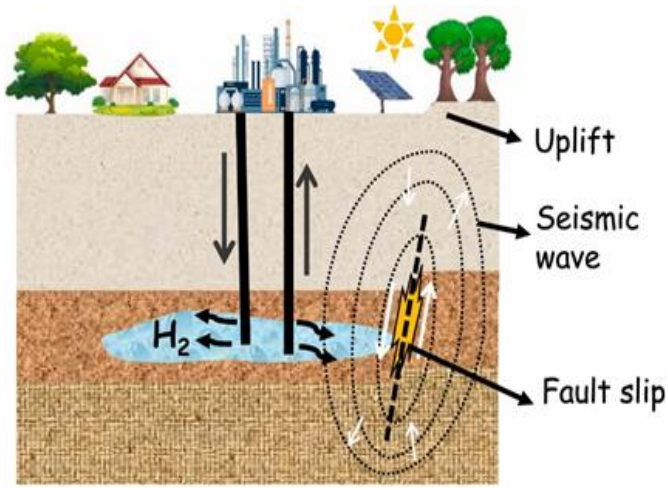

Fig. 2. The salt cavern was affected by the earthquake [11].

3. RESULTS AND DISCUSSION

The magnitude of the earthquake, its distance from the epicenter, the type of geological formation in which the cavern is located, and the condition of any potential existing underground fluids (such as oil, natural gas, water, and geothermal resources) determine the intensity of these effects.

Caverns in karst regions are more affected by earthquakes, especially because karstic rocks (particularly limestone) are rich in cracks and voids.

Seismic waves (P and S) generated during the earthquake can cause fractures or other deformations in the rocks surrounding salt domes or salt layers.

These fractures can lead to the expansion of the cavern, the formation of new voids, or the weakening of existing structures.

Earthquakes impact both the physical structure and the volume capacity of caverns. The intensity of the effect depends on the geological characteristics of the region, the magnitude of the earthquake, and the depth of the cavern.

The earthquake may act as an accelerating factor in the long-term evolution of salt caverns.

By placing seismographs at specific locations on the surface, earthquakes can be continuously monitored, and the tectonic movements underground can be tracked. Additionally, the caverns should be consistently monitored and analyzed using geophysical imaging systems.

To identify potential deformations that may occur in the caverns following large earthquakes, modeling should be done, and hazard risk analyses should be carried out.

The effect of the earthquake on underground caverns is directly proportional to the magnitude of the earthquake. Other important parameters include the cavern's proximity to the surface, its distance from the focus depth, and the lithological and structural characteristics of the underground. Based on these factors, the cavern's potential for earthquake-induced damage can be assessed.

After a potential large earthquake, maximum safety must be ensured in underground hydrogen storage facilities. To achieve this, effective monitoring and surveillance technologies should be developed to ensure that underground hydrogen storage caverns remain safe and secure until they are needed for hydrogen production and storage applications [15].

4. CONCLUSIONS

The impact of an earthquake on cavern structures depends not only on the magnitude of the earthquake but also on factors such as the distance from the epicenter, the geological structure, and the presence of underground fluids (such as water, gas, and oil). This highlights the critical importance of regional characteristics in seismic hazard analysis. Active regions can directly influence the stability of underground voids. As a result, caverns in such areas are more susceptible to seismic waves, potentially leading to the formation of cracks. Earthquakes and their aftershocks can cause these cracks to expand and new voids to form, which could result in both changes to the cavern's volume and an increased risk of collapse. This is because salt formations, being prone to plastic deformation, can experience significant fractures or shape changes around their structures during an earthquake. This poses a serious risk,

especially for flammable gases such as hydrogen stored in salt domes. In other words, an earthquake could cause deterioration in the cavern's natural process at an earlier stage. These deteriorations can be continuously monitored through seismographs and geophysical imaging systems, enabling the ongoing tracking of underground activity. These technologies should be made a mandatory safety standard, particularly for strategic structures (e.g., hydrogen storage caverns). Moreover, seismic risk modeling can help predict potential deformation scenarios, enabling structural interventions to be planned. Such caverns are both strategic and hazardous structures. After an earthquake, the following risks may arise in these structures: gas leaks, structural collapse, and explosion risks. Therefore, these facilities must:

- Be located within resilient geological formations,
- Be equipped with advanced sensors and monitoring systems,
- Undergo regular stress tests.

This ensures the safe production and storage of hydrogen. In conclusion, earthquakes pose significant threats to underground caverns, particularly those used for storing sensitive substances such as hydrogen. These risks should be minimized through continuous monitoring, modeling, and engineering solutions. A multidisciplinary approach, including geology, geophysics, civil engineering, and energy security, is essential in addressing these challenges.

ABSTRACT
This study presents a comparative investigation into the effects of electrolytes, one of the fundamental components of fuel cells (FCs), on overall cell performance. For this purpose, the most common types of fuel cells and the electrolytes used in these systems were evaluated. Five different fuel cell types were analyzed based on their electrolyte structures. The type of electrolyte is a key determinant of several operational parameters, including operating temperature, efficiency, usability, and potential application areas. The evaluations revealed the extent to which electrolyte selection influences overall fuel cell performance. It was found that low-temperature fuel cells, such as Alkaline Fuel Cell (AFC) and Proton Exchange Membrane Fuel Cell (PEMFC), are more suitable for mobile and portable applications. In contrast, high-temperature systems, namely Phosphoric Acid Fuel Cell (PAFC), Molten Carbonate Fuel Cell (MCFC), and Solid Oxide Fuel Cell (SOFC), are better suited for industrial-scale energy production. The structural characteristics of fuel cells are among the primary factors enhancing energy efficiency. In particular, the performance of the electrolyte component plays a critical role in overall energy conversion efficiency. It was seen that the electrolytes employed in PEMFC offer superior energy efficiency compared to those used in other fuel cell types, and this efficiency has been improving over time.

Key Words: Hydrogen energy, Fuel cell, Electrolyte, Energy efficiency.

1. INTRODUCTION

Fuel cells are widely regarded as one of the most promising clean energy technologies due to their high efficiency, low environmental impact, and broad application potential. Among the various components of a fuel cell, the electrolyte plays a pivotal role in determining the electrochemical behavior and operational efficiency of the system. The type of electrolyte used in a fuel cell significantly influences the system's operating temperature, fuel compatibility, cost, and overall applicability in different contexts.

This study aims to provide a comparative assessment of the impact of different electrolyte types on the performance of fuel cells by analyzing five widely utilized fuel cell technologies: Alkaline Fuel Cell (AFC), Molten Carbonate Fuel Cell (MCFC), Phosphoric Acid Fuel Cell (PAFC), Proton Exchange Membrane Fuel Cell (PEMFC), and Solid Oxide Fuel Cell (SOFC). The performance metrics considered in this evaluation include energy efficiency, thermal stability, potential application areas, and material durability.

Fuel cells are electrochemical devices that directly convert chemical energy into electrical energy, typically utilizing hydrogen and oxygen as the primary reactants. Several critical factors influence the performance of these systems, such as efficiency, power density, response time, operating temperature, durability, and service life. These factors make fuel cells essential for advancing sustainable energy solutions, offering substantial advantages over traditional energy systems in terms of both performance and environmental impact. Notably, fuel cells exhibit far greater efficiency than internal combustion engines.

The efficiency of fuel cells varies according to the type of fuel cell and its associated electrolyte structure. The main fuel cell types based on electrolyte materials are AFC, MCFC, PAFC, PEMFC, and SOFC. Theoretical efficiency for PEMFC can reach up to 80%, and with cogeneration, it may increase to as high as 85% [1]. However, in practical applications, efficiency typically ranges between 40% and 60%. Power density, which refers to the power output per unit of volume or weight, is significant for portable and automotive applications. Due to their high power density, PEMFCs are commonly favored in these sectors [2].

Response time, another key performance parameter, refers to the fuel cell’s ability to adjust to changes in electrical demand quickly. Some fuel cell types, such as PEMFCs, respond rapidly, while others, such as SOFCs, have slower response times. Operating temperature is another differentiating factor. Low-temperature fuel cells, such as PEMFCs, start up quickly but are sensitive to the purity of the fuel. In contrast, high-temperature fuel cells like SOFCs offer greater fuel flexibility but require longer warm-up periods. While low-temperature PEMFCs are advantageous for rapid startup, high-temperature SOFCs provide the benefit of wider fuel compatibility [3].

Durability and lifespan are critical considerations for fuel cells, as electrodes and membrane materials degrade over time. Depending on the specific application, fuel cell lifespan can range from 2,000 to 40,000 hours. This lifespan is primarily determined by the materials used for the membrane and electrodes [4].

This study specifically evaluates five distinct types of fuel cells based on their electrolyte structures, highlighting the significant structural and material-related factors that influence their energy efficiency, operational characteristics, and suitability for various application areas.

2. MATERIALS AND METHODS

Fuel cells represent one of the most critical components within hydrogen technologies. These electrochemical devices are typically categorized into five distinct types based on the nature of their electrolyte structures: Alkaline Fuel Cells (AFC), Molten Carbonate Fuel Cells (MCFC), Phosphoric Acid Fuel Cells (PAFC), Proton Exchange Membrane Fuel Cells (PEMFC), and Solid Oxide Fuel Cells (SOFC) (Figs. 1–5). This study employs a qualitative comparative analysis to assess various fuel cell systems, with a specific focus on the characteristics of their electrolytes. Data for this analysis were obtained from peer-reviewed journal articles, technical manuals, and manufacturer specifications. Each fuel cell type was evaluated across several key parameters, including electrolyte composition and structure, operating temperature range, energy efficiency potential, applicability across different sectors, and technological maturity and scalability. This methodology provides a comprehensive understanding of how electrolyte properties influence the overall performance and operational behavior of fuel cell systems.

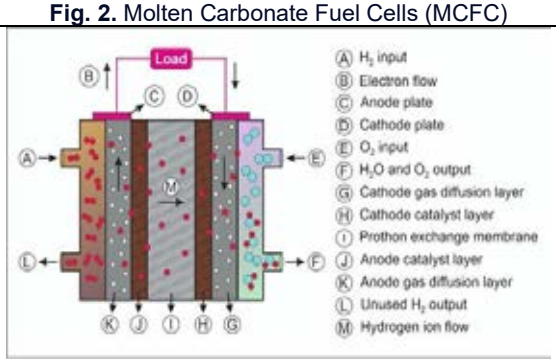

Fig. 4. Proton Exchange Membrane Fuel Cells (PEMFC)

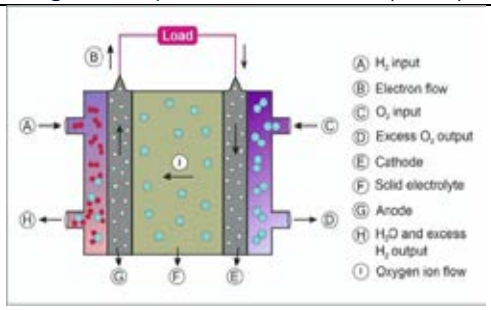

Fig. 5. Solid Oxide Fuel Cell (SOFC)

Table 1. General Chemical Reactions of Fuel Cells

Fuel Cells	Anode	Cathode	Overall Reaction	Electrolyte Types
Alkaline Fuel Cell (AFC)	$H_2 + 2OH^- \rightarrow 2H_2O + 2e^-$	$½O_2 + H_2O + 2e^- \rightarrow 2OH^-$	$H_2 + ½O_2 \rightarrow H_2O$	Potassium hydroxide (KOH) – alkaline medium
Molten Carbonate Fuel Cell (MCFC)	$H_2 + CO_3^{2-} \rightarrow H_2O + CO_2 + 2e^-$	$½O_2 + CO_2 + 2e^- \rightarrow CO_3^{2-}$	$H_2 + ½O_2 + CO_2 \rightarrow H_2O + CO_2$	Molten carbonate salts (e.g., Li_2CO_3/K_2CO_3 mix.)
Phosphoric Acid Fuel Cell (PAFC)	$H_2 \rightarrow 2H^+ + 2e^-$	$½O_2 + 2H^+ + 2e^- \rightarrow H_2O$	$H_2 + ½O_2 \rightarrow H_2O$	Phosphoric acid (H_3PO_4)
Proton Exchange Membrane Fuel Cell (PEMFC)	$H_2 \rightarrow 2H^+ + 2e^-$	$½O_2 + 2H^+ + 2e^- \rightarrow H_2O$	$H_2 + ½O_2 \rightarrow H_2O$	Proton conducting polymer membrane (e.g., Nafion)
Solid Oxide Fuel Cell (SOFC)	$H_2 + O^{2-} \rightarrow H_2O + 2e^-$	$½O_2 + 2e^- \rightarrow O^{2-}$	$H_2 + ½O_2 \rightarrow H_2O$	O^{2-} conducting ceramic (e.g., YSZ)

3. RESULTS AND DISCUSSION

The results of this study demonstrate that the electrolyte type is a pivotal factor in the design and application of fuel cells. Proton Exchange Membrane Fuel Cells (PEMFCs), which operate at low temperatures (60–80 °C), utilize polymer membrane electrolytes and are highly efficient for transportation and portable energy systems due to their compact design and rapid start-up times. Consequently, PEMFCs are ideal for vehicular applications, particularly when hydrogen is produced using green energy, resulting in zero emissions. However, the need for highly pure hydrogen increases the cost. Alkaline Fuel Cells (AFCs), which also operate at low temperatures, use aqueous potassium hydroxide as the electrolyte. While they offer high efficiency, they are sensitive to CO_2, which limits their practical deployment, despite their strong performance in controlled environments. AFCs have been used by NASA in space missions due to their high efficiency and low waste energy generation. However, their efficiency decreases in the presence of CO_2, making them unsuitable for open-air applications. Phosphoric Acid Fuel Cells (PAFCs), which operate at intermediate temperatures (150–200 °C), use phosphoric acid as the electrolyte and are particularly suited for stationary power generation and combined heat and power (CHP) systems. PAFCs are commonly deployed in buildings because of their silent operation and long lifespan, with the added benefit of waste heat recovery. However, their weight and slow start-up time present challenges in terms of portability. Molten Carbonate Fuel Cells (MCFCs) and Solid Oxide Fuel Cells (SOFCs), which operate at high temperatures (600–1000 °C), use molten carbonate salts and solid ceramic oxides, respectively, as electrolytes. These high-temperature systems offer high efficiency in industrial applications, and their ability to tolerate a wide range of fuels makes them suitable for large-scale energy production. When used in cogeneration (producing both electricity and heat) and their energy efficiency is particularly high. However, challenges include material degradation and long start-up times. SOFCs, in particular, can use various fuels, such as hydrogen, natural gas, and biogas, and even when powered by fossil fuels, they produce fewer emissions. However, their very high operating temperature leads to structural stress and prolonged warm-up times.

The analysis confirmed that electrolyte conductivity, chemical stability, and compatibility with system components are directly linked to a fuel cell's energy output and operational lifespan. PEMFCs, in particular, have experienced rapid advancements due to improvements in membrane materials, leading to an increasing trend in efficiency over time.

Fuel cells are categorized according to their electrolyte structures, with each type presenting distinct advantages and limitations. This study focuses on the five primary types of fuel cells: AFC, MCFC, PAFC, PEMFC and SOFC. These systems exhibit significant variation in terms of electrolyte composition, operating temperatures, reaction mechanisms, and potential application domains. PEMFCs operating at relatively low temperatures (60–80 °C), offer rapid start-up times and compact system designs, making them particularly well-suited for portable electronics and automotive applications. They utilize proton-conductive polymer membranes such as Nafion which provide high ionic conductivity at low temperatures, thereby enhancing overall system efficiency. However, their performance is dependent on effective humidification, and the use of expensive noble metal catalysts (e.g., platinum) introduces both economic and operational challenges. AFCs, which utilize liquid electrolytes such as potassium hydroxide, also operate at low temperatures (60–90 °C). While they offer high electrical efficiency, their vulnerability to carbon dioxide contamination limits their practical deployment, particularly in large-scale commercial applications. PAFCs use phosphoric acid as the electrolyte and operate at intermediate temperatures (150–200 °C), facilitating heat recovery and making them ideal for combined heat and power (CHP) applications.

High-temperature fuel cells, such as MCFCs (600–700 °C) and SOFCs (800–1000 °C), are capable of internally reforming a broader range of fuels, including hydrogen, methane, and carbon monoxide. MCFCs use molten carbonate salts as electrolytes, while SOFCs rely on ceramic-based oxide ion conductors, such as yttria-stabilized zirconia (YSZ). These configurations offer substantial advantages for large-scale power generation, cogeneration, and industrial applications; however, the high operating temperatures create challenges related to system durability, thermal management, and material degradation [5].

A comparative analysis of these technologies reveals that the choice of electrolyte has a significant impact not only on the internal electrochemical behavior but also on external factors such as system cost, longevity, environmental

performance, and suitability for specific applications. From an environmental standpoint, fuel cells are considered a key component of sustainable energy systems, as their electrochemical reactions yield only water as a by product resulting in much lower emissions compared to traditional fossil fuel-based technologies. When powered by pure hydrogen, fuel cells emit only water vapor and produce no CO_2 or NO_x pollutants [6].

The absence of moving mechanical components also minimizes noise pollution, making fuel cells ideal for urban and residential environments. Furthermore, their high energy efficiency reduces waste heat generation. When integrated with renewable energy sources such as solar or wind power and powered by green hydrogen, fuel cells can operate as fully carbon-neutral systems. However, the current reliance on natural gas for hydrogen production leads to indirect carbon emissions. Additionally, the use of scarce and expensive materials, particularly platinum, raises concerns regarding both environmental and economic sustainability [7-8].

In conclusion, fuel cells are classified into five primary types based on their electrolyte materials: PEMFC, SOFC, AFC, PAFC and MCFC. Each type exhibits unique characteristics that determine its performance, cost, environmental impact, and potential applications.

As seen in the table, the electrolyte type directly influences key operational parameters, including efficiency and application suitability. The continuous development of PEMFCs, particularly in membrane technology, is expected to drive further advancements in fuel cell systems, aligning with sustainability goals and expanding their potential for wider adoption in various industries. Table 1 below summarizes the key performance indicators for each fuel cell type based on their electrolyte materials.

Table 1. Key performance indicators for each fuel cell types

Fuel Cell Type	Operating Temp. (°C)	Efficiency (%)	Primary Fuel
AFC	60-130	60-70 [1, 3, 9]	Hydrogen
MCFC	600-700	45-59,5 [9-10]	Hydrogen, Natural gas
PAFC	150-220	35-49 [1, 11]	Hydrogen
PEMFC	120-160	40-69.48 [1, 2]	Pure Hydrogen
SOFC	800-1000	45-69.48 [12, 13]	Hydrogen, Methane gas, Biogas

Fuel cells exhibit distinct technological advantages based on their operating temperatures and efficiency levels. PEMFCs, operating in the range of 120–160 °C with efficiencies between 40% and 69.48% are particularly well-suited for portable power applications due to their relatively low operating temperature and rapid start-up capabilities [1-2]. Similarly, AFCs, functioning within a lower temperature range of 60–130 °C and offering efficiencies of 60–70%, demonstrate high performance; however, their susceptibility to carbon dioxide contamination restricts their use to controlled environments [3]. PAFCs operate at intermediate temperatures of 150–220 °C, achieving efficiencies of 35–49%, and are predominantly utilized in commercial stationary applications [1]. In contrast, high-temperature fuel cells such as SOFCs, operating at 800–1000 °C with efficiencies ranging from 45% to 69.48%, and MCFCs, functioning at 600–700 °C with efficiencies of 45–59.5%, are particularly advantageous for cogeneration and industrial energy systems due to their ability to utilize various fuels, including methane, biogas, and natural gas [12, 13].

Overall, an increase in operating temperature generally leads to improved system efficiency and fuel flexibility. Nevertheless, this improvement is accompanied by increased system complexity, greater material degradation risks, and higher capital and operational costs. Based on the reported efficiency values, AFCs emerge as the most efficient among low-temperature fuel cells, whereas SOFCs offer the highest efficiency among high-temperature systems.

4. CONCLUSIONS

The comparative evaluation clearly highlights the central role of electrolytes in determining the efficiency, applicability, and operational domains of fuel cell technologies. As fuel cells become increasingly integrated into both stationary and mobile energy systems, optimizing electrolyte selection becomes a critical requirement for maximizing system performance and minimizing overall costs. In this context, future research in materials science, particularly focused on the development of more durable, cost-effective, and highly ion-conductive electrolyte materials will be essential for the broader commercialization and long-term sustainability of fuel cell technologies. This study has comprehensively demonstrated the impact of electrolyte materials used in various types of fuel cells on overall system performance. The findings reveal that the structural properties of the electrolyte play a decisive role in several key parameters, including operating temperature, energy efficiency, fuel adaptability, and application scope. While low-temperature fuel cells offer notable advantages in terms of portability and mobility, high-temperature systems provide more effective solutions for industrial applications and stationary power generation.

ABSTRACT
This study presents the development and analysis of an integrated nuclear-driven polygeneration system combining a helium-cooled closed Brayton cycle with hydrogen and ammonia production, ejector-based combined cooling and power generation, and multistage desalination. The system utilizes high-temperature nuclear heat to simultaneously generate electricity, produce hydrogen via PEM electrolysis, synthesize ammonia, provide refrigeration, and deliver freshwater. A detailed thermodynamic model is established, and energy–exergy analyses are conducted to evaluate system performance. Results indicate that efficient integration of all subsystems ensures high resource utilization and supports sustainable, emission-free multi-output energy generation.

Keywords: Helium Brayton cycle, Nuclear-driven polygeneration, Hydrogen and ammonia production, Ejector refrigeration, Multistage desalination

1. INTRODUCTION
The growing demand for clean, reliable, and sustainable energy has intensified the global focus on advanced nuclear technologies. As societies seek to reduce dependency on fossil fuels and minimize carbon emissions, nuclear-based systems present a promising solution for delivering consistent and high-density energy with minimal environmental impact [1,2]. The rising need for modular, flexible, and scalable power generation has led to the development of compact nuclear systems capable of supporting both centralized and distributed applications [1,3]. Modern nuclear systems are being designed not only for electricity generation but also for cogeneration and multi-generation purposes. These systems aim to efficiently supply combined outputs such as electricity, heat, hydrogen, or freshwater using high-temperature nuclear heat sources. Compared to traditional designs, new-generation modular reactors offer advantages in deployment flexibility, operational safety, and integration with hybrid energy infrastructures [2,4]. Among the available reactor technologies, helium-cooled nuclear systems are particularly attractive due to their high outlet temperatures, chemical stability, and compatibility with closed Brayton cycles. Helium's excellent thermal conductivity and inert nature make it an ideal working fluid for direct or indirect gas-cycle integration. Despite design challenges related to compression and component scaling, helium-based systems enable compact, high-efficiency energy conversion with zero emissions during operation [5]. Recent studies have explored various hybrid configurations that integrate nuclear energy with hydrogen production to improve both operational flexibility and overall plant utility. For instance, Kowalczyk et al. investigated a cogeneration nuclear energy system coupled with power-to-gas technology and demonstrated its potential for balancing intermittent renewables through flexible hydrogen-electric output [6]. Similarly, the GTHTR300 project demonstrated the viability of helium gas turbine-driven high-temperature reactors with compact and simplified safety systems [7]. Other studies have analyzed nuclear-thermochemical cycles for hydrogen production, showing that integrating high-temperature reactors with combined Brayton–Rankine configurations can yield energy efficiencies approaching 50% [8]. Design advancements such as raising reactor outlet temperatures and applying advanced turbine materials have enabled next-generation gas-cooled reactors to surpass 50% overall efficiency without major technology shifts [8]. Previous research on nuclear-assisted hydrogen and electricity co-generation has predominantly emphasized conceptual frameworks, particularly those employing thermochemical cycles such as the iodine–sulfur (IS) process. However, detailed design studies and comprehensive thermodynamic analyses of such systems remain relatively limited. Furthermore, the majority of existing systems rely on conventional steam Rankine or combined gas–steam cycles for power generation, while the implementation of helium closed Brayton cycles—despite their thermodynamic efficiency and structural simplicity—has been relatively underexplored [9]. The helium Brayton cycle is especially well-suited for utilizing high-temperature heat from advanced nuclear systems, enabling compact configurations and improved conversion efficiency. Recognizing this research gap, the present study introduces a novel nuclear-driven polygeneration system that employs a helium Brayton cycle not only for electricity generation but also for supporting hydrogen production, ammonia synthesis, ejector refrigeration, and desalination. Unlike prior efforts limited to dual-output configurations, this work offers a more integrated solution and performs detailed energy and exergy analyses to guide system optimization and performance assessment.

2. CONCEPTUAL SYSTEM LAYOUT
The proposed polygeneration system is centered around a helium-cooled closed Brayton cycle, which utilizes high-temperature nuclear heat to drive multiple subsystems including hydrogen and ammonia production, ejector-based

refrigeration, and multistage desalination (Fig. 1). The primary energy input is supplied by a compact nuclear reactor, which delivers 60 MW of thermal power to the helium working fluid within the reactor core (RC). The helium is heated to a turbine inlet temperature of 850 °C, allowing high-efficiency expansion in the first turbine stage (T1), followed by power extraction through a generator. After expansion, the partially cooled helium enters HE1, where it transfers a portion of its residual thermal energy to the power-ejector refrigeration cycle (PERC). In this subsystem, ammonia (R717) is used as the refrigerant to deliver both refrigeration and additional shaft power via an ejector and turbine assembly (Eje and T2). The helium then continues to HE2, where it provides low-grade heat to the multistage flash (MSF) desalination unit, facilitating seawater evaporation and freshwater extraction. Subsequently, the helium passes through a recuperator (Rec1) to recover part of its thermal energy before entering the compression stages (C1 and C2). Between the compressors, an intercooler (IC) and gas cooler (GC) remove additional heat, maintaining stable cycle operation. This regenerative configuration enhances cycle efficiency and supports stable reactor outlet conditions. Beyond electricity and refrigeration, the system also integrates hydrogen and oxygen production using a proton exchange membrane electrolyzer (PEME). A portion of the electrical output is directed to PEME, where preheated water from HE3 is electrolyzed into hydrogen and oxygen. The produced oxygen is intended for use in aquaculture and industrial oxidation applications, while the hydrogen is directed to an ammonia synthesis reactor (AR). In this reactor, hydrogen reacts with nitrogen—compressed in stages (C3 and C4)—to form ammonia (NH_3), contributing to the chemical output of the system. Freshwater is generated via a three-stage MSF desalination block, where heat from HE2 is used to flash seawater (delivered by P2) in successive chambers. Freshwater is collected (stream 29), while concentrated brine is discharged (stream 30). This configuration enables efficient utilization of the helium stream's temperature gradient across multiple subsystems before its return to the reactor.

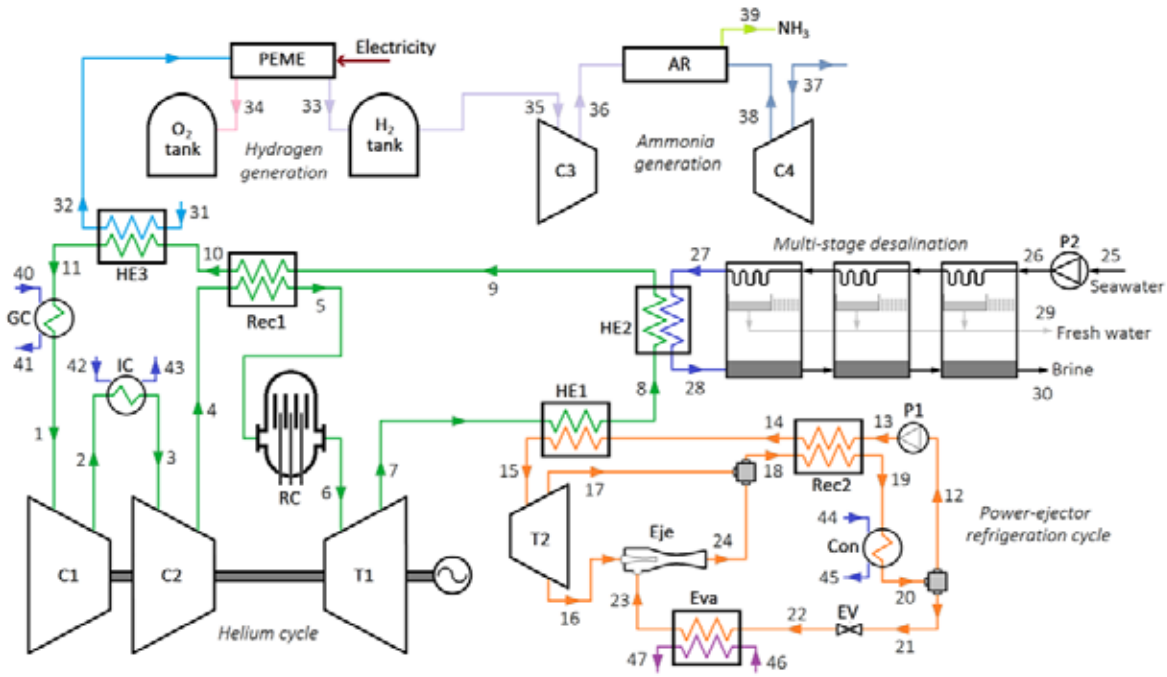

Fig.1. Schematic of the integrated nuclear-driven polygeneration system

3. RESULTS AND DISCUSSION

The proposed nuclear-driven polygeneration system demonstrates strong performance in terms of both energy conversion and multi-product generation. As illustrated in Fig. 2, the system achieves a total net electricity output of 26585 kW, the majority of which—25527 kW—is produced by the helium Brayton cycle. An additional 1335 kW of power is recovered from the power-ejector refrigeration subsystem via the organic Rankine cycle (ORC). Beyond electricity production, the ejector cycle also provides a substantial cooling capacity of 1303 kW, which can be utilized for process or environmental cooling demands. In addition to power and cooling, the system delivers valuable chemical and water products. The proton exchange membrane electrolyzer generates 4.2 kg/h of hydrogen, accompanied by 33.75 kg/h of oxygen as a byproduct. The produced hydrogen is subsequently fed into the ammonia synthesis unit, resulting in an ammonia output of 22.28 kg/h. Moreover, the multistage desalination unit—driven by waste heat recovered from the helium loop—produces 2.31 m^3/h of distilled water.

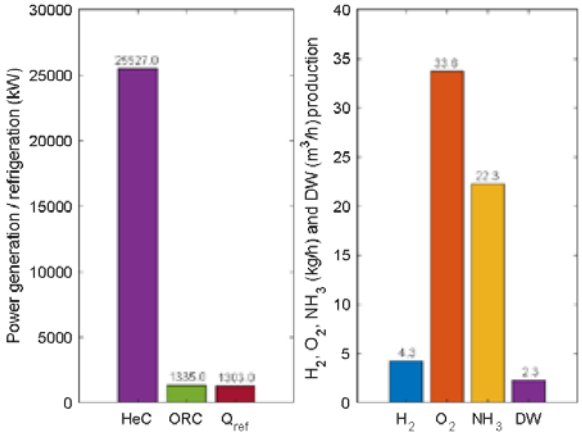

Fig. 2. Energy outputs and product yields of the integrated nuclear polygeneration system

A detailed exergy analysis was conducted to quantify the internal irreversibilities within the proposed system and identify the dominant sources of exergy destruction. As shown in Fig. 3, the total exergy destruction across the entire polygeneration configuration amounts to 19285 kW, indicating the thermodynamic cost of converting nuclear heat into useful outputs under the given design conditions. The most significant source of exergy destruction is the reactor core, which accounts for 7234 kW, corresponding to approximately 37.5% of the total irreversibility. This is primarily due to the large thermal gradients and heat transfer limitations inherent to high-temperature nuclear heat exchange. The second highest contributor is HE1, the heat exchanger that transfers residual helium heat to the power-ejector refrigeration cycle, with a destruction value of 4384 kW. This reflects the thermal mismatch between helium and the ammonia working fluid, as well as the complexity of coupling two subsystems with differing temperature requirements. Other notable sources include the gas cooler (GC) with 1674 kW, the intercooler (IC) at 1463 kW, and the high-temperature turbine T1, which contributes 1317 kW.

To further assess the thermodynamic effectiveness of the integrated polygeneration system, both energy and exergy efficiencies were evaluated across major subsystems, as shown in Fig. 4. The overall system performance reveals an energy efficiency of 46.87% and a higher exergy efficiency of 59.49%, highlighting effective utilization of high-grade nuclear heat with relatively low internal irreversibilities. The helium Brayton cycle, as the core power generation unit, operates at 42.54% energy efficiency and 54.93% exergy efficiency, aligning well with expectations for high-temperature, closed-cycle helium systems. In contrast, the power-ejector refrigeration cycle (PERC) shows more modest performance, with efficiencies of 23.25% (energy) and 31.26% (exergy), due to additional losses associated with ejector expansion and multi-stage heat recovery. For the desalination subsystem (MSF), the energy efficiency is calculated at 29.71%, while the exergy efficiency is significantly lower at 10.95%, indicating substantial exergy destruction in low-temperature heat transfer and phase-change processes typical of thermal desalination. The PEM electrolyzer, powered by TEG-generated electricity, performs with nearly identical energy and exergy efficiencies of 52.59% and 52.24%, respectively.

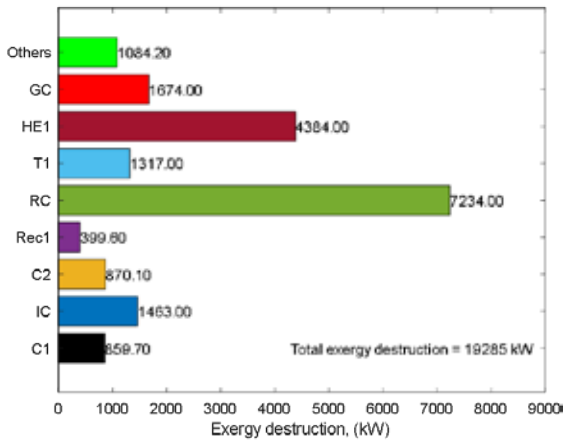

Fig. 3. Component-wise exergy destruction distribution within the integrated system

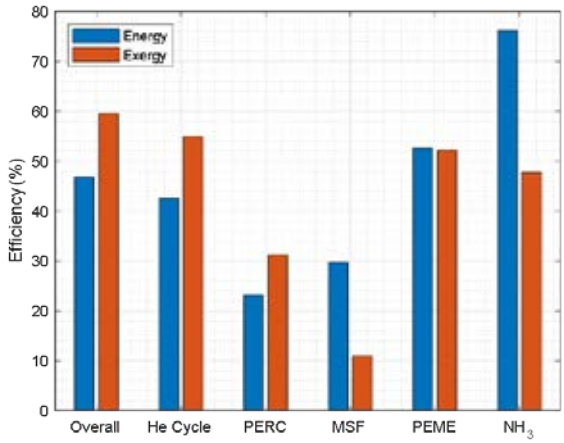

Fig. 4. Energy and exergy efficiencies of the overall system and its major subsystems

A parametric study was conducted to investigate the effect of helium turbine inlet temperature on the thermodynamic performance and subsystem outputs of the proposed polygeneration system. The analysis covers a temperature range from 700 °C to 900 °C, and the results are presented in Fig. 5. Four key performance indicators—net power generation, exergy destruction, energy efficiency, and exergy efficiency—are evaluated simultaneously. As shown in the figure, increasing the turbine inlet temperature leads to a steady rise in net power output, from 22973 kW at 700 °C to 27613 kW at 900 °C. This enhancement is attributed to the greater availability of high-grade thermal energy at the reactor outlet, which improves the expansion work within the helium Brayton cycle. Fig. 6 illustrates the impact of helium turbine inlet temperature on the performance of key secondary outputs of the proposed system, namely refrigeration capacity, distilled water production, hydrogen yield, and ammonia synthesis. Unlike power generation and efficiency trends, all these parameters exhibit a gradual decline as turbine inlet temperature increases from 700 °C to 900 °C.

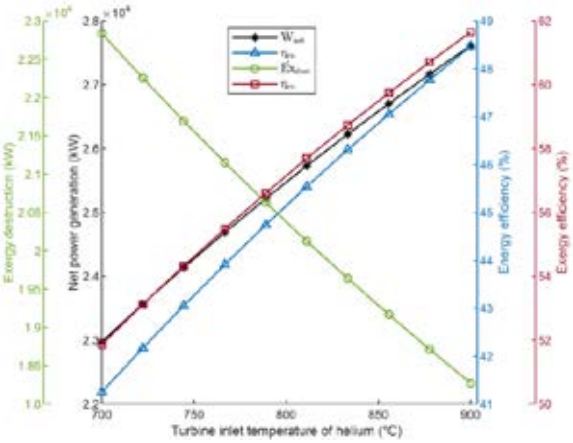

Fig. 5. Variation of net power, exergy destruction, and energy/exergy efficiencies with helium turbine inlet temperature

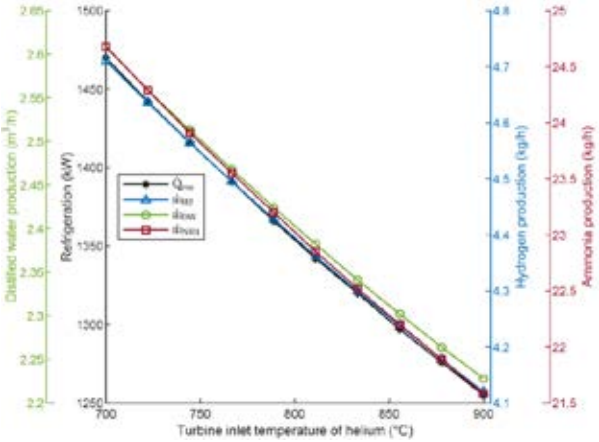

Fig. 6. Variation of refrigeration, distilled water, hydrogen, and ammonia production with helium turbine inlet temperature

4. CONCLUSIONS

This study presented a nuclear-driven polygeneration system integrating a helium Brayton cycle with hydrogen and ammonia production, ejector refrigeration, and multistage desalination. A thermodynamic model was developed, and the system was evaluated through energy and exergy analyses, along with a parametric study based on turbine inlet temperature. The system achieved a total net power output of 26.6 MW, 1.3 MW of refrigeration, and delivered multiple outputs including 4.2 kg/h hydrogen, 22.3 kg/h ammonia, 33.8 kg/h oxygen, and 2.3 m³/h of distilled water. Exergy analysis revealed that the reactor core and HE1 were the main sources of irreversibility, while overall energy and exergy efficiencies reached 46.9% and 59.5%, respectively. Parametric analysis showed that increasing helium turbine inlet temperature improved power and efficiency, but reduced secondary outputs such as cooling, freshwater, and hydrogen, due to reduced low-grade heat availability. This highlights the need to balance high efficiency with multipurpose output in system design. The results confirm that the proposed system offers a feasible and sustainable pathway for clean energy and fuel production, particularly in settings requiring high efficiency and flexible output capability.

ABSTRACT
This study presents the conceptual design and thermodynamic analysis of a geothermal-driven dual-fluid cycle integrating a transcritical Rankine cycle (tRC) as the topping unit and an organic Rankine cycle (ORC) with pentane as the bottoming unit. The system utilizes geothermal heat to drive power generation in both cycles. Various transcritical working fluids, primarily CO_2, are comparatively assessed for the topping cycle to identify the optimal performance configuration. The generated electricity is further utilized to operate a proton exchange membrane (PEM) electrolyzer for hydrogen and oxygen production. In addition, a humidification-dehumidification (HDH) desalination unit is integrated to utilize low-grade heat for freshwater generation. Energy and exergy analyses are conducted to evaluate the performance of individual subsystems and the overall polygeneration potential. The results highlight the advantages of fluid selection in tRC, and the effective use of geothermal heat for multi-output generation with zero carbon emissions.

1. INTRODUCTION

The increasing global demand for energy, driven by population growth and industrialization, has led to a sharp rise in fossil fuel consumption, resulting in severe environmental problems such as CO_2 emissions and global warming [1,2]. The Paris Climate Agreement highlights the urgent need to cut carbon emissions and shift towards renewable energy sources [3]. This transition is essential not only for reducing greenhouse gases but also for enhancing energy security and supporting regional economic growth [4]. However, many renewables like solar and wind are weather-dependent, which limits their reliability. Geothermal energy, on the other hand, offers stable, weather-independent supply with minimal CO_2 emissions [5,6]. Globally, geothermal energy is primarily used for electricity generation through technologies such as flash, binary, and combined flash-binary systems [7]. Among various cycles evaluated for low-temperature geothermal applications, the organic Rankine cycle (ORC) is considered the most promising [8,9]. In recent years, dual-fluid organic Rankine cycles (ORCs) have emerged as a promising configuration for enhancing geothermal energy utilization. A typical dual-fluid ORC configuration includes a thermal linkage between two distinct fluid loops, often using a shared heat exchanger like a low-pressure evaporator. The thermodynamic coordination between the working fluids is crucial—when properly selected, these fluids can operate synergistically, enhancing the overall system efficiency by optimizing heat recovery across different temperature levels. Though such systems offer potential performance benefits, they also introduce added complexity and cost due to their multi-loop architecture and integration demands [10]. Recent studies have demonstrated that dual-fluid ORCs can outperform conventional single-fluid systems in terms of both power output and thermal efficiency, primarily owing to the ability to select different fluids tailored to each cycle's temperature range [11]. This flexibility allows designers to better match the thermodynamic profiles of available heat sources and achieve improved operating conditions [11]. However, dual-fluid configurations that employ a transcritical Rankine cycle (tRC) as the topping cycle and an organic Rankine cycle (ORC) as the bottoming unit are scarcely found in the literature. This combined structure offers potential thermodynamic advantages, yet remains underexplored, particularly for geothermal applications. Despite the widespread focus on geothermal power generation, systems that simultaneously produce electricity, hydrogen, and fresh water remain largely unaddressed in the literature. Few studies have investigated the integration of dual-fluid ORCs with hydrogen production via PEM electrolyzers and desalination technologies [12]. However, to the best of the authors' knowledge, no study has yet examined a dual-fluid configuration utilizing a transcritical Rankine cycle (tRC) as the topping unit and an organic Rankine cycle (ORC) as the bottoming unit for such polygeneration purposes. In the present work, a novel geothermal-based system is proposed that combines a tRC–ORC dual-fluid structure, a proton exchange membrane (PEM) electrolyzer, a humidification–dehumidification (HDH) desalination unit, and a thermoelectric generator (TEG) for enhanced heat recovery. The system is evaluated through detailed energy and exergy analyses to assess its performance in delivering multiple outputs—namely, electricity, hydrogen, and freshwater—with high efficiency and minimal environmental impact. Furthermore, the thermodynamic performance is assessed for various topping cycle fluids, including R744 (carbon dioxide), R170 (ethane), R41 (fluoromethane), and R125 (pentafluoroethane), to identify the optimal working fluid configuration.

2. SYSTEM ARCHITECTURE AND PROCESS FLOW

As illustrated in Fig. 1, the geothermal fluid is extracted from the reservoir at a temperature of 150°C and a pressure of 1200 kPa. It first passes through heat exchanger HE1, where it transfers thermal energy to the working fluid of the transcritical Rankine cycle (tRC). Subsequently, in HE2, the supercritical fluid undergoes a preheating process before entering the high-pressure turbine (T1) and the low-pressure turbine (T2), generating mechanical power. After expansion,

the supercritical working fluid enters HE4, where it transfers residual heat to the organic Rankine cycle (ORC) loop, which uses n-pentane as the working fluid. The partially cooled tRC fluid then flows through TEG1, a thermoelectric generator that converts a portion of the remaining thermal energy—based on the temperature gradient between the working fluid and ambient conditions—into electricity. Finally, the fluid is pressurized by Pump P1 and recirculated to continue the tRC cycle. In the ORC loop, n-pentane is pressurized by Pump P2 (state 15) and preheated in HE3 using geothermal heat. It is further heated in HE4, using waste heat from the tRC cycle, and then expanded through an ORC turbine to produce power. The exhaust from the turbine enters TEG2, generating additional electrical power before the working fluid completes the cycle.

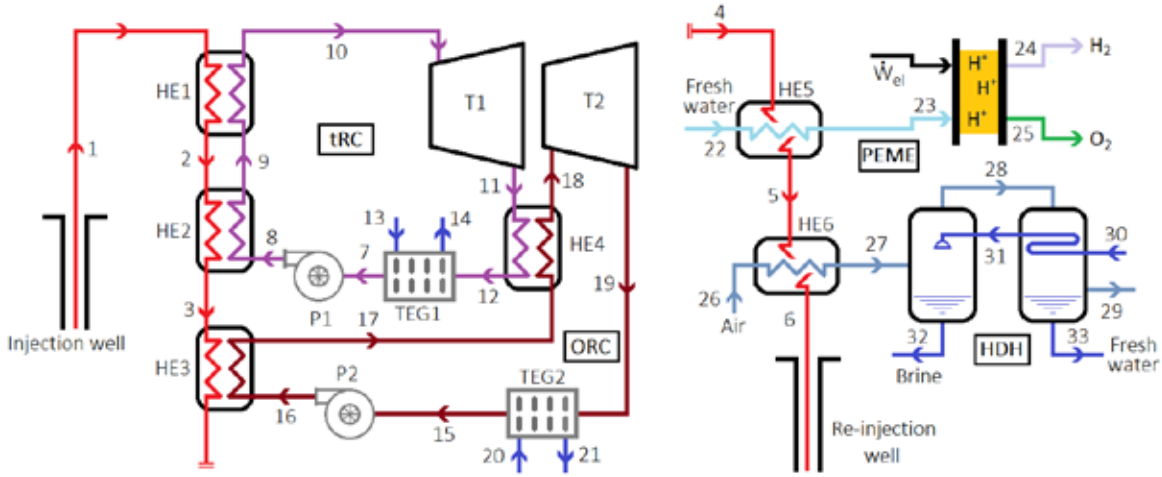

Fig.1. Schematic of the proposed geothermal-based dual-fluid polygeneration system

A portion of the residual heat from the geothermal fluid, after serving both Rankine cycles, is directed to HE5. Here, it is used to preheat deionized water (state 22), which then enters the PEME. The required electrical power for electrolysis is supplied by the TEG units. In the PEME, water is split into hydrogen (H_2) and oxygen (O_2) gases, which are extracted at states 24 and 25, respectively. Following its final heat recovery duty, the geothermal fluid is directed to the air heated HDH desalination unit before re-injection into the reservoir. In this subsystem, ambient air (state 26) is heated in HE6 to approximately 70 °C and enters the humidifier, where it comes into direct contact with a warm saline water stream. The air becomes saturated with moisture and then flows into the dehumidifier, where it transfers heat to incoming cold saline water, causing the moisture in the air to condense. The condensed water is collected as freshwater (state 33), while the remaining brine is discharged at state 32.

3. RESULTS AND DISCUSSION

Fig. 2 presents the comparison of total net power output and total exergy destruction for different topping cycle fluids: carbon dioxide (R744), ethane (R170), fluoromethane (R41), and pentafluoroethane (R125). Among the evaluated options, R170 provides the highest net power generation at 1884 kW, followed closely by R744 (1790 kW) and R41 (1770 kW). The lowest power output is obtained with R125, reaching 1710 kW. In terms of total exergy destruction, R744 exhibits the best performance with 4220.7 kW, indicating lower thermodynamic irreversibility compared to the other fluids. R125, on the other hand, results in the highest exergy destruction (4647.6 kW), which correlates with its relatively low power output. The exergy losses of R170 and R41 are found to be close to each other at approximately 4290.1 kW and 4254.1 kW, respectively. These results indicate that R170 (ethane) offers a favorable balance between high power output and moderate exergy destruction, while R744 (carbon dioxide) stands out for its superior exergy efficiency despite a slightly lower net power output. Thus, both fluids appear as promising candidates for the transcritical topping cycle in geothermal-based polygeneration systems.

Fig. 3 presents the variation in hydrogen production rate (kg/h) and total TEG power output (kW) for different supercritical fluids used in the topping cycle. Although detailed discussion of TEG performance is beyond the current scope, it is important to note that the electrical energy required for the PEM electrolyzer is supplied entirely by the thermoelectric generators, which directly influences the amount of hydrogen produced. Among the evaluated working fluids, R125 (pentafluoroethane) enables the highest hydrogen generation rate, reaching 9.64 kg/h, followed by R170 (ethane) with 8.70 kg/h. These two fluids benefit from higher TEG power outputs and thus yield greater electrolysis capacity. In contrast, R744 (CO_2) and R41 (fluoromethane) result in lower hydrogen production, at 7.60 kg/h and 7.37 kg/h, respectively. This strong correlation highlights the dependency of hydrogen output on TEG-generated power, which in turn is affected by the thermodynamic characteristics of each working fluid.

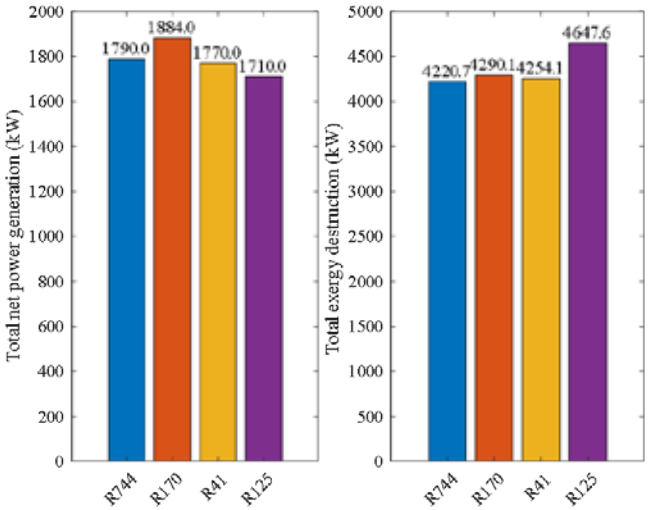

Fig. 2. Total net power output and exergy destruction for different transcritical working fluids

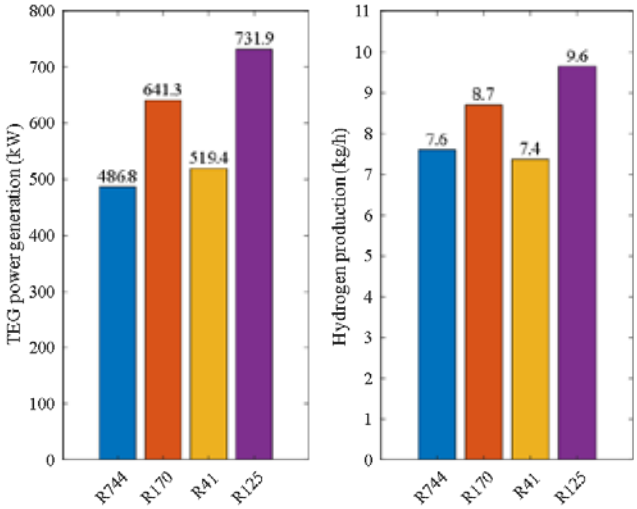

Fig. 3. TEG power generation and corresponding hydrogen production for different transcritical working fluids

Fig. 4 illustrates the total energy and exergy efficiencies of the integrated system for each transcritical working fluid. R170 (ethane) yields the highest performance in both metrics, with an energy efficiency of 12.55% and an exergy efficiency of 30.96%. R744 (carbon dioxide) follows closely, achieving 12.13% energy and 30.87% exergy efficiency. In contrast, R41 and R125 show lower overall performance, with exergy efficiencies of 27.62% and 24.82%, respectively, and energy efficiencies around 10.8%. These results reinforce the thermodynamic advantages of ethane and CO_2 as topping cycle fluids, offering better energy utilization and lower irreversibilities across the polygeneration system.

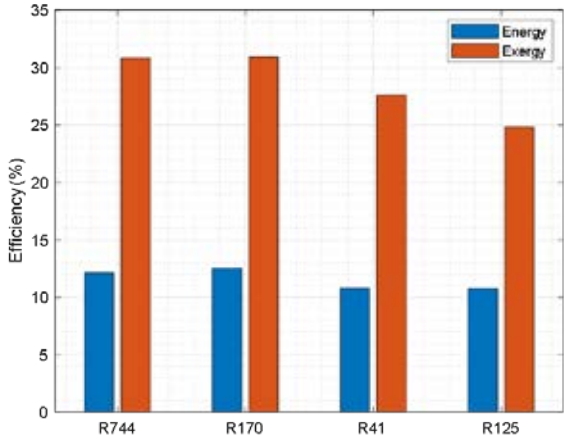

Fig. 4. Total energy and exergy efficiencies of the proposed system for different transcritical working fluids

Fig. 5 illustrates the component-wise exergy destruction distribution for each working fluid. In all cases, the highest

irreversibility occurs in HE2, the primary heat exchanger in the tRC preheating section. For instance, R125 exhibits the greatest exergy destruction in HE2 (1694 kW), followed by R41 (1573 kW), indicating substantial thermal mismatches or inefficiencies during high-temperature heat transfer. HE6, responsible for heating feedwater for the HDH and PEME subsystems, also contributes significantly across all cases (approx. 1070–1108 kW).

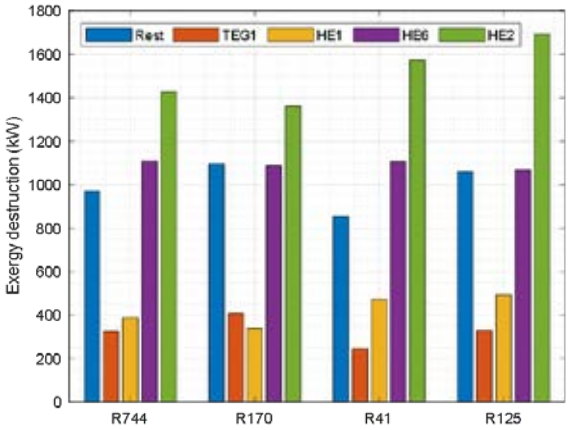

Fig. 5. Component-wise exergy destruction distribution for different transcritical working fluids

4. CONCLUSIONS

This study investigated a novel geothermal-driven polygeneration system integrating a tRC, an ORC, TEGs, a PEM electrolyzer, and an HDH desalination unit. A comparative thermodynamic analysis was conducted for different topping cycle working fluids. The key findings are summarized below:

- Ethane (R170) achieved the highest net power output (1884 kW) and overall system energy (12.55%) and exergy (30.96%) efficiencies.
- CO_2 (R744) demonstrated the lowest exergy destruction (4220.7 kW) and competitive efficiency levels, making it a strong candidate for sustainable operation.
- The highest hydrogen production was obtained with R125, reaching 9.64 kg/h, due to greater TEG power generation (731.9 kW).
- All fluids except R170 provided similar freshwater production via the HDH unit (≈ 4.1 m3/h), while R170 yielded the lowest (1.78 m^3/h) due to limited residual heat.

ABSTRACT
With the enhancing global energy demand, the environmental impact of carbon emissions from fossil fuels, and concerns about global warming have significantly increased interest in clean and sustainable energy technologies. This study aims to develop and optimize innovative catalyst materials to enhance the performance of Anion Exchange Membrane (AEM) electrolyzers, which hold significant potential for green hydrogen production. In this context, the low-cost transition metal nickel (Ni) was coated onto graphite-based substrates using various electrodeposition techniques, and the electrochemical performance of these electrodepositions was investigated. Electrochemical analyses, including chronoamperometry, chronopotentiometry, cyclic voltammetry (CV), and multi-step chronopotentiometry, were used to compare the effects of different electrodeposition methods on catalytic activity. The results indicate that the electrodepositions obtained via the chronoamperometry method formed more homogeneous and catalytically active surfaces, leading to lower overpotential values and higher hydrogen production performance.

Keywords: AEM Electrolyzer, Electrodeposition Methods, Catalyst, Green Hydrogen

1. INTRODUCTION

The rapidly increasing global energy demand, the environmental impact of fossil fuel dependency, and the worsening climate crisis have made the transition to sustainable and clean energy sources imperative. In this context, hydrogen has emerged as a promising energy carrier due to its high energy density, carbon-free utilization, and wide range of applications. In particular, water electrolysis technologies integrated with renewable energy sources pave the way for carbon-neutral hydrogen production and improve the economic feasibility of green hydrogen. Among electrochemical water-splitting methods, Anion Exchange Membrane (AEM) electrolyzers have attracted considerable attention by combining the advantages of both Proton Exchange Membrane (PEM) and Alkaline Water Electrolyzers (AWE). Among current electrolysis technologies, AEM electrolyzers demonstrate significant potential. However, several challenges must be overcome for their widespread adoption. These include the development of membranes with high ionic conductivity and chemical stability, the enhancement of catalyst efficiency, and the optimization of electrode structures. Operating in an alkaline environment, AEM electrolyzers eliminate the need for expensive and scarce platinum group metals (PGMs), allowing the use of more abundant and cost-effective transition metals such as nickel, iron, and cobalt [1, 2].

The high efficiency of AEM electrolyzers depends not only on membrane materials but also on the performance of electrodes, particularly the effectiveness of catalytic electrodeposition techniques. Electrodes produced using advanced electrodeposition methods with nickel-based materials exhibit high catalytic activity for both the hydrogen evolution reaction (HER) and the oxygen evolution reaction (OER), as well as good mechanical durability and chemical stability. These electrodepositions increase the active surface area of the electrodes, thereby enhancing electrochemical reaction performance [3]. Advanced electrodeposition techniques such as electrodeposition, atomic layer deposition (ALD), and spray pyrolysis have enabled the formation of uniform, nanostructured, and porous catalytic layers that provide a larger electrochemically active surface area and more accessible active sites [4]. This morphological control is critical for reducing charge transfer resistance and improving mass transport during electrolysis. For instance, CP deposition has been shown to produce conformal and homogeneously distributed nickel-based electrodepositions, resulting in electrodes that exhibit lower Tafel slopes and higher current densities at reduced overpotentials [5]. Moreover, surface modifications—such as incorporation of oxygen vacancies or heteroatom doping—can further optimize the electronic structure of catalysts, thereby enhancing their intrinsic activity. Furthermore, the mechanical robustness and chemical stability of these electrodepositions under prolonged electrolysis conditions are critical for the operational durability of AEM electrolyzers. Ni-based electrodes with optimized nanostructures have shown to maintain their structural integrity and catalytic activity over extended testing periods, making them promising candidates for long-term green hydrogen production systems [6].

In this study, the low-cost transition metal nickel (Ni) was deposited onto graphite-based substrates using various electrodeposition techniques, and the resulting electrodes' electrochemical performances were comparatively evaluated.

The electrodepositions were examined with a focus on their impact on catalytic activity, overpotential values, and long-term stability, particularly regarding hydrogen production capability. Electrochemical characterization techniques—such as chronoamperometry, chronopotentiometry, cyclic voltammetry (CV), and multi-step chronopotentiometry—were employed to explore the relationship between surface morphology generated by different electrodeposition methods and hydrogen generation efficiency. The results demonstrated that electrodepositions applied via the chronoamperometric method produced more homogeneous and active surfaces, operated at lower overpotential values, and significantly improved hydrogen production performance. In conclusion, the electrodeposition strategies developed in this study pave the way for the design of optimized electrodes capable of operating AEM electrolyzers with higher efficiency. These strategies offer a sustainable and cost-effective roadmap for green hydrogen production. This research highlights the potential of transition metals in developing low-cost, environmentally friendly, and high-performance electrodes, underscoring their crucial role in the advancement of AEM technology.

2. MATERIALS AND METHODS

For the preparation of the nickel-plating bath, three different chemical components were used: 30 grams of nickel (II) chloride hexahydrate ($NiCl_2 \cdot 6H_2O$), 1.25 grams of nickel (II) sulfate hexahydrate ($NiSO_4 \cdot 6H_2O$) and 1.25 grams of boric acid (H_3BO_3). After weighing these components with a precision balance, they were placed in a beaker and some pure water was added. The resulting mixture was stirred with a magnetic stirrer for approximately 30 minutes until complete dissolution was achieved. After the solution was prepared, it was diluted with pure water to a total volume of 100 mL with a graduated cylinder and finally transferred to a volumetric flask to make the plating bath ready for use. Before the plating process, preliminary cleaning processes were carried out to prepare electrodes suitable for surface electrodeposition. The electrode surfaces were first cleaned in an ultrasonic bath using isopropanol and pure water, and then the drying process was applied. The cleaned electrodes were made suitable for operation in a three-electrode system. In this system, Ag/AgCl was used as a reference electrode, platinum wire as an auxiliary electrode and the sample was used as an electrode. The electrodeposition processes were carried out using different electrochemical methods. Figure 1 shows the I-V curves of different electrodeposition methods.

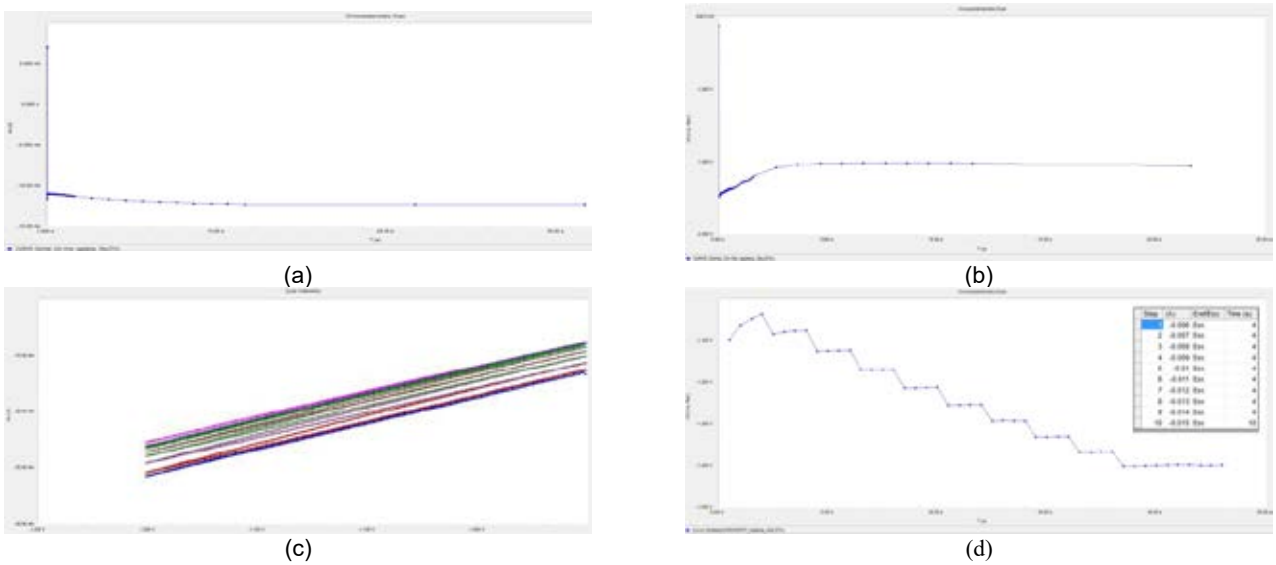

Fig. 1. Electrochemical deposition techniques a) chronoamperometry (CA) b) chronopotentiometry (CP) c) cyclic voltammetry (CV) and d) multi-step chronopotentiometry (MSCP)

With the chronoamperometry (CA) method, a current of 12.3 mA was applied at a constant -1.2 V potential and approximately 0.43 C charge transfer was achieved during this time. In the chronopotentiometry (CP) method, electrodeposition was carried out with a potential of -1.51 V under a constant 14 mA current and a total charge of 0.42 C was transferred. In the cyclic voltammetry (CV) technique, potential scans were performed in three cycles at 5 mV/s, 10 mV/s and 50 mV/s scanning speeds and the electrodeposition characteristics obtained at each speed were compared. In addition, ten steps were applied with multi-step chronopotentiometry method at current values starting from 6 mA and increasing up to 15 mA, a total of 40 seconds of electrodeposition was performed for 4 seconds at each step and approximately 0.42 C charge transfer was achieved. With this multi-step method, it was aimed to obtain a more active and homogeneous electrodeposition on the electrode surface.

3. RESULTS AND DISCUSSION

In this study, various electrochemical electrodeposition techniques were employed to deposit nickel (Ni) onto graphite-

based substrates for use in AEM electrolyzers, and their catalytic performance was evaluated with respect to hydrogen evolution reaction (HER) efficiency. The electrodeposition methods investigated included chronoamperometry (CA), chronopotentiometry (CP), cyclic voltammetry (CV), and multi-step chronopotentiometry (MSCP). Each method influenced the morphology and electrochemical activity of the resulting Ni electrodepositions, thereby affecting hydrogen production performance. Among these techniques, the CA method demonstrated the most promising results. The application of a constant current at -1.2 V produced a uniform and homogeneous Ni electrodeposition, as evidenced by lower overpotential values and higher current densities observed in subsequent electrochemical analyses. Electrodes coated using the CA method exhibited enhanced HER performance due to an increased electrochemically active surface area and improved charge transfer kinetics. Electrodepositions obtained via the CP and MSCP methods also showed moderate catalytic activity, with the MSCP method offering better homogeneity than CP. This improvement was attributed to the stepwise application of current in MSCP, which provided better control over nucleation and growth of the Ni layer. However, both methods exhibited slightly higher overpotentials and less uniform electrodepositions compared to CA. CV-based electrodeposition technique, although useful for understanding redox behavior, resulted in relatively poor catalytic performance. This was primarily due to the less controlled nature of the deposition process and the potential aggregation of Ni particles, which reduced the number of accessible active sites. The superior performance of the CA-based electrodeposition technique can be attributed to the uniform deposition of fine Ni particles, leading to enhanced catalytic activity, improved charge transfer characteristics, and better mechanical stability under operating conditions.

4. CONCLUSIONS

This study successfully demonstrated the development of Ni-based catalyst layers using various electrochemical electrodeposition methods for application in AEM electrolyzers. The CA-based electrodeposition method produced the most homogeneous and catalytically active electrodepositions, leading to lower overpotential values and higher hydrogen production efficiency. These findings highlight the critical role of the electrodeposition technique in determining catalyst morphology, electrochemical performance, and long-term durability. The use of low-cost and abundant transition metals such as nickel, in combination with optimized electrochemical deposition strategies, presents a sustainable and scalable approach to advancing green hydrogen production through AEM electrolyzers. Future research may focus on incorporating dopants or exploring alloying strategies to further enhance catalytic activity and stability.
